Biomaterials Science: A Multidisciplinary Endeavor

BUDDY D. RATNER, ALLAN S. HOFFMAN, FREDERICK J. SCHOEN,
AND JACK E. LEMONS

1

A History of Biomaterials

BUDDY D. RATNER

10

PART I MATERIALS SCIENCE AND ENGINEERING

CHAPTER 1 Properties of Materials

1.1 Introduction
JACK E. LEMONS

23

1.2 Bulk Properties of Materials
FRANCIS W. COOKE

23

1.3 Finite Element Analysis
IVAN VESELY AND EVELYN OWEN CAREW

32

1.4 Surface Properties and Surface
Characterization of Materials
BUDDY D. RATNER

40

1.5 Role of Water in Biomaterials
ERWIN A. VOGLER

59

CHAPTER 2 Classes of Materials Used in Medicine

2.1 Introduction
ALLAN S. HOFFMAN

67

2.2 Polymers
STUART L. COOPER, SUSAN A. VISSER,
ROBERT W. HERGENROTHER, AND NINA M. K. LAMBA

67

2.3 Silicone Biomaterials: History
and Chemistry
ANDRÉ COLAS AND JIM CURTIS

80

2.4 Medical Fibers and Biotextiles
STEVEN WEINBERG AND MARTIN W. KING

86

2.5 Hydrogels
NICHOLAS A. PEPPAS

100

2.6 Applications of “Smart Polymers” as
Biomaterials
ALLAN S. HOFFMAN

107

2.7 Bioresorbable and Bioerodible Materials
JOACHIM KOHN, SASCHA ABRAMSON, AND ROBERT LANGER

115

2.8 Natural Materials
IOANNIS V. YANNAS

127

2.9 Metals
JOHN B. BRUNSKI

137

2.10 Ceramics, Glasses, and Glass-Ceramics
LARRY L. HENCH AND SERENA BEST

153

2.11 Pyrolytic Carbon for Long-Term Medical
Implants
ROBERT B. MORE, AXEL D. HAUBOLD, AND JACK C. BOKROS

170

2.12 Composites
CLAUDIO MIGLIARESI AND HAROLD ALEXANDER

181

2.13 Nonfouling Surfaces
BUDDY D. RATNER AND ALLAN S. HOFFMAN

197

2.14	Physicochemical Surface Modification of Materials Used in Medicine BUDDY D. RATNER AND ALLAN S. HOFFMAN	201	4.6	Blood Coagulation and Blood–Materials Interactions STEPHEN R. HANSON	332
2.15	Textured and Porous Materials JOHN A. JANSEN AND ANDREAS F. VON RECUM	218	4.7	Tumorigenesis and Biomaterials FREDERICK J. SCHOEN	338
2.16	Surface-Immobilized Biomolecules ALLAN S. HOFFMAN AND JEFFREY A. HUBBELL	225	4.8	Biofilms, Biomaterials, and Device-Related Infections BILL COSTERTON, GUY COOK, MARK SHIRTLIFF, PAUL STOODLEY, AND MARK PASMORE	345

PART II BIOLOGY, BIOCHEMISTRY, AND MEDICINE

CHAPTER 3 Some Background Concepts

3.1	Background Concepts BUDDY D. RATNER	237
3.2	The Role of Adsorbed Proteins in Tissue Response to Biomaterials THOMAS A. HORBETT	237
3.3	Cells and Cell Injury RICHARD N. MITCHELL AND FREDERICK J. SCHOEN	246
3.4	Tissues, the Extracellular Matrix, and Cell–Biomaterial Interactions FREDERICK J. SCHOEN AND RICHARD N. MITCHELL	260
3.5	Mechanical Forces on Cells LARRY V. MCINTIRE, SUZANNE G. ESKIN, AND ANDREW YEE	282

CHAPTER 4 Host Reactions to Biomaterials and Their Evaluation

4.1	Introduction FREDERICK J. SCHOEN	293
4.2	Inflammation, Wound Healing, and the Foreign-Body Response JAMES M. ANDERSON	296
4.3	Innate and Adaptive Immunity: The Immune Response to Foreign Materials RICHARD N. MITCHELL	304
4.4	The Complement System RICHARD J. JOHNSON	318
4.5	Systemic Toxicity and Hypersensitivity ARNE HENSTEN-PETTERSEN AND NILS JACOBSEN	328

CHAPTER 5 Biological Testing of Biomaterials

5.1	Introduction to Testing Biomaterials BUDDY D. RATNER	355
5.2	<i>In Vitro</i> Assessment of Tissue Compatibility SHARON J. NORTHUP	356
5.3	<i>In Vivo</i> Assessment of Tissue Compatibility JAMES M. ANDERSON AND FREDERICK J. SCHOEN	360
5.4	Evaluation of Blood-Materials Interactions STEPHEN R. HANSON AND BUDDY D. RATNER	367
5.5	Large Animal Models in Cardiac and Vascular Biomaterials Research and Testing RICHARD W. BIANCO, JOHN F. GREHAN, BRIAN C. GRUBBS, JOHN P. MRACHEK, ERIK L. SCHROEDER, CLARK W. SCHUMACHER, CHARLES A. SVENDSEN, AND MATT LAHTI	379
5.6	Microscopy for Biomaterials Science KIP D. HAUCH	396

CHAPTER 6 Degradation of Materials in the Biological Environment

6.1	Introduction: Degradation of Materials in the Biological Environment BUDDY D. RATNER	411
6.2	Chemical and Biochemical Degradation of Polymers ARTHUR J. COURY	411
6.3	Degradative Effects of the Biological Environment on Metals and Ceramics DAVID F. WILLIAMS AND RACHEL L. WILLIAMS	430
6.4	Pathological Calcification of Biomaterials FREDERICK J. SCHOEN AND ROBERT J. LEVY	439

CHAPTER 7 Application of Materials in Medicine, Biology, and Artificial Organs		7.18 Diagnostics and Biomaterials	685
		PETER J. TARCHA AND THOMAS E. ROHR	
7.1 Introduction	455	7.19 Medical Applications of Silicones	698
JACK E. LEMONS AND FREDERICK J. SCHOEN		JIM CURTIS AND ANDRÉ COLAS	
7.2 Nonthrombogenic Treatments and Strategies	456	CHAPTER 8 Tissue Engineering	
MICHAEL V. SEFTON AND CYNTHIA H. GEMMELL		8.1 Introduction	709
7.3 Cardiovascular Medical Devices	470	FREDERICK J. SCHOEN	
ROBERT F. PADERA, JR., AND FREDERICK J. SCHOEN		8.2 Overview of Tissue Engineering	712
7.4 Implantable Cardiac Assist Devices	494	SIMON P. HOERSTRUP AND JOSEPH P. VACANTI	
WILLIAM R. WAGNER, HARVEY S. BOROVETZ, AND BARTLEY P. GRIFFITH		8.3 Immunoisolation	728
7.5 Artificial Red Blood Cell Substitutes	507	MICHAEL J. LYSAGHT AND DAVID REIN	
THOMAS MING SWI CHANG		8.4 Synthetic Bioresorbable Polymer Scaffolds	735
7.6 Extracorporeal Artificial Organs	514	ANTONIOS G. MIKOS, LICHUN LU, JOHNNA S. TEMENOFF, AND JOERG K. TESSMAR	
PAUL S. MALCHESKY		PART III	
7.7 Orthopedic Applications	527	PRACTICAL ASPECTS OF

PREFACE

The interest and excitement in the field of biomaterials has been validated by sales of the first edition of this textbook: more than 10,000 copies sold. Also, the first edition has been widely adopted for classroom use throughout the world. The concept behind the first edition was that a balanced textbook on the subject of biomaterials science was needed. As with the first edition, the intended audience is multidisciplinary: students of medicine, dentistry, veterinary science, engineering, materials science, chemistry, physics, and biology (not an all-inclusive list) can find essential introductory material to permit them a reasonably knowledgeable immersion into the key professional issues in biomaterials science.

Textbooks by single authors too strongly emphasize their own areas of expertise and ignore other important subjects. Articles from the literature are commonly used in the classroom setting, but these are difficult to weave into a cohesive curriculum. Handout materials from professors are often graphically unsophisticated, and again, slanted to the specific interests of the individual. In *Biomaterials Science: An Introduction to Materials in Medicine*, 2nd edition, we the editors (whose 140+ person-year expertise spans materials science, pathology, and hard- and soft-tissue applications), endeavor to present a balanced perspective on an evolving discipline by integrating the experience of many leaders in the biomaterials field. Balanced presentation means appropriate representation of hard biomaterials and soft biomaterials; of orthopedic ideas, cardiovascular concepts, ophthalmologic ideas, and dental issues; a balance of fundamental biological concepts, materials science background, medical/clinical concerns, and government/societal issues; and coverage of biomaterials past, present, and future. In this way, we hope that the reader can visualize the scope of the field, absorb the unifying principles common to all materials in contact with biological systems, and gain a solid appreciation for the special significance of the word *biomaterial* as well as the rapid and exciting evolution and expansion of biomaterials science and its applications in medicine.

More than 108 biomaterials professionals from academia, industry, and government have contributed to this work. Certainly, such a distinguished group of authors provides the needed balance and perspective. However, such a diverse group

of authors also leads to unique complexities in a project of this type. Do the various writing styles clash? Does the presentation of material, particularly controversial material, result in one chapter contradicting another? Even with so many authors, all subjects relevant to biomaterials cannot be addressed—subjects should be included and which left out? How should such a project be refereed to ensure scientific quality, pedagogical effectiveness, and the balance we strive for?

These are some of the issues the editors grappled with over the years from conception of the second edition in 1998 to publication in 2004. From this complex editorial process, a unique volume has evolved that the editors feel can make an ongoing contribution to the development of the biomaterials field. An educational tool has been synthesized here directing those new to biomaterials, be they engineers, physicians, materials scientists, or biochemists, on a path to appreciating the scope, complexity, basic principles, and importance of this enterprise.

What's new in *Biomaterials Science: An Introduction to Materials in Medicine*, 2nd edition? All chapters have been updated and rewritten, most extensively. A large number of new chapters have been added. The curricular organization for teaching the fundamental cell biology, molecular biology, tissue organization, and histology, key subjects that support the modern biomaterials research endeavor, has been restructured. A new, three-chapter section on tissue engineering has been added. The total content and size of the book have been significantly increased. A Web site has been coupled to the book offering supplemental material including surgery movies and homework problems. The graphics design has been upgraded. You have in your hands a new book that can address biomaterials in the 21st century.

Acknowledgments and thanks are in order. First, let us address the Society For Biomaterials that served as sponsor and inspiration for this book. The Society For Biomaterials is a model of “scientific cultural diversity” with engineers, physicians, scientists, veterinarians, industrialists, inventors, regulators, attorneys, educators, and ethicists all participating in an endeavor that is intellectually exciting, humanitarian, and profitable. As with the first edition, all royalties from this volume are being returned to the Society For Biomaterials to further education and professional advancement related

to biomaterials. For further information on the Society For Biomaterials, visit the SFB Web site (<http://www.biomaterials.org/>).

Next, we offer a special thanks to those who enthusiastically invested time, energy, experience, and intelligence to author the chapters that are this textbook. The many scientists, physicians, and engineers who contributed their expertise and perspectives are clearly the backbone of this work and they deserve high praise—their efforts will strongly affect the education of the next generation of biomaterials scientists. Also, some reviewers assisted the editors in carefully refereeing chapters. We thank Kip Hauch, Colleen Irvin, Gayle Winters, Tom Horbett, and Steven Slack.

The support, encouragement, organizational skills, and experience of the staff, first at Academic Press and now at Elsevier Publishers, have led this second edition from vision to volume. Thank you, Elsevier, for this contribution to the field of biomaterials.

Finally, a unique person at the University of Washington has contributed to the assembly and production aspects of

this work. We offer special thanks to Elizabeth Sharpe for her superb editorial/organizational efforts. This volume, deep down, has Elizabeth's intelligent and quality-oriented stamp all over it. Clearly, she cares!

The biomaterial field has always been ripe with opportunities, stimulation, compassion, and intellectual ideas. As a field we look to the horizons where the new ideas from science, technology, and medicine arise. We aim to improve the quality of life for millions through biomaterials-based, improved medical devices and tissue engineering. We editors hope the biomaterials overview you now hold will stimulate you as much as it has us.

Biomaterials Science: A Multidisciplinary Endeavor

BUDDY D. RATNER, ALLAN S. HOFFMAN, FREDERICK J. SCHOEN, JACK E. LEMONS

BIOMATERIALS AND BIOMATERIALS SCIENCE

Biomaterials Science: An Introduction to Materials in Medicine addresses the properties and applications of materials (synthetic and natural) that are used in contact with biological systems. These materials are commonly called biomaterials. Biomaterials, an exciting field with steady, strong growth over its approximately half century of existence, encompasses aspects of medicine, biology, chemistry, and materials science. It sits on a foundation of engineering principles. There is also a compelling human side to the therapeutic and diagnostic application of biomaterials. This textbook aims to (1) introduce these diverse elements, particularly focusing on their interrelationships rather than differences and (2) systematize the subject into a cohesive curriculum.

We title this textbook *Biomaterials Science: An Introduction to Materials in Medicine* to reflect, first, that the book highlights the scientific and engineering fundamentals behind biomaterials and their applications, and second, that this volume contains sufficient background material to guide the reader to a fair appreciation of the field of biomaterials. Furthermore, every chapter in this textbook can serve as a portal to an extensive contemporary literature. The magnitude of the biomaterials endeavor, its interdisciplinary scope, and examples of biomaterials applications will be revealed in this introductory chapter and throughout the book.

Although biomaterials are primarily used for medical applications (the focus of this text), they are also used to grow cells in culture, to assay for blood proteins in the clinical laboratory, in equipment for processing biomolecules for biotechnological applications, for implants to regulate fertility in cattle, in diagnostic gene arrays, in the aquaculture of oysters, and for investigational cell-silicon “biochips.” How do we reconcile these diverse uses of materials into one field? The common thread is the interaction between biological systems and synthetic or modified natural materials.

In medical applications, biomaterials are rarely used as isolated materials but are more commonly integrated into devices

or implants. Although this is a text on materials, it will quickly become apparent that the subject cannot be explored without also considering biomedical devices and the biological response to them. Indeed, both the effect of the materials/device on the recipient and that of the host tissues on the device can lead to device failure. Furthermore, a biomaterial must always be considered in the context of its final fabricated, sterilized form. For example, when a polyurethane elastomer is cast from a solvent onto a mold to form the pump bladder of a heart assist device, it can elicit different blood reactions than when injection molding is used to form the same device. A hemodialysis system serving as an artificial kidney requires materials that must function in contact with a patient’s blood and also exhibit appropriate membrane permeability and mass transport characteristics. It also must employ mechanical and electronic systems to pump blood and control flow rates.

Because of space limitations and the materials focus of this work, many aspects of device design are not addressed in this book. Consider the example of the hemodialysis system. The focus here is on membrane materials and their biocompatibility; there is little coverage of mass transport through membranes, the burst strength of membranes, flow systems, and monitoring electronics. Other books and articles cover these topics in detail.

The words “biomaterial” and “biocompatibility” have already been used in this introduction without formal definition. A few definitions and descriptions are in order and will be expanded upon in this and subsequent chapters.

A definition of “biomaterial” endorsed by a consensus of experts in the field, is:

A biomaterial is a nonviable material used in a medical device, intended to interact with biological systems (Williams, 1987).

If the word “medical” is removed, this definition becomes broader and can encompass the wide range of applications suggested above.

If the word “nonviable” is removed, the definition becomes even more general and can address many new

tissue-engineering and hybrid artificial organ applications where living cells are used.

“Biomaterials science” is the physical and biological study of materials and their interaction with the biological environment. Traditionally, the most intense development and investigation have been directed toward biomaterials synthesis, optimization, characterization, testing, and the biology of host–material interactions. Most biomaterials introduce a non-specific, stereotyped biological reaction. Considerable current effort is directed toward the development of engineered surfaces that could elicit rapid and highly precise reactions with cells and proteins, tailored to a specific application.

Indeed, a complementary definition essential for understanding the goal (i.e., specific end applications) of biomaterials science is that of “biocompatibility.”

Biocompatibility is the ability of a material to perform with an appropriate host response in a specific application (Williams, 1987).

Examples of “appropriate host responses” include the resistance to blood clotting, resistance to bacterial colonization, and normal, uncomplicated healing. Examples of specific applications include a hemodialysis membrane, a urinary catheter, or a hip-joint replacement prosthesis. Note that the hemodialysis membrane might be in contact with the patient’s blood for 3 hours, the catheter may be inserted for a week, and the hip joint may be in place for the life of the patient.

This general concept of biocompatibility has been extended recently in the broad approach called “tissue engineering” in which *in-vitro* and *in-vivo* pathophysiological processes are harnessed by careful selection of cells, materials, and metabolic and biomechanical conditions to regenerate functional tissues.

Thus, in these definitions and discussion, we are introduced to considerations that set biomaterials apart from most materials explored in materials science. Table 1 lists a few applications for synthetic materials in the body. It includes many materials that are often classified as “biomaterials.” Note that metals, ceramics, polymers, glasses, carbons, and composite materials are listed. Such materials are used as molded or machined parts, coatings, fibers, films, foams and fabrics. Table 2 presents estimates of the numbers of medical devices containing biomaterials that are implanted in humans each year and the size of the commercial market for biomaterials and medical devices.

Five examples of applications of biomaterials now follow to illustrate important ideas. The specific devices discussed were chosen because they are widely used in humans with good success. However, key problems with these biomaterial devices are also highlighted. Each of these examples is discussed in detail in later chapters.

EXAMPLES OF BIOMATERIALS APPLICATIONS

Heart Valve Prostheses

Diseases of the heart valves often make surgical repair or replacement necessary. Heart valves open and close over 40 million times a year and they can accumulate damage sufficient to require replacement in many individuals. More than

TABLE 1 Some Applications of Synthetic Materials and Modified Natural Materials in Medicine

Application	Types of materials
Skeletal system	
Joint replacements (hip, knee)	Titanium, Ti–Al–V alloy, stainless steel, polyethylene
Bone plate for fracture fixation	Stainless steel, cobalt–chromium alloy
Bone cement	Poly(methyl methacrylate)
Bony defect repair	Hydroxylapatite
Artificial tendon and ligament	Teflon, Dacron
Dental implant for tooth fixation	Titanium, Ti–Al–V alloy, stainless steel, polyethylene Titanium, alumina, calcium phosphate
Cardiovascular system	
Blood vessel prosthesis	Dacron, Teflon, polyurethane
Heart valve	Reprocessed tissue, stainless steel, carbon
Catheter	Silicone rubber, Teflon, polyurethane
Organs	
Artificial heart	Polyurethane
Skin repair template	Silicone–collagen composite
Artificial kidney (hemodialyzer)	Cellulose, polyacrylonitrile
Heart–lung machine	Silicone rubber
Senses	
Cochlear replacement	Platinum electrodes
Intraocular lens	Poly(methyl methacrylate), silicone rubber, hydrogel
Contact lens	Silicone-acrylate, hydrogel
Corneal bandage	Collagen, hydrogel

80,000 replacement valves are implanted each year in the United States because of acquired damage to the natural valve and congenital heart anomalies. There are many types of heart valve prostheses and they are fabricated from carbons, metals, elastomers, plastics, fabrics, and animal or human tissues chemically pretreated to reduce their immunologic reactivity and to enhance durability. Figure 1 shows a bileaflet tilting-disk mechanical heart valve, one of the most widely used designs. Other types of heart valves are made of chemically treated pig valve or cow pericardial tissue. Generally, almost as soon as the valve is implanted, cardiac function is restored to near normal levels and the patient shows rapid improvement. In spite of the overall success seen with replacement heart valves, there are problems that may differ with different types of valves; they include induction of blood clots, degeneration of tissue, mechanical failure, and infection. Heart valve substitutes are discussed in Chapter 7.3.

Artificial Hip Joints

The human hip joint is subjected to high levels of mechanical stress and receives considerable abuse in the course of

TABLE 2 The Biomaterials and Healthcare Market—Facts and Figures (per year) (U.S. numbers—Global numbers are typically 2–3 times the U.S. number)

Total U.S. health care expenditures (2000)	\$1,400,000,000,000
Total U.S. health research and development (2001)	\$82,000,000,000
Number of employees in the medical device industry (2003)	300,000
Registered U.S. medical device manufacturers (2003)	13,000
Total U.S. medical device market (2002)	\$77,000,000,000
U.S. market for disposable medical supplies (2003)	\$48,600,000,000
U.S. market for biomaterials (2000)	\$9,000,000,000
Individual medical device sales:	
Diabetes management products (1999)	\$4,000,000,000
Cardiovascular Devices (2002)	\$6,000,000,000
Orthopedic-Musculoskeletal Surgery U.S. market (1998)	\$4,700,000,000
Wound care U.S. market (1998)	\$3,700,000,000
In Vitro diagnostics (1998)	\$10,000,000,000
Numbers of devices (U.S.):	
Intraocular lenses (2003)	2,500,000
Contact lenses (2000)	30,000,000
Vascular grafts	300,000
Heart valves	100,000
Pacemakers	400,000
Blood bags	40,000,000
Breast prostheses	250,000
Catheters	200,000,000
Heart-Lung (Oxygenators)	300,000
Coronary stents	1,500,000
Renal dialysis (number of patients, 2001)	320,000
Hip prostheses (2002)	250,000
Knee prostheses (2002)	250,000
Dental implants (2000)	910,000

FIG. 2. A metallic hip joint. (Photograph courtesy of Zimmer, Inc.)

normal activity. It is not surprising that after 50 or more years of cyclic mechanical stress, or because of degenerative or rheumatological disease, the natural joint wears out, leading to considerable loss of mobility and often confinement to a wheelchair. Hip-joint prostheses are fabricated from titanium, stainless steel, special high-strength alloys, ceramics, composites, and ultrahigh-molecular-weight polyethylene. Replacement hip joints (Fig. 2) are implanted in more than 200,000 humans each year in the United States alone. With some types of replacement hip joints and surgical procedures that use a polymeric cement, ambulatory function is restored within days after surgery. For other types, a healing-in period is required for integration between bone and the implant before the joint can bear the full weight of the body. In most cases, good function is restored. Even athletic activities are possible, although they are generally not advised. After 10–15 years, the implant may loosen, necessitating another operation. Artificial hip joints are discussed in Chapter 7.7.

Dental Implants

The widespread introduction of titanium implants (Fig. 3) has revolutionized dental implantology. These devices form an implanted artificial tooth anchor upon which a crown is affixed and are implanted in approximately 300,000 people each year, with some individuals receiving more than 12 implants. A special requirement of a material in this application is the ability to form a tight seal against bacterial invasion where the implant traverses the gingiva (gum). One of the primary advantages originally cited for the titanium implant was its osseous integration with the bone of the jaw. In recent years, however, this attachment has been more accurately described as a tight apposition or mechanical fit and not true bonding. Loss of tissue support leading to loosening remains an occasional problem along with infection and issues associated with the mechanical properties of unalloyed titanium that is subjected to long-term cyclic loading. Dental implants are discussed in Chapter 7.8.

FIG. 3. A titanium dental implant. (Photograph courtesy of Dr. A. Norman Cranin, Brookdale Hospital Medical Center, Brooklyn, NY.)

Intraocular Lenses

A variety of intraocular lenses (IOLs) have been fabricated of poly(methyl methacrylate), silicone elastomer, soft acrylic polymers, or hydrogels and are used to replace a natural lens when it becomes cloudy due to cataract formation (Fig. 4). By the age of 75, more than 50% of the population suffers from cataracts severe enough to warrant IOL implantation.

FIG. 4. An intraocular lens. (Photograph courtesy of Alcon Laboratories, Inc.)

This translates to almost 4 million implantations in the United States alone each year, and double that number worldwide. Good vision is generally restored almost immediately after the lens is inserted and the success rate with this device is high. IOL surgical procedures are well developed and implantation is often performed on an outpatient basis. Recent observations of implanted lenses using a microscope to directly observe the implanted lens through the cornea show that inflammatory cells migrate to the surface of the lenses after implantation. Thus, the conventional healing pathway is seen with these devices, similar to that observed with materials implanted in other sites in the body. Outgrowth of cells from the posterior lens capsule stimulated by the IOL can cloud the vision, and this is a significant complication. IOLs are discussed in Chapter 7.11.

Left Ventricular Assist Device

With a large population of individuals with seriously failing hearts (estimated at as many as 50,000 per year) who need cardiac assist or replacement and an available pool of donor hearts for transplantation of approximately 3000 per year, effective and safe mechanical cardiac assist or replacement has been an attractive goal. Left ventricular assist devices (LVADs), that can be considered as one half of a total artificial heart, have evolved from a daring experimental concept to a life-prolonging tool. They are now used to maintain a patient with a failing heart while the patient awaits the availability of a transplant heart and some patients receive these LVADs as a permanent (“destination”) therapy. An LVAD in an active adult is illustrated in Fig. 5. He is not confined to the hospital bed, although this pump system is totally supporting his circulatory needs. Patients have lived on LVAD support for more than 4 years. However, a patient with an LVAD is always at risk for infection and serious blood clots initiated within the device. These could break off (embolize) and possibly obstruct blood flow to a vital organ. LVADs are elaborated upon in Chapter 7.4.

These five cases, only a small fraction of the many important medical devices that could have been described here, spotlight a number of themes. Widespread application with good success is generally noted. A broad range of synthetic materials varying in chemical, physical, and mechanical properties are used in the body. Many anatomical sites are involved. The mechanisms by which the body responds to foreign bodies and heals wounds are observed in each case. Problems, concerns, or unexplained observations are noted for each device. Companies are manufacturing each of the devices and making a profit. Regulatory agencies are carefully looking at device performance and making policy intended to control the industry and protect the patient. Are there ethical or social issues that should be addressed? To set the stage for the formal introduction of biomaterials science, we will return to the five examples just discussed to examine the issues implicit to each case.

CHARACTERISTICS OF BIOMATERIALS SCIENCE

Now that we’ve defined some terms and reviewed a few specific examples, we can discern characteristics central to the

FIG. 5. A left ventricular assist device worn by a patient. (Photograph courtesy of Novacor.)

field of biomaterials. Here are a few considerations that are so central that it is hard to imagine biomaterials without them.

Multidisciplinary

More than any other field of contemporary technology, biomaterials science brings together researchers from diverse backgrounds who must communicate clearly. Figure 6 lists some of the disciplines that are encountered in the progression from identifying the need for a biomaterial or device to its manufacture, sale, and implantation.

Many Diverse Materials

The biomaterials scientist will have an appreciation of materials science. This may range from an impressive command of the theory and practice of the field demonstrated by the professional materials scientist to a general understanding of the properties of materials that might be demonstrated by the physician or biologist investigator involved in biomaterials-related research.

A wide range of materials is routinely used (Table 1), and no one researcher will be comfortable synthesizing, characterizing,

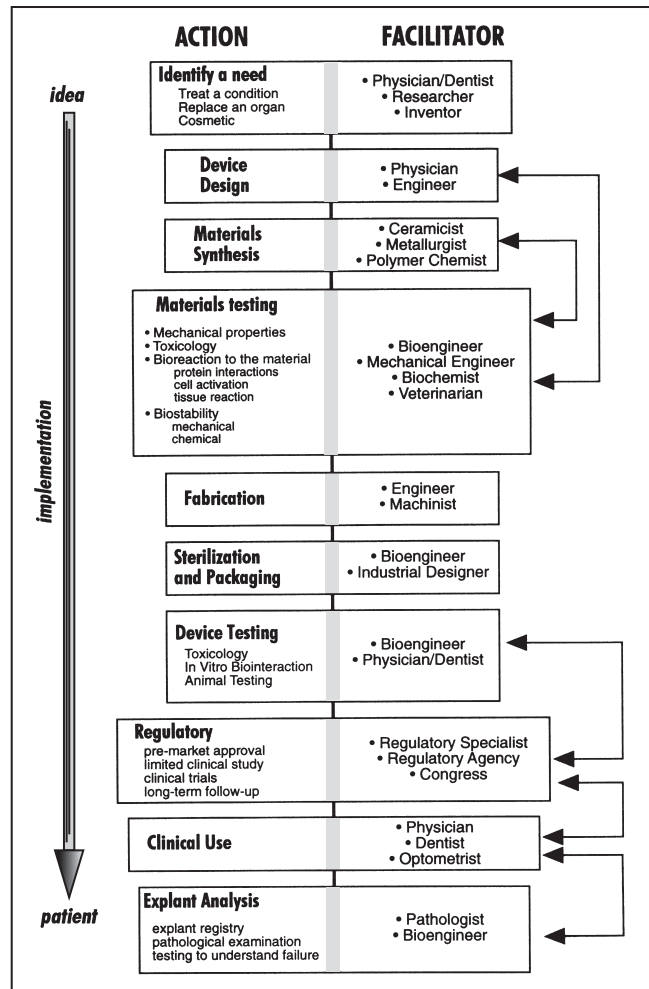

FIG. 6. Disciplines involved in biomaterials science and the path from a need to a manufactured medical device.

and designing with all these materials. Thus, specialization is common and appropriate. However, a broad appreciation of the properties and applications of these materials, the palette from which the biomaterials scientist creates, is a hallmark of professionals in the field.

There is a tendency to group biomaterials and researchers into the “hard-tissue replacement” camp, typically represented by those involved in orthopedic and dental materials, and the “soft-tissue replacement” camp, frequently associated with cardiovascular implants and general plastic-surgery materials. Hard-tissue biomaterials researchers are thought to focus on metals and ceramics while soft-tissue biomaterials researchers are considered polymer experts. In practice, this division is artificial: a heart valve may be fabricated from polymers, metals, and carbons. A hip joint will be composed of metals and polymers (and sometimes ceramics) and will be interfaced to the body via a polymeric bone cement. There is a need for a general understanding of all classes of materials and the common conceptual theme of their interaction with the biological milieu. This book provides a background to the important classes of materials, hard and soft.

Development of Biomaterials Devices

Thomas Edison once said that he would only invent things that people would buy. In an interesting way, this idea is central to biomaterials device development. The process of biomaterial/medical device innovation is driven by clinical need: a patient or a physician defines a need and then initiates an invention. Figure 6 illustrates multidisciplinary interactions in biomaterials and shows the progression in the development of a biomaterial or device. It provides a perspective on how different disciplines work together, starting from the identification of a need for a biomaterial through development, manufacture, implantation, and removal from the patient.

Magnitude of the Field

The magnitude of the medical device field expresses both a magnitude of need and a sizeable commercial market (Table 2). A conflict of interest can arise with pressures from both the commercial quarter and from patient needs. Consider four commonly used biomaterial devices: a contact lens, a hip joint, a hydrocephalus drainage shunt, and a heart valve. All fill medical needs. The contact lens offers improved vision and, some will argue, a cosmetic enhancement. The hip joint offers mobility to the patient who would otherwise need a cane or crutch or be confined to a bed or wheelchair. The hydrocephalus shunt will allow an infant to survive without brain damage. The heart valve offers a longer life with improved quality of life. The contact lens may sell for \$100, and the hip joint, hydrocephalus shunt, and heart valve may sell for \$1000–4000 each. Each year there will be 75 million contact lenses purchased worldwide, 275,000 heart valves, 5000 hydrocephalus shunts, and 500,000 total artificial hip and knee prostheses. Here are the issues for consideration: (1) the number of devices (an expression of both human needs and commercial markets), (2) medical significance (cosmetic to life saving), and (3) commercial potential (who will manufacture it and why—for example, what is the market for the hydrocephalus shunt?). Always, human needs and economic issues color this field we call “biomaterials science.” Medical practice, market forces, and bioethics come into play most every day.

Lysaght and O’Laughlin (2000) have estimated that the magnitude and economic scope of the contemporary organ replacement enterprise are much larger than is generally recognized. In the year 2000, the lives of more than 20 million patients were sustained, supported, or significantly improved by functional organ replacement. The impacted population grows at over 10% per year. Worldwide, first-year and follow-up costs of organ replacement and prostheses exceeds \$300 billion U.S. dollars per year and represents between 7% and 8% of total worldwide health-care spending. In the United States, the costs of therapies enabled by organ-replacement technology exceed 1% of the gross national product. The costs are also impressive when reduced to the needs of the individual patient. For example, the cost of a substitute heart valve is roughly \$4000. The surgery to implant the device entails a hospital bill and first-year follow-up costs of approximately \$60,000. Reoperation for replacing a failed valve will have

these same costs. Reoperations for failed valves now exceed 10% of all valve replacements.

Success and Failure

Most biomaterials and medical devices perform satisfactorily, improving the quality of life for the recipient or saving lives. However, no manmade construct is perfect. All manufactured devices have a failure rate. Also, all humans are different with differing genetics, gender, body chemistries, living environment, and degrees of physical activity. Furthermore, physicians implant or use these devices with varying degrees of skill. The other side to the medical device success story is that there are problems, compromises, and complications that occur with medical devices. Central issues for the biomaterials scientist, manufacturer, patient, physician, and attorney are, (1) what represents good design, (2) who should be responsible when devices perform “with an inappropriate host response,” and (3) what are the cost/risk or cost/benefit ratios for the implant or therapy?

Some examples may clarify these issues. Clearly, heart valve disease is a serious medical problem. Patients with diseased aortic heart valves have a 50% chance of dying within 3 years. Surgical replacement of the diseased valve leads to an expected survival of 10 years in 70% of the cases. However, of these patients whose longevity and quality of life have clearly been enhanced, approximately 60% will suffer a serious valve-related complication within 10 years after the operation. Another example involves LVADs. A clinical trial called Randomized Evaluation of Mechanical Assistance for the Treatment of Congestive Heart Failure (REMATCH) led to the following important statistics (Rose *et al.*, 2001). Patients with an implanted Heartmate LVAD (Thoratec Laboratories) had a 52% chance of surviving for 1 year, compared with a 25% survival rate for patients who took medication. Survival for 2 years in patients with the Heartmate was 23% versus 8% in the medication group. Also, the LVAD enhanced the quality of life for the patients—they felt better, were less depressed, and were mobile. Importantly, patients participating in the REMATCH trial were not eligible for a heart transplant. In the cases of the heart valve and the LVAD, long-term clinical complications associated with imperfect performance of biomaterials do not preclude clinical success overall.

These five characteristics of biomaterials science: multidisciplinary, multimaterial, need-driven, substantial market, and risk–benefit, flavor all aspects of the field. In addition, there are certain subjects that are particularly prominent in our field and help delineate biomaterials science as a unique endeavor. Let us review a few of these.

SUBJECTS INTEGRAL TO BIOMATERIALS SCIENCE

Toxicology

A biomaterial should not be toxic, unless it is specifically engineered for such a requirement (e.g., a “smart” drug delivery system that targets cancer cells and destroys them). Since the

nontoxic requirement is the norm, toxicology for biomaterials has evolved into a sophisticated science. It deals with the substances that migrate out of biomaterials. For example, for polymers, many low-molecular-weight “leachables” exhibit some level of physiologic activity and cell toxicity. It is reasonable to say that a biomaterial should not give off anything from its mass unless it is specifically designed to do so. Toxicology also deals with methods to evaluate how well this design criterion is met when a new biomaterial is under development. Chapter 5.2 provides an overview of methods in biomaterials toxicology. Implications of toxicity are addressed in Chapters 4.2, 4.3 and 4.5.

Biocompatibility

The understanding and measurement of biocompatibility is unique to biomaterials science. Unfortunately, we do not have precise definitions or accurate measurements of biocompatibility. More often than not, biocompatibility is defined in terms of performance or success at a specific task. Thus, for a patient who is doing well with an implanted Dacron fabric vascular prosthesis, few would argue that this prosthesis is not “biocompatible.” However, the prosthesis probably did not recellularize (though it was designed to do so) and also is embolic, though the emboli in this case usually have little clinical consequence. This operational definition of biocompatible (“the patient is alive so it must be biocompatible”) offers us little insight in designing new or improved vascular prostheses. It is probable that biocompatibility may have to be specifically defined for applications in soft tissue, hard tissue, and the cardiovascular system (blood compatibility). In fact, biocompatibility may have to be uniquely defined for each application.

The problems and meanings of biocompatibility will be explored and expanded upon throughout this textbook, in particular, see Chapters 4 and 5.

Functional Tissue Structure and Pathobiology

Biomaterials incorporated into medical devices are implanted into tissues and organs. Therefore, the key principles governing the structure of normal and abnormal cells, tissues, and organs, the techniques by which the structure and function of normal and abnormal tissue are studied, and the fundamental mechanisms of disease processes are critical considerations to workers in the field.

Healing

Special processes are invoked when a material or device heals in the body. Injury to tissue will stimulate the well-defined inflammatory reaction sequence that leads to healing. Where a foreign body (e.g., an implant) is present in the wound site (surgical incision), the reaction sequence is referred to as the “foreign-body reaction” (Chapter 4.2). The normal response of the body will be modulated because of the solid implant. Furthermore, this reaction will differ in intensity and duration

depending upon the anatomical site involved. An understanding of how a foreign object alters the normal inflammatory reaction sequence is an important concern for the biomaterials scientist.

Dependence on Specific Anatomical Sites of Implantation

Consideration of the anatomical site of an implant is essential. An intraocular lens may go into the lens capsule or the anterior chamber of the eye. A hip joint will be implanted in bone across an articulating joint space. A substitute heart valve will be sutured into cardiac muscle and will contact both soft tissue and blood. A catheter may be placed in an artery, a vein, or the urinary tract. Each of these sites challenges the biomedical device designer with special requirements for geometry, size, mechanical properties, and bioresponses. Chapter 3.4 introduces these ideas about special requirements to consider for specific anatomical sites.

Mechanical and Performance Requirements

Each biomaterial and device has mechanical and performance requirements that originate from the need to perform a physiological function consistent with the physical (bulk) properties of the material. These requirements can be divided into three categories: mechanical performance, mechanical durability, and physical properties. First, consider mechanical performance. A hip prosthesis must be strong and rigid. A tendon material must be strong and flexible. A tissue heart valve leaflet must be flexible and tough. A dialysis membrane must be strong and flexible, but not elastomeric. An articular cartilage substitute must be soft and elastomeric. Then, we must address mechanical durability. A catheter may only have to perform for 3 days. A bone plate may fulfill its function in 6 months or longer. A leaflet in a heart valve must flex 60 times per minute without tearing for the lifetime of the patient (realistically, at least for 10 or more years). A hip joint must not fail under heavy loads for more than 10 years. The bulk physical properties will also address other aspects of performance. The dialysis membrane has a specified permeability, the articular cup of the hip joint must have high lubricity, and the intraocular lens has clarity and refraction requirements. To meet these requirements, design principles are borrowed from physics, chemistry, mechanical engineering, chemical engineering, and materials science.

Industrial Involvement

A significant basic research effort is now under way to understand how biomaterials function and how to optimize them. At the same time, companies are producing implants for use in humans and, appropriate to the mission of a company, earning profits on the sale of medical devices. Thus, although we are now only learning about the fundamentals of bio-interaction, we manufacture and implant millions of devices in humans. How is this dichotomy explained? Basically, as a result of considerable experience we now have a set of materials that

performs satisfactorily in the body. The medical practitioner can use them with reasonable confidence, and the performance in the patient is largely acceptable. Though the devices and materials are far from perfect, the complications associated with the devices are less than the complications of the original diseases.

The complex balance between the desire to alleviate suffering and death, the excitement of new scientific ideas, the corporate imperative to turn a profit, the risk/benefit relationship, and the mandate of the regulatory agencies to protect the public forces us to consider the needs of many constituencies. Obviously, ethical concerns enter into the picture. Also, companies have large investments in the development, manufacture, quality control, clinical testing, regulatory clearance, and distribution of medical devices. How much of an advantage (for the company and the patient) will be realized in introducing an improved device? The improved device may indeed work better for the patient. However, the company will incur a large expense that will be perceived by the stockholders as reduced profits. Moreover, product liability issues are a major concern of manufacturers. The industrial side of the biomaterials field raises questions about the ethics of withholding improved devices from people who need them, the market share advantages of having a better product, and the gargantuan costs (possibly nonrecoverable) of introducing a new product into the medical marketplace. If companies did not have the profit incentive, would there be any medical devices, let alone improved ones, available for clinical application?

When the industrial segment of the biomaterials field is examined, we see other essential contributions to our field. Industry deals well with technologies such as packaging, sterilization, storage, distribution, and quality control and analysis. These subjects are grounded in specialized technologies, often ignored in academic communities, but have the potential to generate stimulating research questions. Also, many companies support in-house basic research laboratories and contribute in important ways to the fundamental study of biomaterials science.

Ethics

A wide range of ethical considerations impact biomaterials science. Some key ethical questions in biomaterials science are summarized in Table 3. Like most ethical questions, an absolute answer may be difficult to come by. Some articles have addressed ethical questions in biomaterials and debated the important points (Saha and Saha, 1987; Schiedermayer and Shapiro, 1989). Chapter 10.4 introduces ethics in biomaterials.

Regulation

The consumer (the patient) demands safe medical devices. To prevent inadequately tested devices and materials from coming on the market, and to screen out individuals clearly unqualified to produce biomaterials, the United States

TABLE 3 Ethical Concerns Relevant to Biomaterials Science

Is the use of animals justified? Specifically, is the experiment well designed and important so that the data obtained will justify the suffering and sacrifice of the life of a living creature?
How should research using humans be conducted to minimize risk to the patient and offer a reasonable risk-to-benefit ratio? How can we best ensure informed consent?
Companies fund much biomaterials research and own proprietary biomaterials. How can the needs of the patient be best balanced with the financial goals of a company? Consider that someone must manufacture devices—these would not be available if a company did not choose to manufacture them.
Since researchers often stand to benefit financially from a successful biomedical device and sometimes even have devices named after them, how can investigator bias be minimized in biomaterials research?
For life-sustaining devices, what is the trade-off between sustaining life and the quality of life with the device for the patient? Should the patient be permitted to “pull the plug” if the quality of life is not satisfactory?
With so many unanswered questions about the basic science of biomaterials, do government regulatory agencies have sufficient information to define adequate tests for materials and devices and to properly regulate biomaterials?
Should the government or other “third-party payors” of medical costs pay for the health care of patients receiving devices that have not yet been formally approved for general use by the FDA and other regulatory bodies?
Should the CEO of a successful multimillion dollar company that is the sole manufacturer a polymer material (that is a minor but crucial component of the sewing ring of nearly all heart valves) yield to the stockholders’ demands that he/she terminate the sale of this material because of litigation concerning one model of heart valve with a large cohort of failures? The company sells 32 pounds of this material annually, yielding revenue of approximately \$40,000?
Should an orthopedic appliance company manufacture two models of hip joint prostheses: one with an expected “lifetime” of 20 years (for young, active recipients) and another that costs one-fourth as much with an expected lifetime of 7 years (for elderly individuals), with the goal of saving resources so that more individuals can receive the appropriate care?

government has evolved a complex regulatory system administered by the U.S. Food and Drug Administration (FDA). Most nations of the world have similar medical device regulatory bodies. The International Standards Organization (ISO) has introduced international standards for the world community. Obviously, a substantial base of biomaterials knowledge went into establishing these standards. The costs to comply with the standards and to implement materials, biological, and clinical testing are enormous. Introducing a new biomedical device to the market requires a regulatory investment of tens of millions of dollars. Are the regulations and standards truly addressing the safety issues? Is the cost of regulation inflating the cost of health care and preventing improved devices from reaching those who need them? Under this regulation topic, we see the intersection of all the players in the biomaterials community: government, industry, ethics, and basic science. The answers are not simple, but the problems must be addressed every day. Chapters 10.2 and 10.3 expand on standards and regulatory concerns.

BIOMATERIALS LITERATURE

Over the past 50 years, the field of biomaterials has evolved from individual medical researchers innovating to save the lives of their patients into the sophisticated, regulatory/ethics-driven multidisciplinary endeavor we see today. Concurrent with the evolution of the discipline, a literature has also developed addressing basic science, applied science, engineering, and commercial issues. A bibliography is provided in Appendix D "The Biomaterials Literature" to highlight key reference works and technical journals in the biomaterials field.

BIOMATERIALS SOCIETIES

The evolution of the biomaterials field, from its roots with individual researchers and clinicians who intellectually associated their efforts with established disciplines such as medicine, chemistry, chemical engineering, or mechanical engineering, to a modern field called "biomaterials," parallels the formation of biomaterials societies. Probably the first biomaterials-related society was the American Society for Artificial Internal Organs (ASAIO). Founded in 1954, this group of visionaries established a platform to consider the development of devices such as the artificial kidney and the artificial heart. A Department of Bioengineering was established at Clemson University, Clemson, South Carolina, in 1963. In 1969, Clemson began organizing annual International Biomaterials Symposia. In 1974–1975, these symposia evolved into the Society For Biomaterials, the world's first biomaterials society.

Founding members, those who joined in 1975 and 1976, numbered about 50 and included clinicians, engineers, chemists, and biologists. Their common interest, biomaterials, was the engaging focus for the multidisciplinary participants. The European Society for Biomaterials was founded in 1975. Shortly after that, the Canadian Society For Biomaterials and the Japanese Society of Biomaterials were formed. The Controlled Release Society, a group strongly rooted in biomaterials for drug delivery, was founded in 1978. At this time there are many national biomaterials societies and related societies. The development of biomaterials professionalism and a sense of identity for the field called biomaterials can be attributed to these societies and the researchers who organized and led them.

SUMMARY

This chapter provides a broad overview of the biomaterials field. It provides a vantage point from which the reader can gain a perspective to see how the subthemes fit into the larger whole.

Biomaterials science may be the most multidisciplinary of all the sciences. Consequently, biomaterials scientists must master certain key material from many fields of science, technology, engineering, and medicine in order to be competent and conversant in this profession. The reward for mastering this volume of material is immersion in an intellectually stimulating endeavor that advances a new basic science of biointeraction and contributes to reducing human suffering.

A History of Biomaterials

BUDDY D. RATNER

At the dawn of the 21st century, biomaterials are widely used throughout medicine, dentistry and biotechnology. Just 50 years ago biomaterials as we think of them today did not exist. The word “biomaterial” was not used. There were no medical device manufacturers (except for external prosthetics such as limbs, fracture fixation devices, glass eyes, and dental devices), no formalized regulatory approval processes, no understanding of biocompatibility, and certainly no academic courses on biomaterials. Yet, crude biomaterials have been used, generally with poor to mixed results, throughout history. This chapter will broadly trace from the earliest days of human civilization to the dawn of the 21st century the history of biomaterials. It is convenient to organize the history of biomaterials into four eras: prehistory, the era of the surgeon hero, designed biomaterials/engineered devices, and the contemporary era leading into a new millennium. However, the emphasis of this chapter will be on the experiments and studies that set the foundation for the field we call biomaterials, largely between 1920 and 1980.

BIOMATERIALS BEFORE WORLD WAR II

Before Civilization

The introduction of nonbiological materials into the human body was noted far back in prehistory. The remains of a human found near Kennewick, Washington, USA (often referred to as the “Kennewick Man”) was dated (with some controversy) to be 9000 years old. This individual, described by archeologists as a tall, healthy, active person, wandered through the region now known as southern Washington with a spear point embedded in his hip. It had apparently healed in and did not significantly impede his activity. This unintended implant illustrates the body’s capacity to deal with implanted foreign materials. The spear point has little resemblance to modern biomaterials, but it was a “tolerated” foreign material implant, just the same.

Dental Implants in Early Civilizations

Unlike the spear point described above, dental implants were devised as implants and used early in history. The Mayan people fashioned nacre teeth from sea shells in roughly 600 A.D. and apparently achieved what we now refer to as bone integration (see Chapter 7.8), basically a seamless integration into the bone (Bobbio, 1972). Similarly, an iron dental implant in a corpse dated 200 A.D. was found in Europe

(Crubezy *et al.*, 1998). This implant, too, was described as properly bone integrated. There were no materials science, biological understanding, or medicine behind these procedures. Still, their success (and longevity) is impressive and highlights two points: the forgiving nature of the human body and the pressing drive, even in prehistoric times, to address the loss of physiologic/anatomic function with an implant.

Sutures for 32,000 Years

There is evidence that sutures may have been used as long as 32,000 years ago (NATNEWS, 1983, 20(5): 15–7). Large wounds were closed early in history by one of two methods—cautery or sutures. Linen sutures were used by the early Egyptians. Catgut was used in the Middle Ages in Europe.

Metallic sutures are first mentioned in early Greek literature. Galen of Pergamon (circa 130–200 A.D.) described ligatures of gold wire. In 1816, Philip Physick, University of Pennsylvania Professor of Surgery, suggested the use of lead wire sutures noting little reaction. In 1849, J. Marion Sims, of Alabama, had a jeweler fabricate sutures of silver wire and performed many successful operations with this metal.

Consider the problems that must have been experienced with sutures in eras with no knowledge of sterilization, toxicology, immunological reaction to extraneous biological materials, inflammation, and biodegradation. Yet sutures were a relatively common fabricated or manufactured biomaterial for thousands of years.

Artificial Hearts and Organ Perfusion

In the 4th century B.C., Aristotle called the heart the most important organ in the body. Galen proposed that veins connected the liver to the heart to circulate “vital spirits throughout the body via the arteries.” English physician William Harvey in 1628 espoused a relatively modern view of heart function when he wrote, “The heart’s one role is the transmission of the blood and its propulsion, by means of the arteries, to the extremities everywhere.” With the appreciation of the heart as a pump, it was a logical idea to think of replacing the heart with an artificial pump. In 1812, the French physiologist Le Gallois expressed his idea that organs could be kept alive by pumping blood through them. A number of experiments on organ perfusion with pumps were performed from 1828–1868. In 1881, Étienne-Jules Marey, a brilliant scientist and thinker who published and invented in photography theory, motion

FIG. 1. An artificial heart by Étienne-Jules Marey, Paris, 1881.

studies and physiology, described an artificial heart device (Fig. 1), but probably never constructed such an apparatus.

In 1938, aviator (and engineer) Charles Lindbergh and surgeon (and Nobel prize winner) Alexis Carrel wrote a visionary book, *The Culture of Organs*. They addressed issues of pump design (referred to as the Lindbergh pump), sterility, blood damage, the nutritional needs of perfused organs and mechanics. This book must be considered a seminal document in the history of artificial organs. In the mid-1950s, Dr. Paul Winchell, better known as a ventriloquist, patented an artificial heart. In 1957, Dr. Willem Kolff and a team of scientists tested the artificial heart in animals. (The modern history of the artificial heart will be presented later in Chapter 7.4).

Contact Lenses

Leonardo DaVinci, in the year 1508, developed the contact lens concept. Rene Descartes is credited with the idea of the corneal contact lens (1632) and Sir John F. W. Herschel (1827) suggested that a glass lens could protect the eye. Adolf Fick, best known for his laws of diffusion, was an optometrist

by profession. One of his inventions (roughly 1860) was a glass contact lens, possibly the first contact lens offering real success. He experimented on both animals and humans with contact lenses. In a period from 1936 to 1948, plastic contact lenses were developed, primarily poly(methyl methacrylate).

Basic Concepts of Biocompatibility

Most implants prior to 1950 had a low probability of success because of a poor understanding of biocompatibility and sterilization. As will be elaborated upon throughout the textbook, factors that contribute to biocompatibility include the chemistry of the implant, leachables, shape, mechanics, and design. Early studies, especially with metals, explored primarily chemistry ideas to explain the observed bioreaction.

Possibly the first study assessing the *in vivo* bioreactivity of implant materials was performed by H. S. Levert (1829). Gold, silver, lead, and platinum specimens were studied in dogs and platinum, in particular, was found to be well tolerated. In 1886, bone fixation plates of nickel-plated sheet steel with nickel-plated screws were studied. In 1924, A. Zierold published a study on tissue reaction to various materials in dogs. Iron and steel were found to corrode rapidly leading to resorption of adjacent bone. Copper, magnesium, aluminum alloy, zinc, and nickel discolored the surrounding tissue while gold, silver, lead, and aluminum were tolerated but inadequate mechanically. Stellite, a Co-Cr-Mo alloy, was well tolerated and strong. In 1926, M. Large noted inertness displayed by 18-8 stainless steel containing molybdenum. By 1929 Vitallium alloy (65% Co-30% Cr-5% Mo) was developed and used with success in dentistry. In 1947, J. Cotton of the UK discussed the possible use for titanium and alloys for medical implants.

The history of plastics as implantation materials is not nearly as old as metals, simply because there were few plastics prior to the 1940s. What is possibly the first paper on the implantation of a modern synthetic polymer, nylon as a suture, appeared in 1941. Papers on the implantation of cellophane, a polymer made from plant sources, were published as early as 1939, where it was used as a wrapping for blood vessels. The response to this implant was described as a "marked fibrotic reaction." In the early 1940s papers appeared discussing the reaction to implanted poly(methyl methacrylate) and nylon. The first paper on polyethylene as a synthetic implant material was published in 1947 (Ingraham *et al.*). The paper pointed out that polyethylene production using a new high-pressure polymerization technique began in 1936. This process enabled the production of polyethylene free of initiator fragments and other additives. Ingraham *et al.* demonstrated good results on implantation (i.e., a mild foreign body reaction) and attributed these results to the high purity of the polymer they used. A 1949 paper commented on the fact that additives to many plastics had a tendency to "sweat out" and this may be responsible for the strong biological reaction to those plastics (LeVeen and Barberio, 1949). They found a vigorous foreign body reaction to cellophane, Lucite, and nylon but extremely mild reaction to "a new plastic," Teflon. The authors incisively concluded, "Whether the tissue reaction is due to the dissolution of traces of the unpolymerized chemical used in plastics manufacture or

actually to the solution of an infinitesimal amount of the plastic itself cannot be determined.” The possibility that cellulose might trigger the severe reaction by activating the complement system could not have been imagined because the complement system was not yet discovered.

POST WORLD WAR II—THE SURGEON/ PHYSICIAN HERO

At the end of World War II, high-performance metal, ceramic, and especially polymeric materials transitioned from wartime restricted to peacetime available. The possibilities for using these durable, novel, inert materials immediately intrigued surgeons with needs to replace diseased or damaged body parts. Materials originally manufactured for airplanes and automobiles were taken “off the shelf” by surgeons and applied to medical problems. These early biomaterials include silicones, polyurethanes, Teflon, nylon, methacrylates, titanium, and stainless steel.

A historical context helps us appreciate the contribution made primarily by medical and dental practitioners. After World War II, there was little precedent for surgeons to collaborate with scientists and engineers. Medical and dental practitioners of this era felt it was appropriate to invent (improvise) on their own where the life or functionality of their patient was at stake. Also, there was minimal government regulatory activity and minimal human subjects protections. The physician was implicitly entrusted with the life and health of the patient and had much more freedom than is seen today to take heroic action where other options were exhausted.¹ These medical practitioners had read about the post-World War II marvels of materials science. Looking at a patient open on the operating table, they could imagine replacements, bridges, conduits, and even organ systems based on such materials. Many materials were tried on the spur of the moment. Some fortuitously succeeded. These were high-risk trials, but usually they took place where other options were not available. The term “surgeon hero” seems justified since the surgeon often had a life (or a quality of life) at stake and was willing to take a huge technological and professional leap to repair the individual. This laissez faire biomaterials era quickly led to a new order characterized by scientific/engineering input, government quality controls, and a sharing of decisions prior to attempting high-risk, novel procedures. Still, a foundation of ideas and materials for the biomaterials field was built by courageous, fiercely committed, creative individuals and it is important to look at this foundation to understand many of the attitudes, trends, and materials common today.

¹The regulatory climate in the United States in the 1950s was strikingly different from now. This can be appreciated in this recollection from Willem Kolff about a pump oxygenator he made and brought with him from Holland to the Cleveland Clinic (Kolff, 1998): “Before allowing Dr. Efler and Dr. Groves to apply the pump oxygenator clinically to human babies, I insisted they do 10 consecutive, successful operations in baby dogs. The chests were opened, the dogs were connected to a heart-lung machine to maintain the circulation, the right ventricles were opened, a cut was made in the interventricular septa, the septa holes were closed, the right ventricles were closed, the tubes were removed and the chests were closed. (I have a beautiful movie that shows these 10 puppies trying to crawl out of a basket).”

Intraocular Lenses

Sir Harold Ridley, M.D. (1906–2001) (Fig. 2), inventor of the plastic intraocular lens (IOL), made early, accurate observations of biological reaction to implants consistent with currently accepted ideas of biocompatibility. After World War II, he had the opportunity to examine aviators who were unintentionally implanted in their eyes with shards of plastic from shattered canopies in Spitfire and Hurricane fighter planes. Most of these flyers had plastic fragments in their eyes for years. The conventional wisdom at that time was that the human body would not tolerate implanted foreign objects, especially in the eye—the body’s reaction to a splinter or a bullet was cited as examples of the difficulty of implanting materials in the body. The eye is an interesting implant site because you can look in through a transparent window to see what happened. When Ridley did so, he noted that the shards had healed in place with no further reaction. They were, by his standard, tolerated by the eye. Today, we would describe this type of stable healing without significant ongoing inflammation or irritation as “biocompatible.” This is an early observation of “biocompatible” in humans, perhaps the first, using criteria similar to those accepted today. Based on this observation, Ridley traced down the source of the plastic domes, ICI Perspex poly(methyl methacrylate), and ordered sheets of the material. He used this material to fabricate implant lenses (intraocular lenses) that were found, after some experimentation, to function reasonably in humans as replacements for surgically removed natural lenses that had been clouded by cataracts. The first implantation in a human was November 29, 1949. For many years, Ridley was the center of fierce controversy because he challenged the dogma that spoke against implanting foreign materials in eyes—it hard to believe in the 21st century that the implantation of a biomaterial would provoke such an outcry. Because of this controversy, this industry did not spontaneously arise—it has to await the early 1980s before IOLs became a major force in the biomedical device market. Ridley’s insightful observation, creativity, persistence, and surgical talent in the late 1940s evolved to an industry that presently puts more than 7,000,000 of these lenses annually in humans. Through all of human history, cataracts meant blindness, or a surgical procedure that left the recipient needing thick, unaesthetic eye glasses that poorly corrected the vision. Ridley’s concept, using a plastic material found to be “biocompatible,” changed the course of history and substantially improved the quality of life for millions of individuals with cataracts. Harold Ridley’s story is elaborated upon in an obituary (Apple and Trivedi, 2002).

Hip and Knee Prostheses

The first hip replacement was probably performed in 1891 by a German surgeon, Theodore Gluck, using a cemented ivory ball. This procedure was not successful. Numerous attempts were made between 1920 and 1950 to develop a hip replacement prosthesis. Surgeon M. N. Smith-Petersen, in 1925, explored a glass hemisphere to fit over the ball of the hip joint. This failed because of poor durability. Chrome-based alloys

FIG. 2. Sir Harold Ridley, inventor of the intraocular lens.

and stainless steel offered improvements in mechanical properties and many variants of these were explored. In 1938, the Judet Brothers of Paris, Robert and Jean, explored an acrylic surface for hip procedures, but it had a tendency to wear and loosen. The idea of using fast-setting dental acrylics to anchor prosthetics to bone was developed by Dr. Edward J. Haboush in 1953. In 1956, McKee and Watson-Farrar developed a “total” hip with an acetabular cup of metal that was cemented in place. Metal-on-metal wear products probably led to high complication rates. It was John Charnley (1911–1982) (Fig. 3), working at an isolated tuberculosis sanatorium in Wrightington, Manchester, England, who invented the first really successful hip joint prosthesis. The femoral stem, ball head, and plastic acetabular cup proved to be a reasonable solution to the problem of damaged joint replacement. In 1958, Dr. Charnley used a Teflon acetabular cup with poor outcomes due to wear debris. By 1961 he was using a high-molecular-weight polyethylene cup and was achieving much higher success rates. Interestingly, Charnley learned of high-molecular-weight polyethylene from a salesman selling novel plastic gears to one of his technicians. Dr. Dennis Smith contributed in an important way to the development of the hip prosthesis by introducing Dr. Charnley to poly(methyl methacrylate) cements, developed in the dental community, and optimizing those cements for hip replacement use. Total knee replacements borrowed elements of the hip prosthesis technology and successful results were obtained in the period 1968–1972 with surgeons Frank Gunston and John Insall leading the way.

FIG. 3. Sir John Charnley.

Dental Implants

Some of the “prehistory” of dental implants was described earlier. In 1809, Maggiolo implanted a gold post anchor into fresh extraction sockets. After allowing this to heal, he fastened to it a tooth. This has remarkable similarity to modern dental implant procedures. In 1887, this procedure was used with a platinum post. Gold and platinum gave poor long-term results and so this procedure was never widely adopted. In 1937, Venable used surgical Vitallium and Co–Cr–Mo alloy for such implants. Also around 1937, Strock at Harvard used a screw-type implant of Vitallium and this may be the first successful dental implant. A number of developments in surgical procedure and implant design (for example, the endosteal blade implant) then took place. In 1952, a fortuitous discovery was made. Per Ingvar Branemark, an orthopedic surgeon at the University of Lund, Sweden, was implanting an experimental cage device in rabbit bone for observing healing reactions. The cage was a titanium cylinder that screwed into the bone. After completing the experiment that lasted several months, he tried to remove the titanium device and found it tightly integrated in the bone (Branemark *et al.*, 1964). Dr. Branemark named the phenomenon osseointegration and explored the application of titanium implants to surgical and dental procedures. He also developed low-impact surgical protocols for tooth implantation that reduced tissue necrosis and enhanced the probability of good outcomes. Most dental implants and many other orthopedic implants are now made of titanium and its alloys.

The Artificial Kidney

Kidney failure, through most of history, was a sentence to unpleasant death lasting over a period of about a month. In 1910, at Johns Hopkins University, the first attempts to

remove toxins from blood were made by John Jacob Abel. The experiments were with rabbit blood and it was not possible to perform this procedure on humans. In 1943, in Nazi-occupied Holland, Willem Kolff (Fig. 4), a physician just beginning his career at that time, built a drum dialyzer system from a 100-liter tank, wood slats, and sausage-casing (cellulose) as the dialysis membrane. Some successes were seen in saving lives where prior to this there was only one unpleasant outcome to kidney failure. Kolff took his ideas to the United States and in 1960, at the Cleveland Clinic, developed a “washing machine artificial kidney” (Fig. 5). Major advances in kidney dialysis were made by Dr. Belding Scribner (1921–2003) at the University of Washington. Scribner devised a method to routinely access the bloodstream for dialysis treatments. Prior to this, after just a few treatments, access sites to the blood were used up and further dialysis was not possible. After seeing the potential of dialysis to help patients, but only acutely, Scribner tells the story of waking up in the middle of the night with an idea to gain easy access to the blood—a shunt implanted between an artery and vein that emerged through the skin as a “U.” Through the exposed portion of the shunt, blood access could be readily achieved. When Dr. Scribner heard about this new plastic, Teflon, he envisioned how to get the blood out of and into the blood vessels. His device used Teflon tubes to access the vessels, a Dacron sewing cuff through the skin, and a silicone rubber tube for blood flow. The Scribner shunt made chronic dialysis possible and is said to be responsible for more than a million patients being alive today. Additional important contributions to the artificial kidney were made by Professor Les Babb of the University of Washington who, working with Scribner, improved dialysis performance and invented a proportioning mixer for the dialysate fluid.

The Artificial Heart

Willem Kolff was also a pioneer in the development of the artificial heart. He implanted the first artificial heart in the Western hemisphere in a dog in 1957 (a Russian artificial heart was implanted in a dog in the late 1930s). The Kolff artificial heart was made of a thermosetting poly(vinyl chloride) cast inside hollow molds to prevent seams. In 1953, the heart–lung machine was invented by John Gibbon, but this was useful only for acute treatment as during open heart surgery. After the National Heart and Lung Institute of the NIH in 1964 set a goal of a total artificial heart by 1970, Dr. Michael DeBakey implanted a left ventricular assist device in a human in 1966 and Dr. Denton Cooley implanted a polyurethane total artificial heart in 1969. In the period 1982–1985, Dr. William DeVries implanted a number of Jarvik hearts with patients living up to 620 days on the devices.

Breast Implants

The breast implant evolved to address the poor results achieved with direct injection of substances into the breast for augmentation. In fact, in the 1960s, California and Utah classified silicone injections as a criminal offense. In the 1950s,

FIG. 4. Dr. Willem Kolff at age 92. (Photo by B. Ratner.)

FIG. 5. Willem Kolff (center) and the washing machine artificial kidney.

poly(vinyl alcohol) sponges were implanted as breast prostheses, but results with these were also poor. University of Texas plastic surgeons Thomas Cronin and Frank Gerow invented the first silicone breast implant in the early 1960s, a silicone shell filled with silicone gel. Many variants of this device have been tried over the years, including cladding the device with polyurethane foam (the Natural Y implant). This variant of the breast implant was fraught with problems. However, the basic silicone rubber–silicone gel breast implant was generally acceptable in performance (Bondurant *et al.*, 1999).

Vascular Grafts

Surgeons have long needed methods and materials to repair damaged and diseased blood vessels. Early in the century, Dr. Alexis Carrel developed methods to anastomose (suture) blood vessels, an achievement for which he won the Nobel Prize in medicine in 1912. In 1942, Blackmore used Vitallium metal tubes to bridge arterial defects in war-wounded soldiers. Columbia University surgical intern Arthur Voorhees (1922–1992), in 1947, noticed during a post-mortem that tissue had grown around a silk suture left inside a lab animal. This observation stimulated the idea that a cloth tube might also heal by being populated by the tissues of the body. Perhaps such a healing reaction in a tube could be used to replace an artery? His first experimental vascular grafts were sewn from a silk handkerchief and then parachute fabric (Vinyon N), using his wife's sewing machine. The first human implant of a prosthetic vascular graft was in 1952. The patient lived many years after this procedure, inspiring many surgeons to copy the procedure. By 1954, another paper was published establishing the clear benefit of a porous (fabric) tube over a solid polyethylene tube (Egdahl *et al.*, 1954). In 1958, the following technique was described in a textbook on vascular surgery (Rob, 1958): "The Terylene, Orlon or nylon cloth is bought from a draper's shop and cut with pinking shears to the required shape. It is then sewn with thread of similar material into a tube and sterilized by autoclaving before use."

Stents

Partially occluded coronary arteries lead to angina, diminished heart functionality, and eventually, when the artery occludes (i.e., myocardial infarction), death of a section of the heart muscle. Bypass operations take a section of vein from another part of the body and replace the occluded coronary artery with a clean conduit—this is major surgery, hard on the patient and expensive. Synthetic vascular grafts in the 3-mm diameter appropriate to the human coronary artery anatomy will thrombose and thus cannot be used. Another option is percutaneous transluminal coronary angioplasty (PTCA). In this procedure, a balloon is threaded on a catheter into the coronary artery and then inflated to open the lumen of the occluding vessel. However, in many cases the coronary artery can spasm and close from the trauma of the procedure. The invention of the coronary artery stent, an expandable metal mesh that holds the lumen open after PTCA, was a major revolution in the treatment of coronary occlusive disease. In his own words,

Dr. Julio Palmaz (Fig. 6) describes the origins and history of the cardiovascular stent.

I was at a meeting of the Society of Cardiovascular and Interventional Radiology in February 1978, New Orleans when a visiting lecturer, Doctor Andreas Gruntzig from Switzerland, was presenting his preliminary experience with coronary balloon angioplasty. As you know, in 1978 the mainstay therapy of coronary heart disease was surgical bypass. Doctor Gruntzig showed his promising new technique to open up coronary atherosclerotic blockages without the need for open chest surgery, using his own plastic balloon catheters. During his presentation, he made it clear that in a third of the cases, the treated vessel closed back after initial opening with the angioplasty balloon because of elastic recoil or delamination of the vessel wall layers. This required standby surgery facilities and personnel, in case of acute closure after balloon angioplasty prompted emergency coronary bypass. Gruntzig's description of the problem of vessel reclosure elicited in my mind the idea of using some sort of support, such as used in mine tunnels or in oil well drilling. Since the coronary balloon goes in small (folded like an umbrella) and is inflated to about 3–4 times its initial diameter, my idealistic support device needed to go in small and expand at the site of blockage with the balloon. I thought one way to solve this was a malleable tubular criss-cross mesh. I went back home in the Bay Area and started making crude prototypes with copper wire and lead solder, which I first tested in rubber tubes mimicking arteries. I called the device a BEIS or balloon-expandable intravascular graft. However, the reviewers of my first submitted paper wanted to call it a stent. When I looked the word up, I found out that it derives from Charles Stent, a British dentist who died at turn of the century. Stent invented a wax material to make dental molds for dentures. This material was later used by plastic surgeons to keep tissues in place, while healing after surgery. The word "stent" was then generically used for any device intended to keep tissues in place while healing.

I made the early experimental device of stainless steel wire soldered with silver. These were materials I thought would be appropriate for initial laboratory animal testing. To carry on with my project I moved to the University of Texas Health Science Center in San Antonio (UTHSCSA) where I had a research laboratory and time for further development. From 1983–86 I performed mainly bench and animal testing. Dozens of ensuing projects showed the promise of the technique and the potential applications it had in many areas of vascular surgery and cardiology. With a UTHSCSA pathologist, Doctor Fermin Tio, we observed our first microscopic specimen of implanted stents in awe. After weeks to months after implantation by catheterization under X-ray guidance, the stent had remained open, carrying blood flow. The metal mesh was covered with translucent, glistening tissue similar to the lining of a normal vessel. The question remained whether the same would happen in atherosclerotic vessels. We tested this question in the atherosclerotic rabbit model and to our surprise, the new tissue free of atherosclerotic plaque encapsulated the stent wires, despite the fact that the animals were still on a high cholesterol diet. Eventually, a large sponsor (Johnson and Johnson) adopted the project and clinical trials were instituted under the scrutiny of the Food and Drug Administration, to compare stents to balloon angioplasty.

Coronary artery stenting is now performed in well over 1.5 million procedures per year.

FIG. 6. Dr. Julio Palmaz, inventor of the coronary artery stent.

Pacemakers

In London, in 1788, Charles Kite wrote “An Essay Upon the Recovery of the Apparently Dead” where he discussed electrical discharges to the chest for heart resuscitation. In the period 1820–1880, it was already known that electric shocks could modulate the heartbeat (and, of course, consider the Frankenstein story from that era). The invention of the portable pacemaker, hardly portable by modern standards, may have taken place almost simultaneously in two groups in 1930–31—Dr. Albert S. Hyman (USA) (Fig. 7) and Dr. Mark C. Lidwill (working in Australia with physicist Major Edgar Booth).

Canadian electrical engineer John Hopps, while conducting research on hypothermia in 1949, invented an early cardiac pacemaker. Hopps’ discovery was that if a cooled heart stopped beating, it could be electrically restarted. This led to Hopps’ invention of a vacuum tube cardiac pacemaker in 1950. Paul M. Zoll developed a pacemaker in conjunction with the Electrodyne Company in 1952. The device was about the size of a large table radio, was powered with external current, and stimulated the heart using electrodes placed on the chest—this therapy caused pain and burns, though it could pace the heart.

In the period 1957–58, Earl E. Bakken, founder of Medtronic, Inc., developed the first wearable transistorized (external) pacemaker at the request of heart surgeon, Dr. C. Walton Lillehei. Bakken quickly produced a prototype that Lillehei used on children with postsurgery heart block. Medtronic commercially produced this wearable, transistorized unit as the 5800 pacemaker.

FIG. 7. The Albert Hyman Model II portable pacemaker, circa 1932–1933. (With permission of NASPE Heart Rhythm Society.)

In 1959, the first fully implantable pacemaker was developed by engineer Wilson Greatbatch and cardiologist W. M. Chardack. He used two Texas Instruments transistors, a technical innovation that permitted small size and low power drain. The pacemaker was encased in epoxy to inhibit body fluids from inactivating it.

Heart Valves

The development of the prosthetic heart valve paralleled developments in cardiac surgery. Until the heart could be stopped and blood flow diverted, the replacement of a valve would be challenging. Charles Hufnagel, in 1952, implanted a valve consisting of a poly(methyl methacrylate) tube and nylon ball in a beating heart. This was a heroic operation and basically unsuccessful, but an operation that inspired cardiac surgeons to consider that valve prostheses might be possible. The 1953 development of the heart–lung machine by Gibbon allowed the next stage in the evolution of the prosthetic heart valve to take place. In 1960, a mitral valve replacement was performed in a human by surgeon Albert Starr using a valve design consisting of a silicone ball and poly(methyl methacrylate) cage (later replaced by a stainless steel cage). The valve was invented by engineer Lowell Edwards. The heart valve was based on a design for a bottle stopper invented in 1858. Starr was quoted as saying, “Let’s make a valve that works and not worry about its looks,” referring to its design that was radically different from the leaflet valve that nature evolved in mammals. Prior to the Starr–Edwards valve, no human had lived with a prosthetic heart valve longer than 3 months. The Starr–Edwards valve was

found to permit good patient survival. The major issues in valve development in that era were thrombosis and durability. Warren Hancock started the development of the first leaflet tissue heart valve in 1969 and his company and valve were acquired by Johnson & Johnson in 1979.

DESIGNED BIOMATERIALS

In contrast to the biomaterials of the surgeon-hero era, largely off-the-shelf materials used to fabricate medical devices, the 1960s saw the development of materials designed specifically for biomaterials applications. Here are some key classes of materials and their evolution from commodity materials to engineered/synthesized biomaterials.

Silicones

Though the class of polymers known as silicones has been explored for many years, it was not until the early 1940s that Eugene Rochow of GE pioneered the scale-up and manufacture of commercial silicones via the reaction of methyl chloride with silicon in the presence of catalysts. In Rochow's 1946 book, *The Chemistry of Silicones* (John Wiley & Sons, Publishers), he comments anecdotally on the low toxicity of silicones but did not propose medical applications. The potential for medical uses of these materials was realized shortly after this. In a 1954 book on silicones, McGregor has a whole chapter titled "Physiological Response to Silicones." Toxicological studies were cited suggesting to McGregor that the quantities of silicones that humans might take into their bodies should be "entirely harmless." He mentions, without citation, the application of silicone rubber in artificial kidneys. Silicone-coated rubber grids were also used to support a dialysis membrane (Skeggs and Leonards, 1948). Many other early applications of silicones in medicine are cited in Chapter 2.3.

Polyurethanes

Polyurethanes, reaction products of diisocyanates and diamines, were invented by Otto Bayer and colleagues in Germany in 1937. The chemistry of polyurethanes intrinsically offered a wide range of synthetic options leading to hard plastics, flexible films, or elastomers (Chapter 2.2). Interestingly, this was the first class of polymers to exhibit rubber elasticity without covalent cross-linking. As early as 1959, polyurethanes were explored for biomedical applications, specifically heart valves (Akutsu *et al.*, 1959). In the mid-1960s a class of segmented polyurethanes was developed that showed both good biocompatibility and outstanding flex life in biological solutions at 37°C (Boretos and Pierce, 1967). Sold under the name Biomer, these segmented polyurethanes comprised the pump diaphragms of the Jarvik 7 hearts that were implanted in seven humans.

Teflon

DuPont chemist Roy Plunkett discovered a remarkably inert polymer, Teflon (polytetrafluoroethylene), in 1938. William L. Gore and his wife Vieve started a company in 1958 to apply Teflon for wire insulation. In 1969, their son Bob found that Teflon, if heated and stretched, forms a porous membrane with attractive physical and chemical properties. Bill Gore tells the story that, on a chairlift at a ski resort, he pulled from his parka pocket a piece of porous Teflon tubing to show to his fellow ski lift passenger. The skier was a physician and asked for a specimen to try as a vascular prosthesis. Now, Goretex porous Teflon is the leading synthetic vascular graft and has numerous applications in surgery and biotechnology.

Hydrogels

Hydrogels have been found in nature since life on earth evolved. Bacterial biofilms, hydrated living tissues, extracellular matrix components, and plant structures are ubiquitous, hydrated, swollen motifs in nature. Gelatin and agar were also explored early in human history. But, the modern history of hydrogels as a class of materials designed for medical applications can be accurately traced.

In 1936, DuPont scientists published a paper on recently synthesized methacrylic polymers. In this paper, poly(2-hydroxyethyl methacrylate) (polyHEMA) was mentioned. It was briefly described as a hard, brittle, glassy polymer and clearly not considered of importance. After that paper, this polymer was essentially forgotten until 1960. Wichterle and Lim published a paper in *Nature* describing the polymerization of HEMA monomer and a cross-linking agent in the presence of water and other solvents (Wichterle and Lim, 1960). Instead of a brittle polymer, they obtained a soft, water-swollen, elastic, clear gel. This innovation led to the soft contact lens industry and to the modern field of biomedical hydrogels as we know them today.

Interest and applications for hydrogels have steadily grown over the years and these are described in detail in Chapter 2.5. Important early applications included acrylamide gels for electrophoresis, poly(vinyl alcohol) porous sponges (Ivalon) as implants, many hydrogel formulations as soft contact lenses, and alginate gels for cell encapsulation.

Poly(ethylene glycol)

Poly(ethylene glycol) (PEG), also called poly(ethylene oxide) (PEO) in its high-molecular-weight form, can be categorized as a hydrogel, especially when the chains are cross-linked. However, PEG has many other applications and implementations. It is so widely used today that it is best discussed in its own section.

The low reactivity of PEG with living organisms has been known since at least 1944 where it was examined as a possible vehicle for intravenously administering fat-soluble hormones (Friedman, 1944). In the mid-1970s, Abuchowski and colleagues (Abuchowski *et al.*, 1977) discovered that if PEG chains were attached to enzymes and proteins, they would have a much longer functional residence time *in vivo* than

biomolecules that were not PEGylated. Professor Edward Merrill of MIT, based upon what he called “various bits of evidence” from the literature, concluded that surface-immobilized PEG would resist protein and cell pickup. The experimental results from his research group in the early 1980s bore this conclusion out (Merrill, 1992). The application of PEGs to wide range of biomedical problems has been significantly accelerated by the synthetic chemistry developments of Dr. Milton Harris while at the University of Alabama, Huntsville.

Poly(lactic–glycolic acid)

Though originally discovered in 1833, the anionic polymerization from the cyclic lactide monomer in the early 1960s made materials with mechanical properties comparable to Dacron possible. The first publication on the application of poly(lactic acid) in medicine may have been by Kulkarni *et al.* (1966). This group demonstrated that the polymer degraded slowly after implantation in guinea pigs or rats and was well tolerated by the organisms. Cutright *et al.* (1971) was the first to apply this polymer for orthopedic fixation. Poly(glycolic acid) and copolymers of lactic and glycolic acid were subsequently developed. Early clinical applications of polymers in this family were for sutures. The glycolic acid/lactic acid polymers have also been widely applied for controlled release of drugs and proteins. Professor Robert Langer’s group was the leader in developing these polymers in the form of porous scaffolds for tissue engineering (Langer and Vacanti, 1993).

Hydroxyapatite

Hydroxyapatite is one of the most widely studied materials for healing in bone. It is both a natural component of bone (i.e., a material of ancient history) and a synthetic material with a modern history. Hydroxyapatite can be easily made as a powder. One of the first papers to apply this material for biomedical application was by Levitt *et al.* (1969), in which they hot-pressed the hydroxyapatite powder into useful shapes for biological experimentation. From this early appreciation of the materials science aspect of a natural biomineral, a literature of thousands of papers has evolved. In fact, the nacre implant described in the prehistory section may owe its effectiveness to hydroxyapatite—recent data have shown that the calcium carbonate of nacre can transform in phosphate solutions to hydroxyapatite (Ni and Ratner, 2003).

Titanium

In 1791, William Gregor, a Cornish amateur chemist, used a magnet to extract the ore that we now know as ilmenite from a local river. He then extracted the iron from this black powder with hydrochloric acid and was left with a residue that was the impure oxide of titanium. After 1932, a process developed by William Kroll permitted the commercial extraction of titanium from mineral sources. At the end of World War II, titanium metallurgy methods and titanium materials made their way from military application to peacetime uses. By 1940, satisfactory results had already been achieved with titanium implants

(Bothe *et al.*, 1940). The major breakthrough in the use of titanium for bony tissue implants was the Branemark discovery of osseointegration, described earlier in the section on dental implants.

Bioglass

Bioglass is important to biomaterials as one of the first completely synthetic materials that seamlessly bonds to bone. It was developed by Professor Larry Hench and colleagues. In 1967 Hench was an assistant professor at the University of Florida. At that time his work focused on glass materials and their interaction with nuclear radiation. In August of that year, he shared a bus ride to an Army Materials Conference in Sagamore, New York, with a U.S. Army Colonel who had just returned from Vietnam where he was in charge of supplies to 15 MASH units. He was not terribly interested in the radiation resistance of glass. Rather, he challenged Hench with the following: hundreds of limbs a week in Vietnam were being amputated because the body was found to reject the metals and polymer materials used to repair the body. “If you can make a material that will resist gamma rays, why not make a material the body won’t resist?”

Hench returned from the conference and wrote a proposal to the U.S. Army Medical R and D Command. In October 1969 the project was funded to test the hypothesis that silicate-based glasses and glass-ceramics containing critical amounts of Ca and P ions would not be rejected by bone. In November 1969 Hench made small rectangles of what he called 45S5 glass (44.5 wt.% SiO₂) and Ted Greenlee, Assistant Professor of Orthopaedic Surgery at the University of Florida, implanted them in rat femurs at the VA Hospital in Gainesville. Six weeks later Greenlee called—“Larry, what are those samples you gave me? They will not come out of the bone. I have pulled on them, I have pushed on them, I have cracked the bone and they are still bonded in place.” Bioglass was born, and with the first composition studied! Later studies by Hench using surface analysis equipment showed that the surface of the Bioglass, in biological fluids, transformed from a silicate-rich composition to a phosphate-rich structure, possibly with resemblance to hydroxyapatite (Clark *et al.*, 1976).

THE CONTEMPORARY ERA (MODERN BIOLOGY AND MODERN MATERIALS)

It is probable that the modern era in the history of biomaterials, biomaterials engineered to control specific biological reactions, was ushered in by rapid developments in modern biology. In the 1960s, when the field of biomaterials was laying down its foundation principles and ideas, concepts such as cell-surface receptors, growth factors, nuclear control of protein expression and phenotype, cell attachment proteins, and gene delivery were either controversial observations or undiscovered. Thus, pioneers in the field, even if so moved, could not have designed materials with these ideas in mind. It is to the credit of the biomaterials community that it has been quick

to embrace and exploit new ideas from biology. Similarly, new ideas from materials science such as phase separation, anodization, self-assembly, surface modification, and surface analysis were quickly assimilated into the biomaterial scientists' toolbox and vocabulary. A few of the important ideas in the biomaterials literature that set the stage for the biomaterials science we see today are useful to list:

- Protein adsorption
- Biospecific biomaterials
- Nonfouling materials
- Healing and the foreign-body reaction
- Controlled release
- Tissue engineering
- Regenerative medicine

Since these topics are well elaborated upon in *Biomaterials Science: An Introduction to Materials in Medicine*, 2nd edition, they will not be expanded upon in this history section. Still, it is important to appreciate the intellectual leadership of many researchers that promoted these ideas that make up modern biomaterials.

CONCLUSIONS

Biomaterials have progressed from surgeon-heroes, sometimes working with engineers, to a field dominated by engineers and scientists, to our modern era with the biologist as a critical player. As *Biomaterials Science: An Introduction to Materials in Medicine*, 2nd edition, is being published, many individuals who were biomaterials pioneers in the formative days of the field are well into their ninth decade. A number of leaders of biomaterials, pioneers who spearheaded the field with vision, creativity, and integrity, have passed away. Biomaterials is a field with a history modern enough so the first-hand accounts of its roots are available. I encourage readers of the textbook to document their conversations with pioneers of the field (many of whom still attend biomaterials conferences), so that the exciting stories that led to the successful and intellectually alive field we see today are not lost.

Properties of Materials

EVELYN OWEN CAREW, FRANCIS W. COOKE, JACK E. LEMONS, BUDDY D. RATNER,
IVAN VESELY, AND ERWIN VOGLER

1.1 INTRODUCTION

Jack E. Lemons

The bulk and surface properties of biomaterials used for medical implants have been shown to directly influence, and in some cases, control the dynamic interactions that take place at the tissue–implant interface. These interactions are included in the concept of compatibility, which should be viewed as a two-way process between the implanted materials and the host environment that is ongoing throughout the *in vivo* lifetime of the device.

It is critical to recognize that synthetic materials have specific bulk and surface properties or characteristics. These characteristics must be known prior to any medical application, but also must be known in terms of changes that may take place over time *in vivo*. That is, changes with time must be anticipated at the outset and accounted for through selection of biomaterials and/or design of the device.

Information related to basic properties is available from national and international standards, plus handbooks and professional journals of various types. However, this information must be evaluated within the context of the intended biomedical use, since applications and host tissue responses are quite specific for given areas, e.g., cardiovascular (flowing blood contact), orthopedic (functional load bearing), and dental (percutaneous).

The following chapters provide two chapters on basic information about bulk and surface properties of biomaterials based on metallic, polymeric, and ceramic substrates, a chapter on finite element modeling and analyses, and a chapter specific to the role(s) of water and surface interaction with biomaterials. Also included are details about how some of these characteristics have been determined. The content of these chapters is intended to be relatively basic and more in-depth information is provided in later chapters and in the references.

1.2 BULK PROPERTIES OF MATERIALS

Francis W. Cooke

INTRODUCTION: THE SOLID STATE

Solids are distinguished from the other states of matter (liquids and gases) by the fact that their constituent atoms are

held together by strong interatomic forces (Pauling, 1960). The electronic and atomic structures, and almost all the physical properties, of solids depend on the nature and strength of the interatomic bonds. For a full account of the nature of these bonds one would have to resort to the modern theory of quantum mechanics. However, the mathematical complexities of this theory are much beyond the scope of this book and we will instead content ourselves with the earlier, classical model, which is still very adequate. According to the classical theory there are three different types of strong or primary interatomic bonds: ionic, covalent, and metallic.

Ionic Bonding

In the ionic bond, electron donor (metallic) atoms transfer one or more electrons to an electron acceptor (nonmetallic) atom. The two atoms then become a cation (e.g., metal) and an anion (e.g., nonmetal), which are strongly attracted by the electrostatic or Coulomb effect. This attraction of cations and anions constitutes the ionic bond (Hummel, 1997).

In ionic solids composed of many ions, the ions are arranged so that each cation is surrounded by as many anions as possible to reduce the strong mutual repulsion of cations. This packing further reduces the overall energy of the assembly and leads to a highly ordered arrangement called a crystal structure (Fig. 1).

Note that in such a crystal no discrete molecules exist, but only an orderly collection of cations and anions. The loosely bound electrons of the atoms are now tightly held in the locality of the ionic bond. These bound electrons are no longer available to serve as charge carriers and ionic solids are poor electrical conductors. Finally, the low overall energy state of these substances endows them with relatively low chemical reactivity. Sodium chloride (NaCl) and magnesium oxide (MgO) are examples of ionic solids.

Covalent Bonding

Elements that fall along the boundary between metals and nonmetals, such as carbon and silicon, have atoms with four valence electrons and about equal tendencies to donate and accept electrons. For this reason, they do not form strong ionic bonds. Rather, stable electron structures are achieved by sharing valence electrons. For example, two carbon atoms can

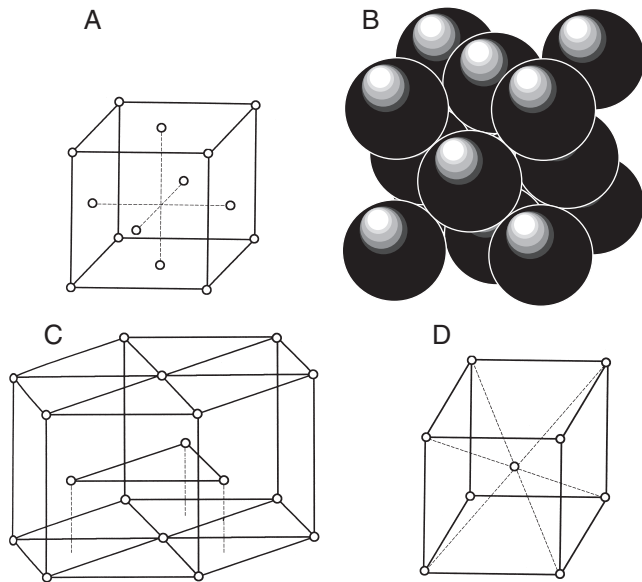

FIG. 1. Typical metal crystal structures (unit cells). (A) Face-centered cubic (FCC). (B) Full size atoms in FCC. (C) Hexagonal close-packed (HCP). (D) Body-centered cubic (BCC).

each contribute an electron to a shared pair. This shared pair of electrons constitutes the covalent bond $\text{--}\overset{\text{||}}{\underset{\text{||}}{\text{C}}}\text{--}\text{C}\text{--}$ (Hummel, 1997).

If a central carbon atom participates in four of these covalent bonds (two electrons per bond), it has achieved a stable outer shell of eight valence electrons. More carbon atoms can be added to the growing aggregate so that every atom has four

nearest neighbors with which it shares one bond each. Thus, in a large grouping, every atom has a stable electron structure and four nearest neighbors. These neighbors often form a tetrahedron, and the tetrahedra in turn are assembled in an orderly repeating pattern (i.e., a crystal) (Fig. 2). This is the structure of both diamond and silicon. Diamond is the hardest of all materials, which shows that covalent bonds can be very strong. Once again, the bonding process results in a particular electronic structure (all valence electrons in pairs localized at the covalent bonds) and a particular atomic arrangement or crystal structure. As with ionic solids, localization of the valence electrons in the covalent bond renders these materials poor electrical conductors.

Metallic Bonding

The third the least understood of the strong bonds is the metallic bond. Metal atoms, being strong electron donors, do not bond by either ionic or covalent processes. Nevertheless, many metals are very strong (e.g., cobalt) and have high melting points (e.g., tungsten), suggesting that very strong interatomic bonds are at work here, too. The model that accounts for this bonding envisions the atoms arranged in an orderly, repeating, three-dimensional pattern, with the valence electrons migrating between the atoms like a gas.

It is helpful to imagine a metal crystal composed of positive ion cores, atoms without their valence electrons, about which the negative electrons circulate. On the average, all the electrical charges are neutralized throughout the crystal and bonding arises because the negative electrons act like a glue between the positive ion cores. This construct is called the free electron model of metallic bonding. Obviously, the bond strength increases as the ion cores and electron “gas” become more

FIG. 2. Crystal structures of carbon. (A) Diamond (cubic). (B) Graphite (hexagonal).

tightly packed (until the inner electron orbits of the ions begin to overlap). This leads to a condition of lowest energy when the ion cores are as close together as possible.

Once again, the bonding leads to a closely packed (atomic) crystal structure and a unique electronic configuration. In particular, the nonlocalized bonds within metal crystals permit plastic deformation (which strictly speaking does not occur in any nonmetals), and the electron gas accounts for the chemical reactivity and high electrical and thermal conductivity of metallic systems (Hummel, 1997).

Weak Bonding

In addition to the three strong bonds, there are several weak secondary bonds that significantly influence the properties of some solids, especially polymers. The most important of these are van der Waals bonding and hydrogen bonding, which have strengths 3 to 10% that of the primary C–C covalent bond.

Atomic Structure

The three-dimensional arrangement of atoms or ions in a solid is one of the most important structural features that derives from the nature of the solid-state bond. In the majority of solids, this arrangement constitutes a crystal. A crystal is a solid whose atoms or ions are arranged in an orderly repeating pattern in three dimensions. These patterns allow the atoms to be closely packed [i.e., have the maximum possible number of near (contacting) neighbors] so that the number of primary bonds is maximized and the energy of the aggregate is minimized.

Crystal structures are often represented by repeating elements or subdivisions of the crystal called unit cells (Fig. 1). Unit cells have all the geometric properties of the whole crystal. A model of the whole crystal can be generated by simply stacking up unit cells like blocks or hexagonal tiles. Note that the representations of the unit cells in Fig. 1 are idealized in that atoms are shown as small circles located at the atomic centers. This is done so that the background of the structure can be understood. In fact, all nearest neighbors are in contact, as shown in Fig. 1B (Newey and Weaver, 1990).

MATERIALS

The technical materials used to build most structures are divided into three classes, metals, ceramics (including glasses), and polymers. These classes may be identified only roughly with the three types of interatomic bonding.

Metals

Materials that exhibit metallic bonding in the solid state are metals. Mixtures or solutions of different metals are alloys.

About 85% of all metals have one of the crystal structures shown in Fig. 1. In both face-centered cubic (FCC) and hexagonal close-packed (HCP) structures, every atom or ion is surrounded by twelve touching neighbors, which is the

closest packing possible for spheres of uniform size. In any enclosure filled with close-packed spheres, 74% of the volume will be occupied by the spheres. In the body-centered cubic (BCC) structure, each atom or ion has eight touching neighbors or eightfold coordination. Surprisingly, the density of packing is only reduced to 68% so that the BCC structure is nearly as densely packed as the FCC and HCP structures (Hummel, 1997).

Ceramics

Ceramic materials are usually solid inorganic compounds with various combinations of ionic and covalent bonding. They also have tightly packed structures, but with special requirements for bonding such as fourfold coordination for covalent solids and charge neutrality for ionic solids (i.e., each unit cell must be electrically neutral). As might be expected, these additional requirements lead to more open and complex crystal structures. Aluminum oxide or alumina (Al_2O_3) is an example of a ceramic that has found some use as an orthopedic implant material. (Kingery, 1976).

Carbon is often included with ceramics because of its many ceramic-like properties, even though it is not a compound and conducts electrons in its graphitic form. Carbon is an interesting material since it occurs with two different crystal structures. In the diamond form, the four valence electrons of carbon lead to four nearest neighbors in tetrahedral coordination. This gives rise to the diamond cubic structure (Fig. 2A). An interesting variant on this structure occurs when the tetrahedral arrangement is distorted into a nearly flat sheet. The carbon atoms in the sheet have a hexagonal arrangement, and stacking of the sheets (Fig. 2B) gives rise to the graphite form of carbon. The (covalent) bonding within the sheets is much stronger than the bonding between sheets.

The existence of an element with two different crystal structures provides a striking opportunity to see how physical properties depend on atomic and electronic structure (Table 1).

Inorganic Glasses

Some ceramic materials can be melted and upon cooling do not develop a crystal structure. The individual atoms have

TABLE 1 Relative Physical Properties of Diamond and Graphite^a

Property	Diamond	Graphite
Hardness	Highest known	Very low
Color	Colorless	Black
Electrical conductivity	Low	High
Density (g/cm^3)	3.51	2.25
Specific heat ($\text{cal}/\text{gm atm}/\text{deg.C}$)	1.44	1.98

^a Adapted from D. L. Cocke and A. Clearfield, eds., *Design of New Materials*, Plenum Publ., New York, 1987, with permission.

nearly the ideal number of nearest neighbors, but an orderly repeating arrangement is not maintained over long distances throughout the three-dimensional aggregates of atoms. Such noncrystals are called glasses or, more accurately, inorganic glasses and are said to be in the amorphous state. Silicates and phosphates, the two most common glass formers, have random three-dimensional network structures.

Polymers

The third category of solid materials includes all the polymers. The constituent atoms of classic polymers are usually carbon and are joined in a linear chainlike structure by covalent bonds. The bonds within the chain require two of the valence electrons of each atom, leaving the other two bonds available for adding a great variety of atoms (e.g., hydrogen), molecules, functional groups, etc.

Based on the organization of these chains, there are two classes of polymers. In the first, the basic chains are all straight with little or no branching. Such “straight” chain or linear polymers can be melted and remelted without a basic change in structure (an advantage in fabrication) and are called thermoplastic polymers. If side chains are present and actually form (covalent) links between chains, a three-dimensional network structure is formed. Such structures are often strong, but once formed by heating will not melt uniformly on reheating. These are thermosetting polymers.

Usually both thermoplastic and thermosetting polymers have intertwined chains so that the resulting structures are quite random and are also said to be amorphous like glass, although only the thermoset polymers have sufficient cross linking to form a three-dimensional network with covalent bonds. In amorphous thermoplastic polymers, many atoms in a chain are in close proximity to the atoms of adjacent chains, and van der Waals and hydrogen bonding holds the chains together. It is these interchain bonds together with chain entanglement that are responsible for binding the substance together as a solid. Since these bonds are relatively weak, the resulting solid is relatively weak. Thermoplastic polymers generally have lower strengths and melting points than thermosetting polymers (Billmeyer, 1984).

Microstructure

Structure in solids occurs in a hierarchy of sizes. The internal or electronic structures of atoms occur at the finest scale, less than 10^{-4} μm (which is beyond the resolving power of the most powerful direct observational techniques), and are responsible for the interatomic bonds. At the next higher size level, around 10^{-4} μm (which is detectable by X-ray diffraction, field ion microscopy, scanning tunneling microscopy, etc.), the long-range, three-dimensional arrangement of atoms in crystals and glasses can be observed.

At even larger sizes, 10^{-3} to 10^2 μm (detectable by light and electron microscopy), another important type of structural organization exists. When the atoms of a molten sample are incorporated into crystals during freezing, many small crystals are formed initially and then grow until they impinge on each

other and all the liquid is used up. At that point the sample is completely solid. Thus, most crystalline solids (metals and ceramics) are composed of many small crystals or crystallites called grains that are tightly packed and firmly bound together.

This is the microstructure of the material that is observed at magnifications where the resolution is between 1 and 100 μm .

In pure elemental materials, all the crystals have the same structure and differ from each other only by virtue of their different orientations. In general, these crystallites or grains are too small to be seen except with a light microscope. Most solids are opaque, however, so the common transmission (biological) microscope cannot be used. Instead, a metallographic or ceramographic reflecting microscope is used. Incident light is reflected from the polished metal or ceramic surface. The grain structure is revealed by etching the surface with a mildly corrosive medium that preferentially attacks the grain boundaries. When this surface is viewed through the reflecting microscope the size and shape of the grains, i.e., the microstructure, is revealed.

Grain size is one of the most important features that can be evaluated by this technique because fine-grained samples are generally stronger than coarse-grained specimens of a given material. Another important feature that can be identified is the coexistence of two or more phases in some solid materials. The grains of a given phase will all have the same chemical composition and crystal structure, but the grains of a second phase will be different in both these respects. This never occurs in samples of pure elements, but does occur in mixtures of different elements or compounds where the atoms or molecules can be dissolved in each other in the solid state just as they are in a liquid or gas solution.

For example, some chromium atoms can substitute for iron atoms in the FCC crystal lattice of iron to produce stainless steel, a solid solution alloy. Like liquid solutions, solid solutions exhibit solubility limits; when this limit is exceeded, a second phase precipitates. For example, if more Cr atoms are added to stainless steel than the FCC lattice of the iron can accommodate, a second phase that is chromium rich precipitates. Many important biological and implant materials are multiphase (Hummel, 1997). These include the cobalt-based and titanium-based orthopedic implant alloys and the mercury-based dental restorative alloys, i.e., amalgams.

MECHANICAL PROPERTIES OF MATERIALS

Solid materials possess many kinds of properties (e.g., mechanical, chemical, thermal, acoustical, optical, electrical, magnetic). For most (but not all) biomedical applications, the two properties of greatest importance are strength (mechanical) and reactivity (chemical). The chemical reactivity of biomaterials will be discussed in Chapters 1.4 and 6. The remainder of this section will, therefore, be devoted to mechanical properties, their measurement, and their dependence on structure. It is well to note that the dependence of mechanical properties on microstructure is so great that it is one of the fundamental objectives of materials science to control mechanical properties by modifying microstructure.

FIG. 3. Initial extension is proportional to load according to Hooke's law.

Elastic Behavior

The basic experiment for determining mechanical properties is the tensile test. In 1678, Robert Hooke showed that a solid material subjected to a tensile (distraction) force would extend in the direction of traction by an amount that was proportional to the load (Fig. 3). This is known as Hooke's law and simply expresses the fact that most solids behave in an elastic manner (like a spring) if the loads are not too great.

Stress and Strain

The extension for a given load varies with the geometry of the specimen as well as its composition. It is, therefore, difficult to compare the relative stiffness of different materials or to predict the load-carrying capacity of structures with complex shapes. To resolve this confusion, the load and deformation can be normalized. To do this, the load is divided by the cross-sectional area available to support the load, and the extension is divided by the original length of the specimen. The load can then be reported as load per unit of cross-sectional area, and the deformation can be reported as the elongation per unit of the original length over which the elongation occurred. In this way, the effects of specimen geometry can be normalized.

The normalized load (force/area) is stress (σ) and the normalized deformation (change in length/original length) is strain (ϵ) (Fig. 4).

Tension and Compression

In tension and compression the area supporting the load is perpendicular to the loading direction (tensile stress), and the change in length is parallel to the original length (tensile strain).

If weights are used to provide the applied load, the stress is calculated by adding up the total number of pounds-force (lb) or newtons (N) used and dividing by the perpendicular cross-sectional area. For regular specimen geometries such as cylindrical rods or rectangular bars, a measuring instrument, such as a micrometer, is used to determine the dimensions. The units of stress are pounds per inch squared (psi) or newtons

FIG. 4. Tensile stress and tensile strain.

per meter squared (N/m^2). The N/m^2 unit is also known as the pascal (Pa).

The measurement of strain is achieved, in the simplest case, by applying reference marks to the specimen and measuring the distance between with calipers. This is the original length, l_o . A load is then applied, and the distance between marks is measured again to determine the final length, l_f . The strain, ϵ , is then calculated by:

$$\epsilon = \frac{l_f - l_o}{l_o} = \frac{\Delta l}{l_o} \quad (1)$$

This is essentially the technique used for flexible materials like rubbers, polymers, and soft tissues. For stiff materials like metals, ceramics, and bone, the deflections are so small that a more sensitive measuring method is needed (i.e., the electrical resistance strain gage).

Shear

For cases of shear, the applied load is parallel to the area supporting it (shear stress, τ), and the dimensional change is perpendicular to the reference dimension (shear strain, γ) (Fig. 5).

FIG. 5. Shear stress and shear strain.

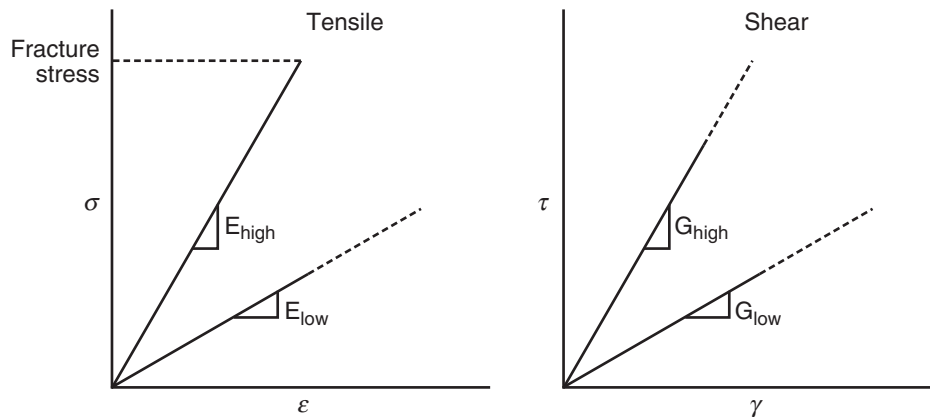

FIG. 6. Stress versus strain for elastic solids.

Elastic Constants

By using these definitions of stress and strain, Hooke's law can be expressed in quantitative terms:

$$\sigma = E \epsilon, \text{ tension or compression,} \quad (2a)$$

$$\tau = G \gamma, \text{ shear.} \quad (2b)$$

E and G are proportionality constants that may be likened to spring constants. The tensile constant, E , is the tensile (or Young's) modulus and G is the shear modulus. These moduli are also the slopes of the elastic portion of the stress versus strain curve (Fig. 6). Since all geometric influences have been removed, E and G represent inherent properties of the material. These two moduli are direct macroscopic manifestations of the strengths of the interatomic bonds. Elastic strain is achieved by actually increasing the interatomic distances in the crystal (i.e., stretching the bonds). For materials with strong bonds (e.g., diamond, Al_2O_3 , tungsten), the moduli are high and a given stress produces only a small strain. For materials with weaker bonds (e.g., polymers and gold), the moduli are lower (Hummel, 1997). The tensile elastic moduli for some important biomaterials are presented in Table 2.

Isotropy

The two constants, E and G , are all that are needed to fully characterize the stiffness of an isotropic material (i.e., a material whose properties are the same in all directions).

Single crystals are anisotropic (not isotropic) because the stiffness varies as the orientation of applied force changes relative to the interatomic bond directions in the crystal. In polycrystalline materials (e.g., most metallic and ceramic specimens), a great multitude of grains (crystallites) are aggregated with multiply distributed orientations. On the average, these aggregates exhibit isotropic behavior at the macroscopic level, and values of E and G are highly reproducible for all specimens of a given metal, alloy, or ceramic.

On the other hand, many polymeric materials and most tissue samples are anisotropic (not the same in all directions) even at the macroscopic level. Bone, ligament, and sutures are all stronger and stiffer in the fiber (longitudinal) direction than they are in the transverse direction. For such materials, more

TABLE 2 Mechanical Properties of Some Implant Materials and Tissues

	Elastic modulus (GPa)	Yield strength (MPa)	Tensile strength (MPa)	Elongation to failure (%)

than two elastic constants are required to relate stress and strain properties.

MECHANICAL TESTING

To conduct controlled load-deflection (stress-strain) tests, a load frame is used that is much stiffer and stronger than the specimen to be tested (Fig. 7). One cross-bar or cross-head is moved up and down by a screw or a hydraulic piston. Jaws that provide attachment to the specimen are connected to the frame and to the movable cross-head. In addition, a load cell to monitor the force being applied is placed in series with the specimen. The load cell functions somewhat like a very stiff spring scale to measure the applied loads.

Tensile specimens usually have a reduced gage section over which strains are measured. For a valid determination of fracture properties, failure must also occur in this reduced section and not in the grips. For compression testing, the direction of cross-head movement is reversed and cylindrical

FIG. 7. Mechanical testing machine.

or prismatic specimens are simply squeezed between flat anvils. Standardized specimens and procedures should be used for all mechanical testing to ensure reproducibility of results (see the publications of the American Society for Testing and Materials, 100 Barr Harbor Dr., West Conshohocken, PA 19428-2959).

Another useful test that can be conducted in a mechanical testing machine is the bend test. In bend testing, the outside of the bowed specimen is in tension and the inside in compression. The outer fiber stresses can be calculated from the load and the specimen geometry (see any standard text on strength of materials; Meriam, 1996). Bend tests are useful because no special specimen shapes are required and no special grips are necessary. Strain gages can also be used to determine the outer fiber strains. The available formulas for the calculation of stress states are only valid for elastic behavior. Therefore, they cannot be used to describe any nonelastic strain behavior.

Some mechanical testing machines are also equipped to apply torsional (rotational) loads, in which case torque versus angular deflection can be determined and used to calculate the torsional properties of materials. This is usually in important consideration when dealing with biological materials, especially under shear loading conditions (Hummel, 1997).

Elasticity

The tensile elastic modulus, E (for an isotropic material), can be determined by the use of strain gages, an accurate load cell,

and cyclic testing in a standard mechanical testing machine. To do so, Hooke's law is rearranged as follows:

$$E = \frac{\sigma}{\varepsilon}. \quad (3)$$

Brittle Fracture

In real materials, elastic behavior does not persist indefinitely. If nothing else intervenes, microscopic defects, which are present in all real materials, will eventually begin to grow rapidly under the influence of the applied tensile or shear stress, and the specimen will fail suddenly by brittle fracture. Until this brittle failure occurs, the stress-strain diagram does not deviate from a straight line, and the stress at which failure occurs is called the fracture stress (Fig. 6). This behavior is typical of many materials, including glass, ceramics, graphite, very hard alloys (scalpel blades), and some polymers like polymethylmethacrylate (bone cement) and unmodified polyvinyl chloride (PVC). The number and size of defects, particularly pores, is the microstructural feature that most affects the strength of brittle materials.

Plastic Deformation

For some materials, notably metals, alloys, and some polymers, the process of plastic deformation sets in after a certain stress level is reached but before fracture occurs. During a tensile test, the stress at which 0.2% plastic strain occurs is called the 0.2% offset yield strength. Once plastic deformation starts, the strains produced are very much greater than those during elastic deformation (Fig. 8); they are no longer proportional to the stress and they are not recovered when the stress is removed. This happens because whole arrays of atoms under the influence of an applied stress are forced to move, irreversibly, to new locations in the crystal structure. This is the microstructural basis of plastic deformation. During elastic straining, on the other hand, the atoms are displaced only slightly by reversible stretching of the interatomic bonds.

Large scale displacement of atoms without complete rupture of the material, i.e., plastic deformation, is only possible in the presence of the metallic bond so only metals and alloys exhibit true plastic deformation. Since long-distance rearrangement of atoms under the influence of an applied stress cannot occur in ionic or convolutedly bonded materials, ceramics and many polymers do not undergo plastic deformation.

Plastic deformation is very useful for shaping metals and alloys and is called ductility or malleability. The total permanent (i.e., plastic) strain exhibited up to fracture by a material is a quantitative measure of its ductility (Fig. 8). The strength, particularly the 0.2% offset yield strength, can be increased significantly by reducing the grain size as well as by prior plastic deformation or cold work. The introductions of alloying elements and multiphase microstructures are also potent strengthening mechanisms.

Other properties can be derived from the tensile stress-strain curve. The tensile strength or the ultimate tensile stress (UTS) is the stress that is calculated from the maximum load experienced during the tensile test (Fig. 8).

FIG. 8. Stress versus strain for a ductile material.

The area under the tensile curve is proportional to the work required to deform a specimen until it fails. The area under the entire curve is proportional to the product of stress and strain, and has the units of energy (work) per unit volume of specimen. The work to fracture is a measure of toughness and reflects a material's resistance to crack propagation (Fig. 8) (Newey and Weaver, 1990). The important mechanical properties derived from a tensile test and their units are listed in Table 3. Representative values of these properties for some important biomaterials are listed in Table 2.

Creep and Viscous Flow

For all the mechanical behaviors considered to this point, it has been assumed that when a stress is applied, the strain response is instantaneous. For many important biomaterials,

TABLE 3 Mechanical Properties Derivable from a Tensile Test

Property	Units		
	Fundamental ^a	International	English
1. Elastic modulus (E)	F/A	N/m^2 (Pa)	$lbf^b/in.^2$ (psi)
2. Yield strength (σ_{yield})	F/A	N/m^2 (Pa)	$lbf/in.^2$ (psi)
3. Ultimate tensile strength (σ_{uts})	F/A	N/m^2 (Pa)	$lbf/in.^2$ (psi)
4. Ductility ($\epsilon_{ductility}$)	%	%	%
5. Toughness (work to fracture per unit volume)	$F \times d/V$	J/m^3	$in\ lbf/in.^3$

^aF, force; A, area; d, length; V, volume.
^blbf, pounds force.

including polymers and tissues, this is not a valid assumption. If a weight is suspended from an excised ligament, the ligament elongates essentially instantaneously when the weight is applied. This is an elastic response. Thereafter the ligament continues to elongate for a considerable time even though the load is constant (Fig. 9A). This continuous, time-dependent extension under load is called "creep."

Similarly, if the ligament is extended in a tensile machine to a fixed elongation and held constant while the load is monitored, the load drops continuously with time (Fig. 9B). The continuous drop in load at constant extension is called stress relaxation. Both these responses are the result of viscous flow in the material. The mechanical analog of viscous flow is a dash-pot or cylinder and piston (Fig. 10A). Any small force is enough to keep the piston moving. If the load is increased, the rate of displacement will increase.

FIG. 9. (A) Elongation versus time at constant load (creep) of ligament. (B) Load versus time at constant elongation (stress relaxation) for ligament.

FIG. 10. (A) Dash pot or cylinder and piston model of viscous flow. (B) Dash pot and spring model of a viscoelastic material.

Despite this liquid-like behavior, these materials are functionally solids. To produce such a combined effect, they act as though they are composed of a spring (elastic element) in series with a dashpot (viscous element) (Fig. 10B). Thus, in the creep test, instantaneous strain is produced when the weight is first applied (Fig. 9A). This is the equivalent of stretching the spring to its equilibrium length (for that load). Thereafter, the additional time-dependent strain is modeled by the movement of the dashpot. Complex arrangements of springs and dashpots are often needed to adequately model the actual behavior of polymers and tissues.

Materials that behave approximately like a spring and dashpot system are viscoelastic. One consequence of viscoelastic behavior can be seen in tensile testing where the load is applied at some finite rate. During the course of load application, there is time for some viscous flow to occur along with the elastic strain. Thus, the total strain will be greater than that due to the elastic response alone. If this total strain is used to estimate the Young's modulus of the material ($E = \sigma/\epsilon$), the estimate will be low. If the test is conducted at a more rapid rate, there will be less time for viscous flow during the test and the apparent modulus will increase. If a series of such tests is conducted at ever higher loading rates, eventually a rate can be reached where no detectable viscous flow occurs and the modulus determined at this critical rate will be the true elastic modulus, i.e., the spring constant of the elastic component. Tests at even higher rates will produce no further increase in modulus. For all viscoelastic materials, moduli determined at rates less than the critical rate are "apparent" moduli and must be identified with the strain rate used. Failure to do this is one reason why values of tissue moduli reported in the literature may vary over wide ranges.

Finally, it should be noted that it may be difficult to distinguish between creep and plastic deformation in ordinary tensile tests of highly viscoelastic materials (e.g., tissues). For this reason, the total nonelastic deformation of tissues or polymers may at times be loosely referred to as plastic deformation even though viscous flow is involved.

OTHER IMPORTANT PROPERTIES OF MATERIALS

Fatigue

It is not uncommon for materials, including tough and ductile ones like 316L stainless steel, to fracture even though the service stresses imposed are well below the yield stress. This occurs when the loads are applied and removed for a great number of cycles, as happens to prosthetic heart valves and prosthetic joints. Such repetitive loading can produce microscopic cracks that then propagate by small steps at each load cycle.

The stresses at the tip of a crack, a surface scratch, or even a sharp corner are locally enhanced by the stress-raising effect. Under repetitive loading, these local high stresses actually exceed the strength of the material over a small region. This phenomenon is responsible for the stepwise propagation of the cracks. Eventually, the load-bearing cross-section becomes so small that the part finally fails completely.

Fatigue, then, is a process by which structures fail as a result of cyclic stresses that may be much less than the ultimate tensile stress. Fatigue failure plagues many dynamically loaded structures, from aircraft to bones (march- or stress-fractures) to cardiac pacemaker leads.

The susceptibility of specific materials to fatigue is determined by testing a group of identical specimens in cyclic tension or bending (Fig. 11A) at different maximum stresses. The number of cycles to failure is then plotted against the maximum applied stress (Fig. 11B). Since the number of cycles to failure is quite variable for a given stress level, the prediction of fatigue life is a matter of probabilities. For design purposes, the stress that will provide a low probability of failure after 10^6 to 10^8 cycles is often adopted as the fatigue strength or endurance limit of the material. This may be as little as one third or one fourth of the single-cycle yield strength. The fatigue strength is sensitive to environment, temperature, corrosion, deterioration (of tissue specimens), and cycle rate (especially for viscoelastic materials) (Newey and Weaver, 1990). Careful attention to these details is required if laboratory fatigue results are to be successfully transferred to biomedical applications.

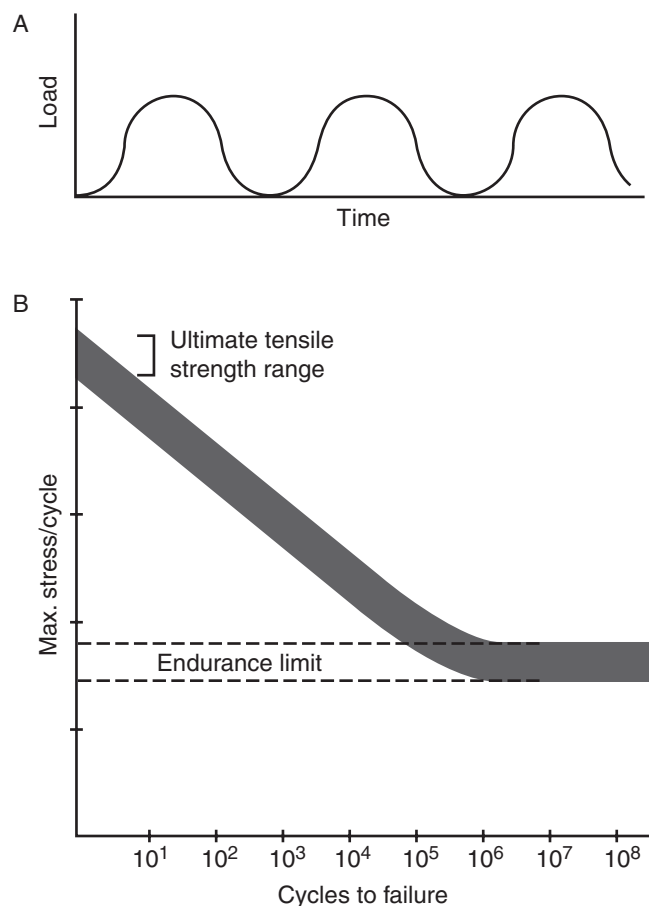

FIG. 11. (A) Stress versus time in a fatigue test. (B) Fatigue curve: fatigue stress versus cycles to failure.

Toughness

The ability of a material to plastically deform under the influence of the complex stress field that exists at the tip of a crack is a measure of its toughness. If plastic deformation does occur, it serves to blunt the crack and lower the locally enhanced stresses, thus hindering crack propagation. To design “failsafe” structures with brittle materials, it has become necessary to develop an entirely new system for evaluating service worthiness. This system is fracture toughness testing and requires the testing of specimens with sharp notches. The resulting fracture toughness parameter is a function of the apparent crack propagation stress and the crack depth and shape. It is called the critical stress intensity factor (K_{Ic}) and has units of $\text{Pa}\sqrt{\text{m}}$ or $\text{N} \cdot \text{m}^{3/2}$ (Meyers and Chawla, 1984). For materials that exhibit extensive plastic deformation at the crack tip, an energy-based parameter, the J integral, can be used. The energy absorbed in impact fracture is also a measure of toughness, but at higher loading rates (Newey and Weaver, 1990).

Effect of Fabrication on Strength

A general concept to keep in mind when considering the strength of materials is that the process by which a material is produced has a major effect on its structure and hence its properties (Newey and Weaver, 1990). For example, plastic deformation of most metals at room temperature flattens the grains and produces strengthening while reducing ductility. Subsequent high-temperature treatment (annealing) can reverse this effect. Polymers drawn into fibers are much stronger in the drawing direction than are undrawn samples of the same material.

Because strength properties depend on fabrication history, it is important to realize that there is no unique set of strength properties of each generic material (e.g., 316L stainless steel, polyethylene, aluminum oxide). Rather, there is a range of properties that depends on the fabrication history and the microstructures produced.

CONCLUSION

The determination of mechanical properties is not only an exercise in basic materials science but is indispensable to the practical design and understanding of load-bearing structures. Designers must determine the service stresses in all structural members and be sure that at every point these stresses are safely below the yield strength of the material. If cyclic loads are involved (e.g., lower-limb prostheses, teeth, heart valves), the service stresses must be kept below the fatigue strength.

In subsequent chapters where the properties and behavior of materials are discussed in detail, it is well to keep in mind that this information is indispensable to understanding the mechanical performance (i.e., function) of both biological and manmade structures.

1.3 FINITE ELEMENT ANALYSIS

Ivan Vesely and Evelyn Owen Carew

INTRODUCTION

The previous chapter introduced the reader to the concepts of elasticity, stress, and strain. Estimations of material stress and strain are necessary during the course of device design to minimize the chance of device failure. For example, artificial hip joints need to be designed to withstand the loads that they are expected to bear without fracture or fatigue. Stress analysis is therefore required to ensure that all components of the device operate below the fatigue limit. For deformable structures such as diaphragms for artificial hearts, an estimate of strains or deformations is required to ensure that during maximal deformation, components do not contact other structures, potentially causing interference and unexpected failure modes such as abrasion.

For simple calculations, such as the sizing of a bolt to connect two components that bear load, simple analytical calculations usually suffice. Often, these calculations are augmented by reference to engineering tables that can be used to refine the stress estimates based on local geometry, such as the pitch of the threads. Such analytical methods are preferred because they are exact and can be supported by a wealth of engineering experience. Unfortunately, analytical solutions are usually limited to linear problems and simple geometries governed by simple boundary conditions. The boundary conditions can be considered input data or constraints on the solution that are applied at the boundaries of the system. Most practical engineering problems involve some combination of material or geometrical nonlinearity, complex geometry, and mixed boundary conditions. In particular, all biological materials have nonlinear elastic behavior and most experience large strains when deformed. As a result, nonlinearities of one form or the other are usually present in the formulation of problems in biomechanics. These nonlinearities are described by the equations relating stress to strain and strain to displacement. Applying analytical methods to such problems would require so many assumptions and simplifications that the results would have poor accuracy and would thus be of little engineering value. There is therefore no alternative but to resort to approximate or numerical methods. The most popular numerical method for solving problems in continuum mechanics is the

finite element method (FEM), also referred to as finite element analysis (FEA).

FEA is a computational approach widely used in solid and fluid mechanics in which a complex structure is divided into a large number of smaller parts, or elements, with interconnecting nodes, each with geometry much simpler than that of the whole structure. The behavior of the unknown variable within the element and the shape of the element are represented by simple functions that are linked by parameters that are shared between the elements at the nodes. By linking these simple elements together, the complexity of the original structure can be duplicated with good fidelity. After boundary conditions are taken into account, a large system of equations for the unknown nodal parameters always results; these equations are solved simultaneously by a computer, using indirect or iterative means.

Finite element analysis is extremely versatile. The size and configuration of the elements can be adjusted to best suit the problem; complex geometries can be discretized and solutions can be stepped through time to analyze dynamic systems. Very often, simple analytical methods are used to make a first approximation to the design of the device, and FEA is subsequently used to further refine the design and identify potential stress concentrations. FEA can be applied to both solids and fluids or, with additional complexity, to systems containing both. FEA software is very mature and computing power is now sufficiently cheap to allow finite element methods to be applied to a wide range of problems. In fluid flow, FEA has been applied to weather forecasting and supersonic flow around aircraft and within engines, and in the medical field, to optimizing blood pumps and cannulas. In solids, FEA has been used to design, build, and crash automobiles, estimate the impact of earthquakes, and reconstruct crime scenes. In biomaterials, FEA has been applied to almost every implantable device, ranging from artificial joints to pacemaker leads. Although originally developed to help structural engineers analyze stress and strain, FEA has been adopted by basic scientists and biologists to study the dynamic environment within arteries, muscles and even cells.

In this chapter we hope to introduce the reader to finite element methods without digressing into detailed discussion of some of the more difficult concepts that are often required to properly define and execute a real-world problem. For that, the reader is referred to the many excellent texts in the field, some of which are included in the bibliography at the end of this chapter.

OVERVIEW OF THE FINITE ELEMENT METHOD

The essential steps in implementing the FEM follow:

- (i) The region of interest (continuum) is discretized, that is, subdivided into a smaller number of regions called elements, interconnected at nodal points. Nodes may also be placed in the interior of an element. In one dimension, the elements are line segments; in two dimensions, they are usually triangles or quadrilaterals (Fig. 1); in three dimensions, they can be rectangular prisms (hexahedra) or triangular prisms (tetrahedra),

FIG. 1. (A) Cross-section of an autopsy-retrieved femur showing a cracked mantle (arrows). (B) Mixed planar quadrilateral/triangle FE representation of (A). (From Middleton *et al.*, 1996, p. 35. Reproduced with permission of Gordon and Breach Publishers, Overseas Publishers Assn., Amsterdam.)

FIG. 2. 3D FE representations of the human femur. (A) Tetrahedral elements; (B) hexahedral elements. (From Middleton *et al.*, 1996, p. 125. Reproduced with permission of Gordon and Breach Publishers, Overseas Publishers Assn., Amsterdam.)

for example (Fig. 2). Elements may be quite general with the possibility of non-planar faces and curvilinear sides or edges (Desai, 1979; Zienkiewicz and Taylor, 1994).

FIG. 3. Examples of two-dimensional elements and their corresponding local coordinate systems [embedded in (A) and (C)]. For the rectangles, the local coordinates (ξ, η) are referred to a cartesian system with $-1 \leq \xi, \eta \leq 1$; for the triangles, the local coordinates (L_1, L_2, L_3) are area coordinates satisfying $0 \leq L_1, L_2, L_3 \leq 1$. Elements with linear interpolating functions (first order) are shown in (A) and (C). Quadratic elements (second-order interpolating functions) are shown in (B) and (D).

- (ii) The unknown variables within the continuum (e.g., displacement, stress, or velocity components) are defined within each element by suitable interpolating functions. Interpolating functions are traditionally piecewise polynomials and are also known as basis or shape functions. The order of the interpolating functions (i.e., first, second, or third order) is usually used to fix the number of nodes in the elements (Fig. 3).
- (iii) The equations that define the behavior of the unknown variable, such as the equations of motion or the relationships between stress and strain or strain and displacement, are formulated for each element in the form of matrices. These element matrices are then assembled into a global system of equations for the entire discretized domain. This system is defined by a coefficient matrix, an unknown vector of nodal values, and a known “right-hand side” (RHS) vector. Boundary conditions in derivative form would already be included in the RHS vector at this stage, but those that set the unknown function to a known value at the boundary have to be incorporated into the system matrix and RHS vector by overwriting relevant rows and columns. Since the RHS vector contains information about the boundary conditions, it is sometimes called the “external load vector.”
- (iv) The final step in FEA involves solving the global system of equations for the unknown vector. In theory, this can be achieved by premultiplying the RHS vector by the inverse of the coefficient matrix. The result is

the discrete (pointwise) solution to the original problem. If the problem is linear and isotropic, the elements of the matrix are constants and the required matrix inversion can be done. If the defining equations are nonlinear or the material is anisotropic, the coefficient matrix itself will be a function of the unknown variables and matrix inversion is not straightforward. Some kind of linearization is necessary before the matrix can be inverted (e.g., successive approximation or Newton’s methods; see, for example, Harris and Stöcker, 1998). In practice, the global system matrix, whether linear or nonlinear, is seldom inverted directly, usually because it is too large. Some indirect method of solving the system of equations is preferred [i.e., lower-upper (LU) decomposition, Gaussian elimination; see, for example, Harris and Stöcker, 1998].

The evaluation of element matrices, their assembly into the global system, and the possible linearization and eventual solution of the global system is a task that is always passed on to a high-speed computer. This usually requires complex computer programs written in a high-level language, such as Fortran. Indeed, it is the advent of high-speed computers and workstations and the continuous improvements in processor speed, memory management, and disk storage that have enabled large-scale FE problems to be tackled with relative ease.

The modern-day FEA toolbox also includes facilities for data pre- and postprocessing. Data preprocessing usually involves input formatting and grid definition, the latter of which may require some ingenuity, because mesh design may affect the convergence and accuracy of the numerical solution. Element size is governed by local geometry and the rate of change of the solution in different parts of the domain. Mesh refinement (a gradation of element size) in the vicinity of sharp corners, boundary layers, high solution gradients, stress concentrations or vortices is done routinely to enhance the accuracy and convergence of the solution. Adaptive procedures that allow the mesh to change with the solution according to some error criteria are usually incorporated into the FE process (George, 1991; Brebbia and Aliabadi, 1993; Zienkiewicz and Taylor, 1994). Typically, this means that the mesh is refined in areas where the solution gradient is high, and elements are removed from regions where the solution is changing slowly. The result is usually a dramatic improvement in convergence, accuracy, and computational efficiency. Postprocessing of data involves the evaluation of *ad hoc* variables such as strains, strain rates, stresses; generating plots such as simple xy -plots, contour plots, and particle paths; and solution visualization and animation. All of the additional information facilitates the understanding and interpretation of the results.

The importance of checking and validating FE solutions cannot be overemphasized. The most basic validation involves a “patch test” (Zienkiewicz and Taylor, 1994) in which a few elements (i.e., a patch of the material) are analyzed to verify the formulation of interpolating functions and the consistency of the code itself. Second, a very simple problem with known analytical solution is simulated with a coarse grid to verify that the code reproduces the known solution with acceptable accuracy. For example, parabolic flow in a tube can be simulated with

a very coarse grid and the result quickly compared against the analytical solution. We caution, however, that reproducing the solution in a simpler problem does not guarantee that the code will work in more realistic and complicated cases. It is also recommended that numerical solutions be obtained from at least three meshes with increasing degrees of mesh refinement. Such solutions should converge with mesh refinement (*b*-convergence, Strang and Fix, 1973). Comparison of numerical results to experimental data should always be made where possible. Last, especially in the absence of analytical solutions or experimental data, numerical solutions should be compared across different numerical methods, or across different numerical codes if the same method is used. There is no gold standard for the number of validation tests that is required for any particular problem. The greater the variety of test problems and checks, the greater the degree of confidence one can have in the results of the finite element method.

THE CONTINUUM EQUATIONS

Whether we use FEA to compute the stress in a prosthetic limb or to simulate blood flow in bifurcating arteries, the first objective in setting up an FEA problem is to identify and specify the equations that define the behavior of unknown variables in the continuum. Such equations typically result from applying the universal laws of conservation mass, momentum, and energy, as well as the constitutive equations that define the stress-strain or other relationships within the material. The resulting differential or integral equations must then be closed by specifying the appropriate boundary conditions.

A “well-behaved” solution to the continuum problem is guaranteed if the differential or integral equations and boundary conditions systems are “well posed.” This means that a solution to the continuum problem should exist, be unique, and only change by a small amount when the input data change by a small amount. Under these circumstances the numerical solution is guaranteed to converge to the true solution. Proving in advance that a general continuum problem is “well posed” is not a trivial exercise. Fortunately, consistency and convergence of the numerical solution can usually be monitored by other means, for example, the already mentioned “patch test” (Zienkiewicz and Taylor, 1994).

The equations governing the description of a continuum can be formulated via a differential or variational approach. In the former, differential equations are used to describe the problem; in the latter, integral equations are used. In some cases, both formulations can be applied to a problem. As an illustration we present a case for which both formulations apply and later show that these lead to the same FE equations.

The Differential Formulation

Consider the function $u(x, y)$, defined in some two-dimensional domain Ω bounded by the curve Γ (Fig. 4), which satisfies the differential equation

$$-\nabla^2 u + qu = f \text{ in } \Omega \quad (1a)$$

FIG. 4. (A) A continuum Ω enclosed by the boundary $\Gamma = \Gamma_1 \cup \Gamma_2$; the function itself is specified on Γ_1 and its derivative on Γ_2 . (B) A finite element representation of the continuum. The domain has been discretized with general arbitrary triangles of size h , with the possibility of having curved sides.

subject to the boundary conditions

$$u = g \text{ on } \Gamma_1 \quad (1b)$$

$$\frac{\partial u}{\partial n} = 0 \text{ on } \Gamma_2 \quad (1c)$$

where $\nabla^2 \equiv \partial^2/\partial x^2 + \partial^2/\partial y^2$ is the Laplacian operator in two dimensions, n is the unit outward normal to the boundary, and q, f, g are assumed to be constants for simplicity, with $q \geq 0$. Here, the boundary Γ is made up of two parts, Γ_1 and Γ_2 , where different boundary conditions apply.

When $f = 0$, Eq. 1a means that the spatial change of the gradient of u at any point in the $x - y$ space is proportional to u . The boundary condition 1b sets u to have a fixed value at one part of the boundary. On another part of the boundary, the rate of change of u in the normal direction is set to zero (boundary condition 1c). The system represented by Eqs. 1a–c can be used to describe the transverse deflection of a membrane, torsion in a shaft, potential flows, steady-state heat conduction, or groundwater flow (Desai, 1979; Zienkiewicz and Taylor, 1994).

The Variational Formulation

A variational equation can arise, for example, from the physical requirement that the total potential energy (TPE) of a mechanical system must be a minimum. Thus the TPE will be a function of a displacement function, for example, itself a function of spatial variables. A “function of a function” is referred to as a functional. We consider, as an example, the functional $I(v)$ of the function $v(x, y)$ of the spatial variables x and y , defined by:

$$I(v) = \iint_{\Omega} \{ (\nabla v)^2 + qv^2 - 2vf \} d\Omega \quad (2)$$

(Strang and Fix, 1973; Zienkiewicz and Taylor, 1994). The relevant question is that of all the possible functions $v(x, y)$ that satisfy Eq. 2, what particular $v(x, y)$ minimizes $I(v)$? We get the answer by equating the first variation of $I(v)$, written $\delta I(v)$, to zero. To perform the variation of a functional, one

uses the standard rules of differentiation. It can be shown that the variation of $I(v)$ over v results in Eq. 1a, provided Eqs. 1b and 1c hold and the variation of v is zero on Γ_1 . Thus the function that minimizes the functional defined in Eq. 2 is the same function that solves the boundary value problem given by Eqs. 1a–c.

THE FINITE ELEMENT EQUATIONS

There are four basic methods of formulating the equations of finite element analysis. These are: (i) the direct or displacement method, (ii) the variational method, (iii) the weighted residual method, and (iv) the energy balance method. Only the more popular variational and weighted residual methods will be described here. The integral equation 2 will be used to illustrate the variational method, while the differential equation system 1a–c will be used to illustrate the weighted residual method.

The Variational Approach

The FEM is introduced in the following way. The region is divided into a finite number of elements of size h (Fig. 4). The h notation is to be interpreted as referring to the subdivided domain. Instead of seeking the function v that minimizes $I(v)$ in the continuous domain, i.e., the exact solution, we instead seek an approximate solution by looking for the function v^h that minimizes $I(v^h)$ in the discrete domain. The following trial functions are defined over the discretized domain:

$$v^h(x, y) = \sum_{i=1}^n v_i N_i(x, y) \quad (3)$$

where N_i are global basis or shape functions and v_i are nodal parameters. The sum is over the total number of nodes n in the mesh. Using Eq. 3 in Eq. 2, the functional becomes

$$\begin{aligned} I(v^h) &= \sum_{i,j} v_i v_j \iint_{\Omega} \nabla N_i \nabla N_j d\Omega \\ &+ q \sum_{i,j} v_i v_j \iint_{\Omega} \nabla N_i N_j d\Omega - 2 \sum_{i,j} v_i \iint_{\Omega} f N_j d\Omega \end{aligned} \quad (4)$$

which can be written in matrix notation as

$$I(v^h) = v^T K v + q v^T M v - 2 v^T F \quad (5)$$

where

$$K = \iint_{\Omega} \nabla N_i \nabla N_j d\Omega, \quad M = \iint_{\Omega} N_i N_j d\Omega, \quad F = \iint_{\Omega} f N_i d\Omega$$

v^T represents the *transpose* of the vector v ; K is known as the stiffness matrix, M as the mass matrix, and F as the local load vector. The function v^h that minimizes Eq. 5 should satisfy $\delta I(v^h) = 0$. This gives

$$(K + qM)v = F \quad (6)$$

that is, a set of simultaneous equations for the nodal parameters v .

Weighted Residual Approach

The weighted residual approach can be applied directly to any system of differential equations such as 1a–c and even to those problems for which a variational principle may not exist. This approach is therefore more general. The method assumes an approximation $u^h(x, y)$ for the real solution $u(x, y)$. Because u^h is approximate, its substitution into Eq. 1a will result in an error or residual R^h :

$$R^h = -\nabla^2 u^h + q u^h - f \quad (7)$$

The weighted residual approach requires that some weighted average of the error due to nonsatisfaction of the differential equation by the approximate solution u^h (Eq. 7) vanish over the domain of interest:

$$\iint_{\Omega} R^h w d\Omega = \iint_{\Omega} (-\nabla^2 u^h + q u^h - f) w d\Omega = 0 \quad (8)$$

where $w(x, y)$ is a weighting function. A function u^h that satisfies Eq. 8 for all possible w selected from a certain class of functions must necessarily satisfy the original differential equations 1a–c. It actually does so only in an average or “weak” sense. Equation 8 is therefore known as a “weak form” of the original equation 1a. The second-order derivatives of the ∇^2 term are usually reduced to first order derivatives by an integration by parts (Harris and Stocker, 1998). The result is another weak form:

$$\iint_{\Omega} \{ \nabla u^h \nabla w + q u^h w - f w \} d\Omega = 0 \quad (9)$$

which has the advantage that approximating functions can now be chosen from a much larger space, a space where the function only needs be once-differentiable. Again, we divide the region into a finite number of elements and assume that the approximate solution can be represented by the sum of the product of unknown nodal values v_j and interpolating functions $N_j(x, y)$, defined at each node j of the mesh:

$$u^h = \sum_{j=1}^n v_j N_j \quad (10)$$

When Eq. 10 is substituted into Eq. 9 with $w = N_i$, Eq. 6 results as before, proving the equivalence of the weighted residual and variational methods for this particular example. We note that the weighting function is required to be zero on those parts of the boundary where the unknown function is specified (Γ_1 , in our example) and that there can be other choices of the weighting function w . Choosing weighting functions to be the same as interpolating functions defines the Galerkin finite element method (Strang and Fix, 1973; Zienkiewicz and Taylor, 1994).

Properties of Interpolating Functions

The process of discretizing the continuum into smaller regions means that the global shape functions $N_j(x, y)$ are replaced by local shape functions $N_j^e(\xi, \eta)$, defined within each

element e , where ξ, η are the local coordinates within the element (Fig. 3). In the FEM, interpolating functions are usually piecewise polynomials that are required to have (a) the minimum degree of smoothness, (b) continuity between elements, and (c) “local support.”

The minimum degree of smoothness is dictated by the highest derivative of the unknown function that occurs in the “weak” or variational form of the continuum problem. The requirement for continuity between elements can always be satisfied by an appropriate choice of the approximating polynomial and number of boundary nodes that define the element. The requirement for “local support” means that within an element,

$$N_i^e(\xi, \eta) = \begin{cases} 1 & \text{at node } i \\ 0 & \text{at all other nodes} \end{cases} \quad (11)$$

as shown in Fig. 5. This is the single most important property of the interpolating functions. This property makes it possible for the contributions of all the elements to be summed up to give the response of the whole domain.

The notation P^m is conventionally used to indicate the degree m of the interpolating polynomial. The notation C^n is

$$\begin{aligned} N_1^e(\xi, \eta) &= \xi\eta(1+\xi)(1+\eta)/4 \\ N_2^e(\xi, \eta) &= -\xi\eta(1-\xi)(1+\eta)/4 \\ N_3^e(\xi, \eta) &= \xi\eta(1-\xi)(1-\eta)/4 \\ N_4^e(\xi, \eta) &= -\xi\eta(1+\xi)(1-\eta)/4 \\ N_5^e(\xi, \eta) &= \eta(1-\xi^2)(1+\eta)/2 \\ N_6^e(\xi, \eta) &= -\xi(1-\xi^2)(1-\eta^2)/2 \\ N_7^e(\xi, \eta) &= -\eta(1-\xi^2)(1-\eta)/2 \\ N_8^e(\xi, \eta) &= \xi(1+\xi^2)(1-\eta^2)/2 \\ N_9^e(\xi, \eta) &= \xi(1-\xi^2)(1-\eta^2) \end{aligned}$$

FIG. 5. Sample shape functions for a nine-noded rectangular element. Shape functions are defined in terms of local coordinates ξ and η where $-1 \leq \xi, \eta \leq 1$; $N_3^e(\xi, \eta)$ is shown in the plot. It can be checked that $N_i = 1$ at node i and zero at all other nodes (compact support) as required.

used to indicate that all derivatives of the interpolating function, up to and including $n - 1$, exist and are continuous. By convention, the notation $P^m - C^n$ is therefore used to indicate the order and smoothness properties of the interpolating polynomials.

EXAMPLES FROM BIOMECHANICS

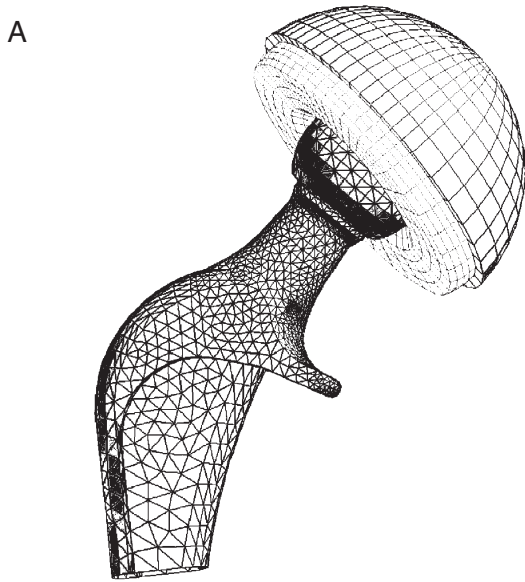

The following are examples of FEA applications in biomaterials science and biomechanics.

Analysis of Commonplace Maneuvers at Risk for Total Hip Dislocation

Dislocation is a frequent complication of total hip arthroplasty (THA). In this FE study (Nadzadi *et al.*, 2003), a motion tracking system and a recessed force plate were used to capture the kinematics and ground reaction forces from several trials of realistic dislocation-prone maneuvers performed by actual subjects. Kinematics and kinetic data associated with the experiments were imported into a FE model of THA dislocation. The FE model was used to compute stresses developed within the implant, given the observed angular motion of the hip and contact force inferred from inverse dynamics. The FE mesh (Fig. 6A) was created using PATRAN version 8.5 and the simulations were executed with ABAQUS version 5.8. In the FE analysis, the resultant resisting moment developed around the hip-cup center was tracked, as a function of hip angle. The peak of this resistive moment was a key outcome measure used to estimate the relative risk of dislocations from the motions. All seven maneuvers studied led to frequent instances of computationally predicted dislocation (Fig. 6B). The authors conclude that this library of dislocation-prone maneuvers appear to substantially extend the information base previously available to study this important complication of THA. Additionally the hope is that their results will contribute to improvements in implant design and surgical technique and reduce *in vivo* incidence.

A Finite Element Model for the Lower Cervical Spine

A parametric study was conducted to determine the variations in the biomechanical responses of the spinal components in the lower cervical spine (Yoganandan *et al.*, 1997). Axial compressive load was imposed uniformly on the superior surface of the C4-C6 unit. The various components were assumed to have linear isotropic and homogeneous elastic behavior and appropriate material parameters were taken from the literature. A detailed 3D finite element model was reconstructed from 1.0-mm CT scans of a human cadaver, resulting in a total of 10,371 elements (Fig. 7A). The results show that an increase in elastic moduli of the disks resulted in an increase in endplate stresses and that the middle C5 vertebral body produced the highest compressive stresses (Fig. 7B). The model appears to confirm clinical experience that cervical fractures are induced by external compressive forces.

B

Maneuver	No. of trials	No. of dislocations	% of trials dislocating
Low sit-to-stand	47	41	87

FIG. 6. (A) Finite element model of a contemporary 22-mm modular THA system. (B) Table of FE dislocation predictions of the seven challenge maneuvers simulated. (Reproduced with permission from Nadzadi *et al.*, 2003.)

Finite Element Analysis of Indentation Tests on Pyrolytic Carbon

Pyrolytic carbon (PyC) heart valves are known to fail through cracks initiated at the contact areas between leaflets and their housing. In Gilpin *et al.* (1996), this phenomenon is simulated with a 5.1-mm steel ball indenting a graphite sheet coated on each side with PyC, similar to the makeup of real heart valves. Two types of contacts were analyzed: when the surface material is thick (rigid backing) and when it is fairly thin (flexible backing). FEA was used to evaluate the stresses resulting from a range of loads. The geometry was taken to be axisymmetric, PyC was assumed to be an elastic material and quadrilateral solid elements were used. Figure 8A shows part of the FE mesh. Note that the mesh is refined in the contact areas but gets progressively coarser toward the noncontact areas. Figure 8B shows the maximum principal stress on the PyC surface adjacent to ball contact, as a function of the indentation load. “Flexible backing” is seen to greatly reduce the maximum principal stress in this area. The FE results were correlated with data from experiments and used to develop failure criteria for contact stresses. This in turn provided criteria for designing contact regions in pyrolytic heart valves.

Numerical Analysis of 3D Flow in an Aorta through an Artificial Heart Valve

Three-dimensional transient flow past a Björk-Shiley valve in the aorta is simulated by the FEM combined with a time-stepping algorithm (Shim and Chang, 1997). The FE mesh is shown in Fig. 9A, comprising some 32,880 elements and 36,110 nodes. The results indicate that the flow is split into two major jet flows by the valve, which later merge downstream. A 3D plot of velocity vectors show large velocities in the upper and lower jet flow regions in the sinus region, large

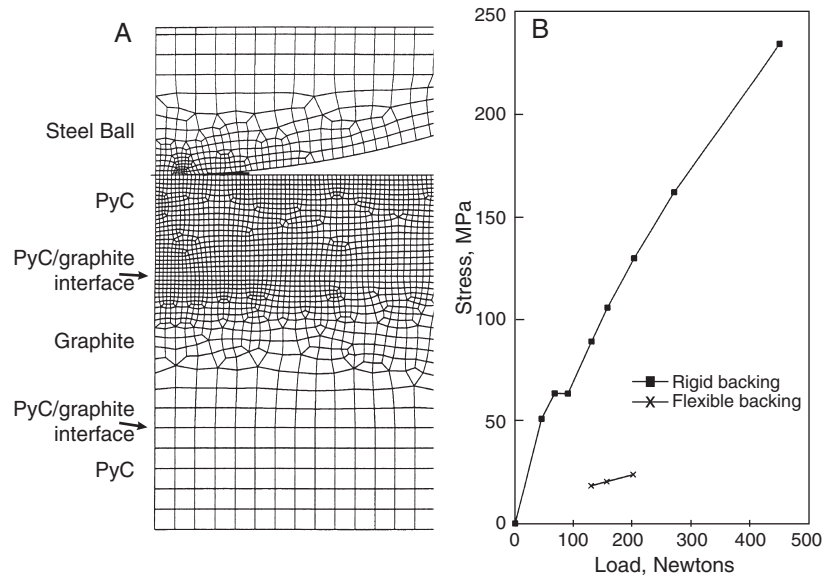

FIG. 8. Finite element analysis of indentation tests on pyrolytic carbon (PyC). (A) Part of the FE mesh showing a steel ball in contact with a PyC/graphite material. (B) Maximum principal stress on the PyC surface adjacent to ball contact radius. (Reproduced with permission from Gilpin *et al.*, 1996.)

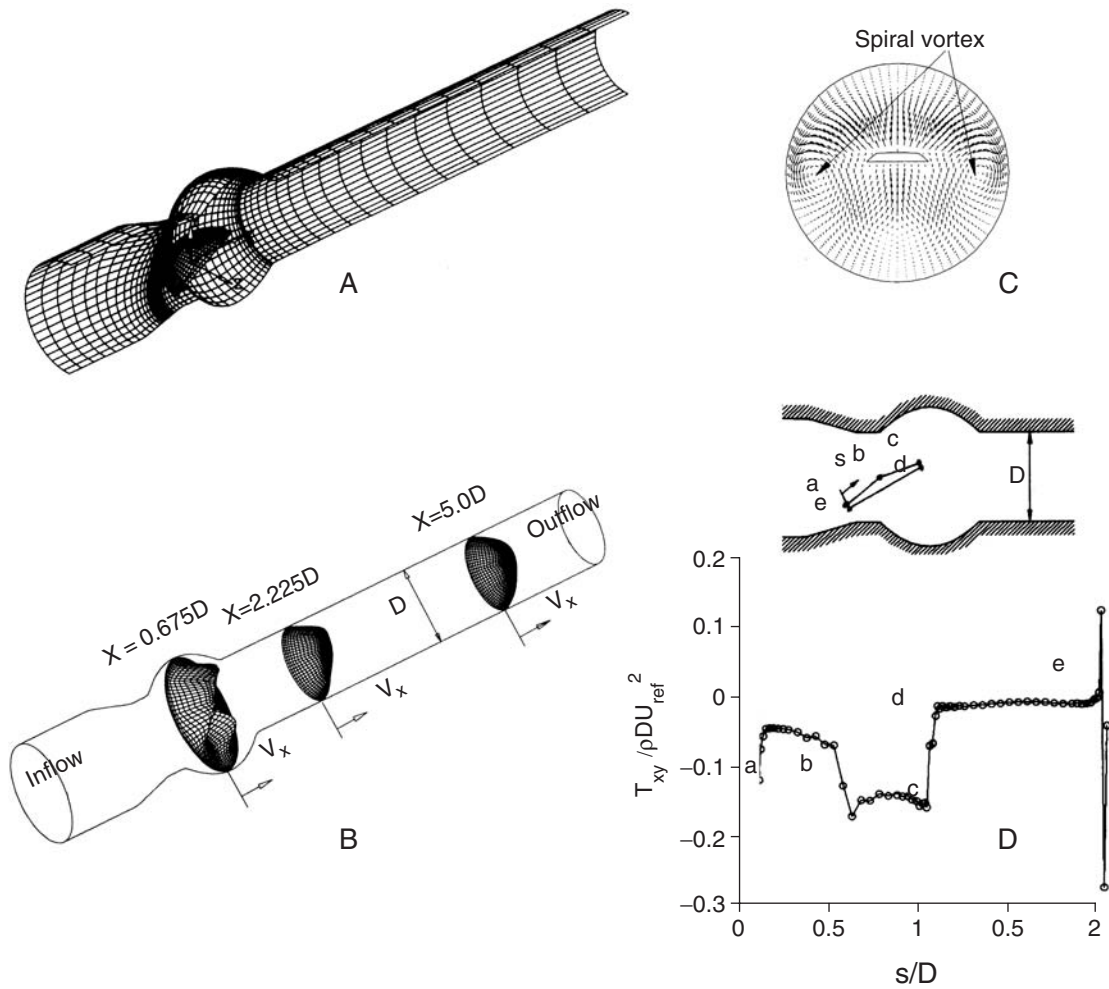

FIG. 9. FE analysis of transient 3D flow past a Bjork-Shiley valve in the aorta: (A) surface grid of aorta and fully opened Bjork-Shiley valve prosthesis, (B) carpet plot of axial velocity vectors, (C) secondary flow vector plot showing spiral vortices, and (D) shear stress along the valve surface in the symmetric mid-plane. (Reproduced with permission from Shim and Chang, 1997.)

velocities only in the upper part of the merged jet, and an almost uniform paraboloid distribution near the outflow region (Fig. 9B). Twin spiral vortices are generated immediately downstream of the valve, in the sinus region (Fig. 9C) and are connected downstream, where they quickly die away by diffusion. Shear stress along the surface of the valve is shown to be a maximum in the vicinity of its leading edge (Fig. 9D). A study such as this provides useful information on the function of the valve *in vivo*.

CONCLUSION

The FEM is an approximate, numerical method for solving boundary-value problems of continuum mechanics that are posed in differential or variational form. The main advantages of the FEM over other numerical methods lie in its generalization to three dimensions and the relative ease in which arbitrary geometries, boundary conditions, and material anisotropy can be incorporated into the solution process. The same FE code can be applied to solve a wide range of nonrelated problems. Its main disadvantage has been its complexity to implement. Fortunately, the abundance and availability of commercial codes in recent years and an emphasis on a “black box” approach with minimum user interaction have reduced the level of expertise required in the implementation of FEA to most engineering problems.

1.4 SURFACE PROPERTIES AND SURFACE CHARACTERIZATION OF MATERIALS

Buddy D. Ratner

INTRODUCTION

Consider the atoms that make up the outermost surface of a biomaterial. As we shall discuss in this section, these atoms that reside at the surface have a special organization and reactivity. They require special methods to characterize them and novel methods to tailor them, and they drive many of the biological reactions that occur in response to the biomaterial (protein adsorption, cell adhesion, cell growth, blood compatibility, etc.). The importance of surfaces for biomaterials science has been appreciated since the 1960s. Almost every biomaterials meeting will have sessions addressing surfaces and interfaces. In this chapter we focus on the special properties of surfaces, definitions of terms, methods to characterize surfaces, and some implications of surfaces for bioreaction to biomaterials.

In developing biomedical implant devices and materials, we are concerned with function, durability, and biocompatibility. In order to function, the implant must have appropriate properties such as mechanical strength, permeability, or elasticity, just to name a few. Well-developed methods typically exist to measure these bulk properties—often these are the classic methodologies of engineers and materials scientists. Durability, particularly in a biological environment, is less well understood. Still, the tests we need to evaluate durability have been developed over the past 20 years (see Chapters 1.2, 6.2, and 6.3). Biocompatibility represents a frontier of knowledge in this field, and its study is often assigned to the biochemist, biologist, and physician. However, an important question in biocompatibility is how the device or material “transduces” its structural makeup to direct or influence the response of proteins, cells, and the organism to it. For devices and materials that do not leach undesirable substances in sufficient quantities to influence cells and tissues (i.e., that have passed routine toxicological evaluation; see Chapter 5.2), this transduction occurs through the surface structure—the body “reads” the surface structure and responds. For this reason we must understand the surface structure of biomaterials. Chapter 9.4 elaborates on the biological implications of this idea.

General Surface Considerations and Definitions

This is the appropriate point in this chapter to highlight general ideas about surfaces, especially solid surfaces. First, the surface region of a material is known to be of unique reactivity (Fig. 1A). Catalysis (for example, as used in petrochemical processing) and microelectronics both capitalize on special surface reactivity—thus, it would be surprising if biology did not also use surfaces to do its work. This reactivity also leads to surface oxidation and other surface chemical reactions. Second, the surface of a material is inevitably different from the bulk. The traditional techniques used to analyze the bulk structure of materials are not suitable for surface determination because they typically do not have the sensitivity to observe

FIG. 1. (A) A two-dimensional representation of a crystal lattice illustrating bonding orbitals (black or crosshatched ovals). For atoms in the center (bulk) of the crystal (crosshatched ovals), all binding sites are associated. At planar exterior surfaces, one of the bonding sites is unfulfilled (black oval). At corners, two bonding sites are unfulfilled. The single atom on top of the crystal (an adatom) has three unfulfilled valencies. Energy is minimized where more of these unfulfilled valencies can interact. (B) In a “real world” material (e.g., a block of metal from an orthopedic device), if we cleave the block (under ultrahigh vacuum to prevent recontamination) we should find hydrocarbon on the outermost layer (perhaps 3 nm, surface energy ~ 22 ergs/cm²), polar organic molecules (>1 nm, surface energy ~ 45 ergs/cm²), adsorbed water (<1 nm, surface energy ~ 72 ergs/cm²), metal oxide (approximately 5 nm, surface energy ~ 200 ergs/cm²), and finally, the uniform bulk interior (surface energy ~ 1000 ergs/cm²). The interface between air and material has the lowest interfacial energy (~ 22 ergs/cm²). The layers are not drawn to scale.

the small amount of material comprising the unique surface chemistry/structure. Third, there is not much total mass of material at a surface. An example may help us to appreciate this—on a 1 cm³ cube of titanium, the 100 Å oxide surrounding the cube is in the same proportion as a 5-m wide beach on each coast of the United States is to the roughly 5,000,000 m distance from coast to coast. Fourth, surfaces readily contaminate with components from the vapor phase (some common examples are hydrocarbons, silicones, thiols, iodine). Under ultrahigh vacuum conditions (pressures $<10^{-7}$ Pa) we can retard this contamination. However, in view of the atmospheric pressure conditions under which all biomedical devices are used, we must learn to live with some contamination. The key questions here are whether we can make devices with controlled and acceptable levels of contamination and also avoid undesirable contaminants. This is critical so that a laboratory experiment on a biomaterial generates the same results when repeated after 1 day, 1 week, or 1 year, and so that the biomedical device is dependable and has a reasonable shelf life. Finally, the surface structure of a material is often mobile. A modern view of what might be seen at the surface of a real-world material is illustrated in Fig. 1B.

The movement of atoms and molecules near the surface in response to the outside environment is often highly significant. In response to a hydrophobic environment (e.g., air), more hydrophobic (lower energy) components may migrate to the surface of a material—a process that reduces interfacial energy (Fig. 1B). Responding to an aqueous environment, the surface may reverse its structure and point polar (hydrophilic) groups outward to interact with the polar water molecules.

Again, energy minimization drives this process. An example of this is schematically illustrated in Fig. 2. For metal alloys, one metal tends to dominate the surface, for example, silver in a silver–gold alloy or chromium in stainless steel.

The nature of surfaces is complex and the subject of much independent investigation. The reader is referred to one of many excellent monographs on this important subject for a complete and rigorous introduction (see Somorjai, 1981, 1994; Adamson and Gast, 1997; Andrade, 1985). For overviews of the relationship between surface science, biology and biomaterials, see Castner and Ratner (2002), Tirrell *et al.* (2000), Ratner (1988).

When we say “surface,” a question that immediately comes to mind is, “how deep into the material does it extend?” Although formal definitions are available, for all practical purposes, the surface is the zone where the structure and composition, influenced by the interface, differs from the average (bulk) composition and structure. This value often scales with the size of the molecules making up the surface. For an “atomic” material, for example gold, after penetration of about five atomic layers (0.5–1 nm), the composition becomes uniform from layer to layer (i.e., you are seeing the bulk structure). At the outermost atomic layer, the organization of the gold atoms at the surface (and their reactivity) can be substantially different from the organization in the averaged bulk. The gold, in air, will always have a contaminant overlayer, largely hydrocarbon, that may be roughly 2 nm thick. This is also a difference in composition between bulk and surface, but it is not the atomic/molecular rearrangements we are discussing here. For a polymer, the unique surface zone may extend from 10 nm

FIG. 2. Many materials can undergo a reversal of surface structure when transferred from air into a water environment. In this schematic illustration, a hydroxylated polymer (for example, a pHEMA contact lens) exhibits a surface rich in methyl groups (from the polymer chain backbone) in air, and a surface rich in hydroxyl groups under water. This has been observed experimentally (Ratner *et al.*, 1978, *J. Appl. Polym. Sci.* 22: 643; Chen *et al.*, 1999, *J. Am. Chem. Soc.* 121(2): 446).

to 100 nm (depending on the polymeric system and the chain molecular weight). Figure 1B addresses some of these issues about surface definitions. Two more definitions must be considered. An interface is the transition between two phases, in principle an infinitely thin separation plane. An interphase is the unique compositional zone between two phases. For the example, for gold, we might say that the interphase between gold and air is 3 nm thick (the structurally rearranged gold atoms + the contaminant layer).

Parameters to Be Measured

Many parameters describe a surface, as shown in Fig. 3. The more of these parameters we measure, the better we can piece together a complete description of the surface. A complete characterization requires the use of many techniques to compile all the information needed. Unfortunately, we cannot yet specify which parameters are most important for understanding biological responses to surfaces. Studies have been published on the importance of roughness, wettability, surface mobility, chemical composition, electrical charge, crystallinity, and heterogeneity to biological reaction. Since we cannot be certain which surface factors are predominant in each situation, the controlling variable or variables must be independently ascertained.

SURFACE ANALYSIS TECHNIQUES

General Principles

A number of general ideas can be applied to all surface analysis. They can be divided into the categories of sample preparation and analysis described in the following paragraphs.

Sample Preparation

A key consideration for sample preparation is that the sample should resemble, as closely as possible, the material or device being subjected to biological testing or implantation. Needless to say, fingerprints on the surface of the sample will cover up things that might be of interest. If the sample is placed in a package for shipping or storage prior to surface analysis, it is critical to know whether the packaging material can induce surface contamination. Plain paper in contact with most specimens will transfer material (often metal ions) to the surface of the material. Many plastics are processed with silicone oils or other additives that can be transferred to the specimen. The packaging material used should be examined by surface analysis methods to ascertain its purity. Samples can be surface analyzed prior to and after storage or shipping in containers to ensure that the surface composition measured is not due to the container. As a general rule, the polyethylene press-close bags used in electron microscopy and cell culture plasticware are clean storage containers. However, abrasive contact must be avoided and each brand must be evaluated so that a meticulous specimen preparation is not ruined by contamination. Many brands of aluminum foil are useful for packing specimens, but some are treated with a surface layer of stearic acid that can surface contaminate wrapped biomaterials, implants or medical devices. Aluminum foil should be checked for cleanliness by surface analysis methods before it is used to wrap important specimens.

Surface Analysis General Comments

Two general principles guide sample analysis. First, all methods used to analyze surfaces also have the potential to alter the surface. It is essential that the analyst be aware of the

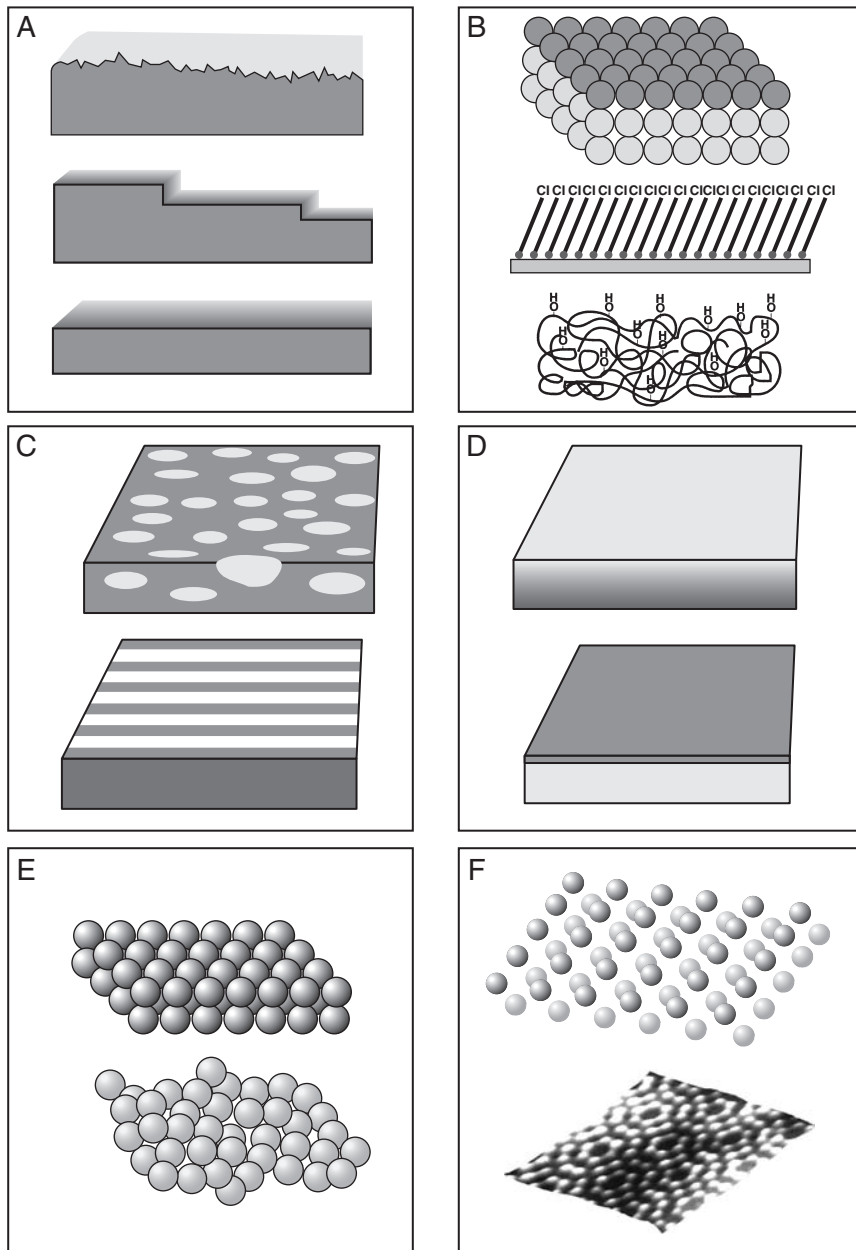

FIG. 3. What might be measured to define surface structure? (A) Surfaces can be rough, stepped or smooth. (B) Surfaces can be composed of different chemistries (atomic, supramolecular, macromolecular). (C) Surfaces may be structurally or compositionally inhomogeneous in the plane of the surface such as phase-separated domains or microcontact printed lanes. (D) Surfaces may be inhomogeneous with depth into the specimen or simply overlaid with a thin film. (E) Surfaces may be highly crystalline or disordered. (F) Crystalline surfaces are found with many organizations such as a silicon (100) unreconstructed surface or a silicon (111)(7×7) reconstructed surface.

damage potential of the method used. Second, because of the potential for artifacts and the need for many pieces of information to construct a complete picture of the surface (Fig. 3), more than one method should be used whenever possible. The data derived from two or more methods should always be corroborative. When data are contradictory, be suspicious and question why. A third or fourth method may then be necessary

to allow confident conclusions to be drawn about the nature of a surface.

These general principles are applicable to all materials. There are properties (only a few of which will be presented here) that are specific to specific classes of materials. Compared with metals, ceramics, glasses, and carbons, organic and polymeric materials are more easily damaged by surface

TABLE 1 Common Methods to Characterize Biomaterial Surfaces

Method	Principle	Depth analyzed	Spatial resolution	Analytical sensitivity	Cost ^c
Contact angles	Liquid wetting of surfaces is used to estimate the energy of surfaces	3–20 Å	1 mm	Low or high depending on the chemistry	\$
ESCA (XPS)	X-rays induce the emission of electrons of characteristic energy	10–250 Å	10–150 μm	0.1 at%	\$\$\$
Auger electron spectroscopy ^a	A focused electron beam stimulates the emission of Auger electrons	50–100 Å	100 Å	0.1 atom%	\$\$\$
SIMS	Ion bombardment sputters secondary ions from the surface	10 Å–1 μm ^b	100 Å	Very high	\$\$\$
FTIR-ATR	IR radiation is adsorbed and excites molecular vibrations	1–5 μm	10 μm	1 mol%	\$\$
STM	Measurement of the quantum tunneling current between a metal tip and a conductive surface	5 Å	1 Å	Single atoms	\$\$
SEM	Secondary electron emission induced by a focused electron beam is spatially imaged	5 Å	40 Å, typically	High, but not quantitative	\$\$

^a Auger electron spectroscopy is damaging to organic materials and is best used for inorganics.

^b Static SIMS ≈ 10 Å, dynamic SIMS to 1 μm

analysis methods. Polymeric systems also exhibit greater surface molecular mobility than inorganic systems. The surfaces of inorganic materials are contaminated more rapidly than polymeric materials because of their higher surface energy. Electrically conductive metals and carbons will often be easier to characterize than insulators using the electron, X-ray, and ion interaction methods. Insulators accumulate a surface electrical charge that requires special methods (e.g., a low-energy electron beam) to neutralize. To learn about other concerns in surface analysis that are specific to specific classes of materials, published papers become a valuable resource for understanding the pitfalls that can lead to artifact or inaccurate results.

Table 1 summarizes the characteristics of many common surface analysis methods, including their depth of analysis and their spatial resolution (spot size analyzed). A few of the more frequently used techniques are described in the next section. However, space limitations prevent a developed discussion of these methods. The reader is referred to many comprehensive books on the general subject of surface analysis (Andrade, 1985; Briggs and Seah, 1983; Feldman and Mayer, 1986; Vickerman, 1997). References on specific surface analysis methods will be presented in sections on each of the key methods.

Contact Angle Methods

A drop of liquid sitting on a solid surface represents a powerful, but simple, method to probe surface properties. Experience tells us that a drop of water on highly polished automobile body surfaces will stand up (bead up), whereas if that car has not been polished in a long time, the liquid will flow evenly over

the surface. This observation, with some understanding of the method, tells us that the highly polished car probably has silicones or hydrocarbons at its surface, while the unpolished car surface consists of oxidized material. This type of observation, backed up with a quantitative measurement of the drop angle with the surface, has been used in biomaterials science to predict the performance of vascular grafts and the adhesion of cells to surfaces.

The phenomenon of the contact angle can be explained as a balance between the force with which the molecules of the liquid (in the drop) are being attracted to each other (a cohesive force) and the attraction of the liquid molecules for the molecules that make up the surface (an adhesive force). An equilibrium is established between these forces, the energy minimum. The force balance between the liquid–vapor surface tension (γ_{lv}) of a liquid drop and the interfacial tension between a solid and the drop (γ_{sl}), manifested through the contact angle (θ) of the drop with the surface, can be used to quantitatively characterize the energy of the surface (γ_{sv}). The basic relationship describing this force balance is:

$$\gamma_{sv} = \gamma_{sl} + \gamma_{lv} \cos \theta$$

The energy of the surface, which is directly related to its wettability, is a useful parameter that has often correlated strongly with biological interaction. Unfortunately, γ_{sv} cannot be directly obtained since this equation contains two unknowns, γ_{sl} and γ_{sv} . Therefore, the γ_{sv} is usually approximated by the Zisman method for obtaining the critical surface tension (Fig. 4), or calculated by solving simultaneous equations with data from liquids of different surface tensions. Some critical surface tensions for common materials are listed in Table 2.

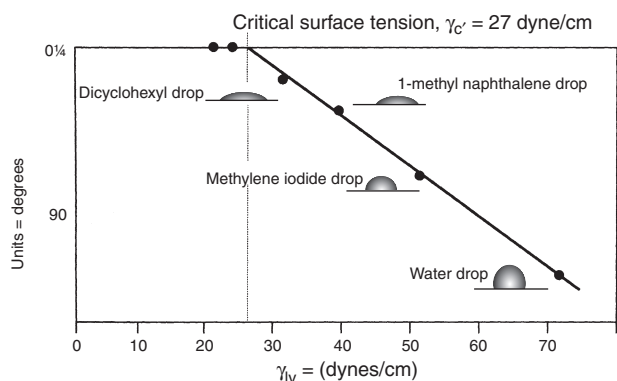

FIG. 4. The Zisman method permits a critical surface tension value, an approximation to the solid surface tension, to be measured. Drops of liquids of different surface tensions are placed on the solid, and the contact angles of the drops are measured. The plot of liquid surface tension versus angle is extrapolated to zero contact angle to give the critical surface tension value.

TABLE 2 Critical Surface Tension Values for Common Materials Calculated from Contact Angle Measurements

Material	Critical surface tension (dyn/cm)
Polytetrafluoroethylene	19
Poly(dimethyl siloxane)	24
Poly(vinylidene fluoride)	25
Poly(vinyl fluoride)	28
Polyethylene	31
Polystyrene	33
Poly(2-hydroxyethyl methacrylate)	37
Poly(vinyl alcohol)	37
Poly(methyl methacrylate)	39
Poly(vinyl chloride)	39
Polycaproamide (nylon 6)	42
Poly(ethylene oxide)-diol	43
Poly(ethylene terephthalate)	43
Polyacrylonitrile	50

Experimentally, there are a number of ways to measure the contact angle, and some of these are illustrated in Fig. 5. Contact angle methods are inexpensive, and, with some practice, easy to perform. They provide a “first line” characterization of materials and can be performed in any laboratory. Contact angle measurements provide unique insight into how the surface will interact with the external world. However, in performing such measurements, a number of concerns must be addressed to obtain meaningful data (Table 3). Review articles are available on contact angle measurement for surface characterization (Andrade, 1985; Good, 1993; Zisman, 1964; McIntire, *et al.*, 1985).

Electron Spectroscopy for Chemical Analysis

Electron spectroscopy for chemical analysis (ESCA) provides unique information about a surface that cannot be obtained by other means (Andrade, 1985; Ratner, 1988; Dilks, 1981; Ratner and McElroy, 1986; Ratner and Castner, 1997; Watts and Wolstenholme, 2003). In contrast to the contact angle technique, ESCA requires complex, expensive apparatus (Fig. 6A) and demands considerable training to perform the measurements. However, since ESCA is available from commercial laboratories, university analytical facilities, national centers (for example, NESAC/BIO at the University of Washington), and specialized research laboratories, most biomaterials scientists can get access to it to have their samples analyzed. The data can be interpreted in a simple but still useful fashion, or more rigorously. ESCA has contributed significantly to the development of biomaterials and medical devices, and to understanding the fundamentals of biointeraction.

The ESCA method (also called X-ray photoelectron spectroscopy, XPS) is based upon the photoelectric effect, properly described by Einstein in 1905. X-rays are focused upon a specimen. The interaction of the X-rays with the atoms in the specimen causes the emission of a core level (inner shell) electron. The energy of this electron is measured and its value provides information about the nature and environment of the atom from which it came. The basic energy balance describing this process is given by the simple relationship:

$$BE = h\nu - KE$$

where BE is the energy binding the electron to an atom (the value desired), KE is the kinetic energy of the emitted electron (the value measured in the ESCA spectrometer), and $h\nu$ is the energy of the X-rays, a known value. A simple schematic diagram illustrating an ESCA instrument is shown in Fig. 6B. Table 4 lists some of the types of information about the nature of a surface that can be obtained by using ESCA. The origin of the surface sensitivity of ESCA is described in Fig. 7.

ESCA has many advantages, and a few disadvantages, for studying biomaterials. The advantages include the high information content, the surface localization of the measurement, the speed of analysis, the low damage potential, and the ability to analyze most samples with no specimen preparation. The last advantage is particularly important because it means that many biomedical devices (or parts of devices) can be inserted, as fabricated and sterilized, directly in the analysis chamber for study. The disadvantages include the need for vacuum compatibility (i.e., no outgassing of volatile components), the vacuum environment (particularly for hydrated specimens), the possibility of sample damage by X-rays if long analysis times are used, the need for experienced operators, and the cost associated with this complex instrumentation. The vacuum limitations can be sidestepped by using an ESCA system with a cryogenic sample stage. At liquid nitrogen temperatures, samples with volatile components, or even wet, hydrated samples, can be analyzed.

The use of ESCA is best illustrated with a brief example. A poly(methyl methacrylate) (PMMA) ophthalmologic device is to be examined. Taking care not to touch or damage the surface of interest, the device is inserted into the ESCA instrument introduction chamber. The introduction chamber is then

FIG. 5. Four possibilities for contact angle measurement: (A) sessile drop, (B) captive air bubble method, (C) capillary rise method, (D) Wilhelmy plate method.

TABLE 3 Concerns in Contact Angle Measurement

The measurement is operator dependent.
Surface roughness influences the results.
Surface heterogeneity influences the results.
The liquids used are easily contaminated (typically reducing their ν_{lv}).
The liquids used can reorient the surface structure.
The liquids used can absorb into the surface, leading to swelling.
The liquids used can dissolve the surface.
Few sample geometries can be used.
Information on surface structure must be inferred from the data obtained.

pumped down to 10^{-6} torr (1.33×10^{-4} Pa) pressure. A gate valve between the introduction chamber and the analytical chamber is opened and the specimen is moved into the analysis chamber. In the analysis chamber, at 10^{-9} torr (1.33×10^{-7} Pa) pressure, the specimen is positioned (on contemporary instruments, using a microscope or TV camera) and the X-ray source is turned on. The ranges of electron energies to be observed are controlled (by computer) with the retardation lens on the spectrometer. First, a wide scan is made in which the energies of all emitted electrons over, typically, a 1000 eV range are detected (Fig. 8). Then, narrow scans are made in which each of the elements detected in the wide scan is examined in higher resolution (Fig. 9).

From the wide scan, we learn that the specimen contains carbon, oxygen, nitrogen, and sulfur. The presence of sulfur and nitrogen is unexpected for PMMA. We can calculate elemental ratios from the wide scan. The sample surface contains 58.2% carbon, 27.7% oxygen, 9.5% nitrogen, and 4.5% sulfur. The narrow scan for the carbon region (C1s spectrum) suggests four species: hydrocarbon, carbons singly bonded to oxygen (the predominant species), carbons in amide-like molecular environments, and carbons in acid or ester environments. This is different from the spectrum expected for pure PMMA. An examination of the peak position in the narrow scan of the sulfur region (S2p spectrum) suggests sulfonate-type groups. The shape of the C1s spectrum, the position of the sulfur peak, and the presence of nitrogen all suggest that heparin was immobilized to the surface of the PMMA device. Since the stoichiometry of the lens surface does not match that for pure heparin, this suggests that we are seeing either some of the PMMA substrate through a <100 Å layer of heparin, or we are seeing some of the bonding links used to immobilize the heparin to the lens surface. Further ESCA analysis will permit the extraction of more detail about this surface-modified device, including an estimate of surface modification thickness, further confirmation that the coating is indeed heparin, and additional information about the nature of the immobilization chemistry.

Secondary Ion Mass Spectrometry

Secondary ion mass spectrometry (SIMS) is an important addition to the armamentarium of tools that the surface analyst can bring to bear on a biomedical problem. SIMS produces

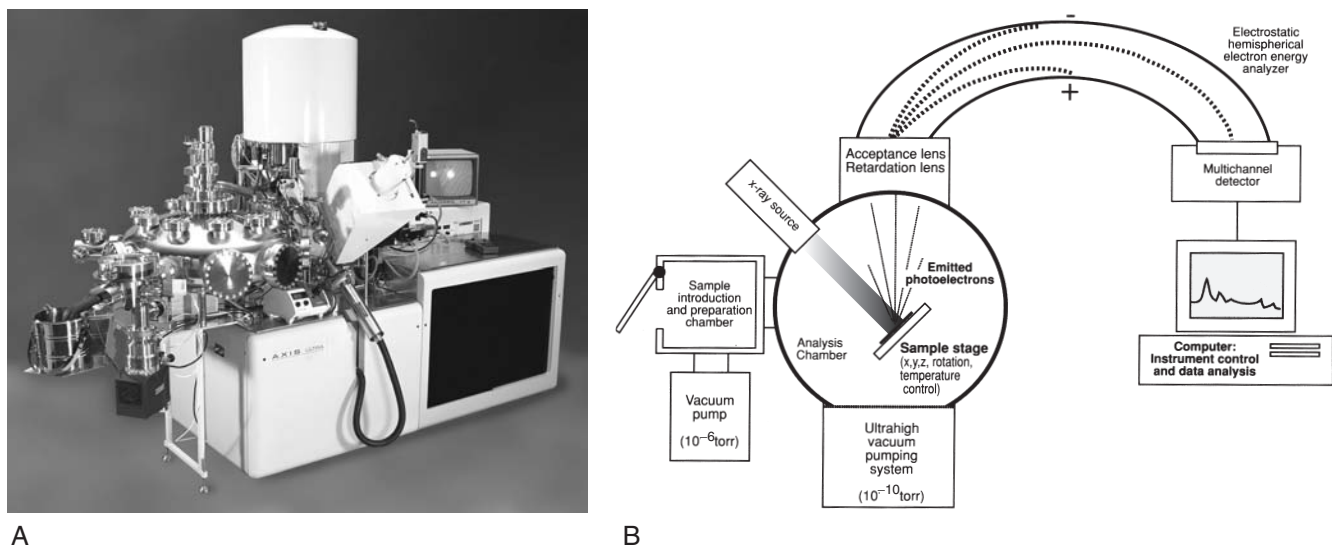

FIG. 6. (A) Photograph of a contemporary ESCA instrument (photo by Kratos Corp.). (B) Schematic diagram of a monochromatized ESCA instrument.

TABLE 4 Information Derived from an ESCA Experiment

In the outermost 100 Å of a surface, ESCA can provide:
Identification of all elements (except H and He) present at concentrations >0.1 at %
Semiquantitative determination of the approximate elemental surface composition ($\pm 10\%$)
Information about the molecular environment (oxidation state, bonding atoms, etc.)
Information about aromatic or unsaturated structures from shake-up $\pi^* \leftarrow \pi$ transitions
Identification of organic groups using derivatization reactions
Nondestructive elemental depth profiles 100 Å into the sample and surface heterogeneity assessment using angular-dependent ESCA studies and photoelectrons with differing escape depths
Destructive elemental depth profiles several thousand angstroms into the sample using argon etching (for inorganics)
Lateral variations in surface composition (spatial resolution 8–150 μm , depending upon the instrument)
“Fingerprinting” of materials using valence band spectra and identification of bonding orbitals
Studies on hydrated (frozen) surfaces

a mass spectrum of the outermost 10 Å of a surface. Like ESCA, it requires complex instrumentation and an ultrahigh vacuum chamber for the analysis. However, it provides unique information that is complementary to ESCA and greatly aids in understanding surface composition. Some of the analytical capabilities of SIMS are summarized in Table 5. Review articles on SIMS are available (Ratner, 1985; Scheutzle *et al.*, 1984;

FIG. 7. ESCA is a surface-sensitive method. Although the X-ray beam can penetrate deeply into a specimen, electrons emitted deep in the specimen (D, E, F, G) will lose their energy in inelastic collisions and never emerge from the surface. Only those electrons emitted near the surface that lose no energy (A, B) will contribute to the ESCA signal used analytically. Electrons that lose some energy but still have sufficient energy to emerge from the surface (C) contribute to the background signal.

Briggs, 1986; Davies and Lynn, 1990; Vickerman *et al.*, 1989; Benninghoven, 1983; Van Vaeck *et al.*, 1999; Belu *et al.*, 2003).

In SIMS analysis, a surface is bombarded with a beam of accelerated ions. The collision of these ions with the atoms and molecules in the surface zone can transfer enough energy to them so they sputter from the surface into the vacuum phase. The process is analogous to racked pool balls that are ejected from the cluster by the impact of the cue ball; the harder the cue ball hits the rack of balls, the more balls are emitted from the rack. In SIMS, the cue balls are ions (xenon, argon, cesium,

FIG. 8. ESCA wide scan of a surface-modified poly(methyl methacrylate) ophthalmologic device.

FIG. 9. The carbon 1s narrow scan ESCA spectrum of a surface-modified poly(methyl methacrylate) ophthalmologic device. Narrow scan spectra can be generated for each element seen in low-energy resolution mode in Fig. 8.

and gallium ions are commonly used) that are accelerated to energies of 5000–20,000 eV. The particles ejected from the surface are positive and negative ions (secondary ions), radicals, excited states, and neutrals. Only the secondary ions are measured in SIMS. In ESCA, the energy of emitted particles (electrons) is measured. SIMS measures the mass of emitted ions (more rigorously, the ratio of mass to charge, m/z) using a time-of-flight (TOF) mass analyzer or a quadrupole mass analyzer.

There are two modes for SIMS analysis, depending on the ion flux: dynamic and static. Dynamic SIMS uses high ion doses in a given analysis time. The primary ion beam sputters so much material from the surface that the surface erodes at an

TABLE 5 Analytical Capabilities of SIMS

	Static SIMS	Dynamic SIMS
Identify hydrogen and deuterium	✓	✓
Identify other elements (often must be inferred from the data)	✓	✓
Suggest molecular structures (inferred from the data)	✓	-
Observe extremely high mass fragments (proteins, polymers)	✓	-
Detection of extremely low concentrations	✓	✓
Depth profile to 1 μm into the sample	*	✓
Observe the outermost 1–2 atomic layers	✓	-
High spatial resolution (features as small as $\sim 400 \text{ \AA}$)	✓	✓
Semiquantitative analysis (for limited sets of specimens)	✓	✓
Useful for polymers	✓	-
Useful for inorganics (metals, ceramics, etc.)	✓	✓
Useful for powders, films, fibers, etc.	✓	✓

*Cluster ion sources may allow depth profiling with static SIMS-like information content

appreciable rate. We can capitalize on this to do a depth profile into a specimen. The intensity of the m/z peak of a species of interest (e.g., sodium ion, $m/z = 23$) might be followed as a function of time. If the ion beam is well controlled and the sputtering rate is constant, the sodium ion signal intensity measured at any time will be directly related to its concentration at the erosion depth of the ion beam into the specimen. A concentration depth profile (sodium concentration versus depth) can be constructed over a range from the outermost atoms to a micron or more into the specimen. However, owing to the damaging nature of the high-flux ion beam, only atomic fragments can be detected. Also, as the beam erodes deeper into the specimen, more artifacts are introduced in the data by “knock-in” and scrambling of atoms.

Static SIMS, in comparison, induces minimal surface destruction. The ion dose is adjusted so that during the period of the analysis less than 10% of one monolayer of surface atoms is sputtered. Since there are typically 10^{13} – 10^{15} atoms in 1 cm^2 of surface, a total ion dose of less than 10^{13} ions/ cm^2 during the analysis period is appropriate. Under these conditions, extensive degradation and rearrangement of the chemistry at the surface does not take place, and large, relatively intact molecular fragments can be ejected into the vacuum for measurement. Examples of molecular fragments are shown in Fig. 10. This figure also introduces some of the ideas behind SIMS spectral interpretation. A more complete introduction to the concepts behind static SIMS spectral interpretation can be found in Van Vaeck *et al.*, (1999) or in standard texts on mass spectrometry.

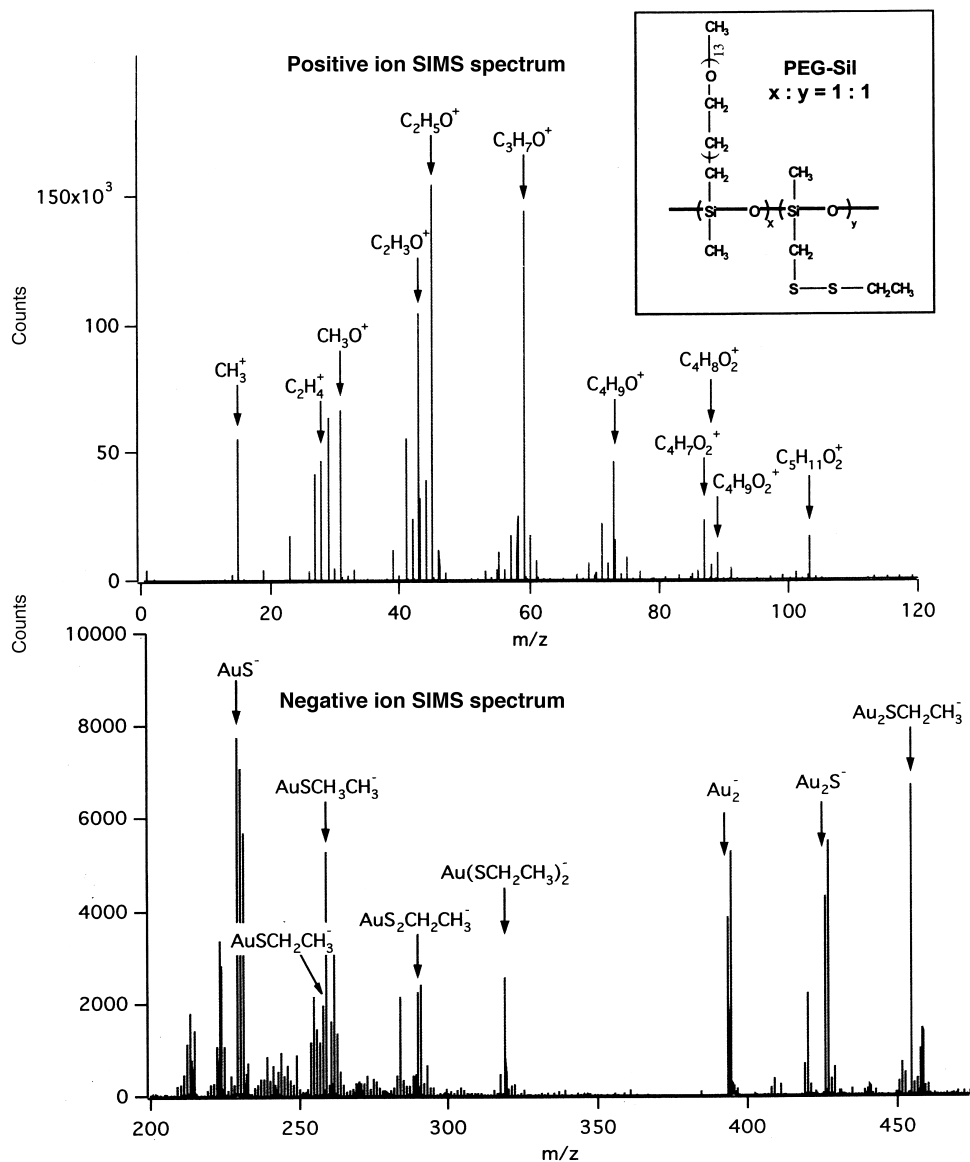

FIG. 10. Static positive and negative ion SIMS spectra of a poly(ethylene glycol)–poly(dimethyl siloxane) copolymer containing disulfide side groups on a gold surface. The primary peaks are identified. The low-mass region of the negative ion spectrum offers little insight into the polymer structure, but the high-mass region is rich in information. In this case, the low-mass positive spectrum is rich in information. Further details on this class of polymers can be found in *Macromolecules* 27: 3053 (1994). (Figure supplied by D. Castner.)

Magnetically or electrostatically focusing the primary ion beam permits the SIMS technique to have high spatial resolution in the x,y plane. In fact, SIMS analysis can be performed in surface regions of 10 nm diameter or smaller. For static SIMS analysis, less than 10% of the atoms in any area are sampled. Thus, as the spot size gets smaller, the challenge to achieve high analytical sensitivity increases sharply. Still, static SIMS measurements have been performed in areas as small as 40 nm. Newly developed cluster ion sources (for example, using gold molecular clusters, Au_3 , or C_{60} as the impacting primary particles) show high secondary ion yields and relatively low surface damage. These may improve spatial resolution and also permit

depth profiling of organic surfaces by sputtering down into a surface while monitoring secondary ion emission as a function of time.

If the focused primary ion beam is rastered over the surface and the x,y position of the beam correlated with the signal emitted from a given spot, the SIMS data can be converted into an elemental image. Patterning and spatial control of chemistry is becoming increasingly important in biomaterials surface design. For example, microcontact printing allows patterned chemistry to be transferred to surfaces at the micron level using a relatively simple rubber stamp. Imaging SIMS is well suited to studying and monitoring such spatially defined chemistry.

FIG. 11. Static SIMS image of protein islands on a poly(ethylene oxide) background. (For details, see Veisoh, M., Wickes, B. T., Castner, D. G., Zhang, M., "Guided cell patterning by surface molecular engineering." In press.)

An example is presented in Fig. 11. Imaging SIMS is also valuable for observing defects in thin films (pinholes), analyzing the chemistry of fine particulates or assessing causes of implant failure.

Scanning Electron Microscopy

Scanning electron microscopy (SEM) images of surfaces have great resolution and depth of field, with a three-dimensional quality that offers a visual perspective familiar to most users. SEM images are widely used and much has been written about the technique. The comments here are primarily oriented toward SEM as a surface analysis tool.

SEM functions by focusing and rastering a relatively high-energy electron beam (typically, 5–100 keV) on a specimen. Low-energy secondary electrons are emitted from each spot where the focused electron beam impacts. The measured intensity of the secondary electron emission is a function of the atomic composition of the sample and the geometry of the features under observation. SEM images surfaces by spatially reconstructing on a phosphor screen [or charged coupled device (CCD) detector] the intensity of the secondary electron emission. Because of the shallow penetration depth of the low-energy secondary electrons produced by the primary electron beam, only secondary electrons generated near the surface can escape from the bulk and be detected (this is analogous to the surface sensitivity described in Fig. 7). Consequently, SEM is a surface analysis method.

Nonconductive materials observed in the SEM are typically coated with a thin, electrically grounded layer of metal

to minimize negative charge accumulation from the electron beam. However, this metal layer is always so thick (>200 Å) that the electrons emitted from the sample beneath cannot penetrate. Therefore, in SEM analysis of nonconductors, the surface of the metal coating is, in effect, being monitored. If the metal coat is truly conformal, a good representation of the surface geometry will be conveyed. However, the specimen surface chemistry no longer influences secondary electron emission. Also, at very high magnifications, the texture of the metal coat and not the surface may be under observation.

SEM, in spite of these limitations in providing true surface information, is an important corroborative method to use in conjunction with other surface analysis methods. Surface roughness and texture can have a profound influence on data from ESCA, SIMS, and contact angle determinations. Therefore, SEM provides important information in the interpretation of data from these methods.

The development of low-voltage SEM offers a technique to truly study the surface chemistry (and geometry) of nonconductors. With the electron accelerating voltage lowered to approximately 1 keV, charge accumulation is not as critical and metallization is not required. Low-voltage SEM has been used to study platelets and phase separation in polymers. Also, the environmental SEM (ESEM) permits wet, uncoated specimens to be studied.

The primary electron beam also results in the emission of X-rays. These X-rays are used to identify elements with the technique called energy-dispersive X-ray analysis (EDXA). However, the high-energy primary electron beam penetrates deeply into a specimen (a micron or more). The X-rays produced from the interaction of these electrons with atoms deep in the bulk of the specimen can penetrate through the material and be detected. Therefore, EDXA is not a surface analysis method.

The primary use of SEM is to image topography. SEM for this application is elaborated upon in the chapter on microscopy in biomaterials research (Chapter 5.6).

Infrared Spectroscopy

Infrared spectroscopy (IRS) provides information on the vibrations of atomic and molecular species. It is a standard analytical method that can reveal information on specific chemistries and the orientation of structures. Fourier transform infrared (FTIR) spectrometry offers outstanding signal-to-noise ratio (S/N) and spectral accuracy. However, even with this high S/N, the small absorption signal associated with the minute mass of material in a surface region can challenge the sensitivity of the spectrometer. Also, the problem of separating the vastly larger bulk absorption signal from the surface signal must be addressed.

Surface FTIR methods couple the infrared radiation to the sample surface to increase the intensity of the surface signal and reduce the bulk signal (Allara, 1982; Leyden and Murthy, 1987; Urban, 1993; Dumas *et al.*, 1999). Some of these sampling modes, and their characteristics, are illustrated in Fig. 12.

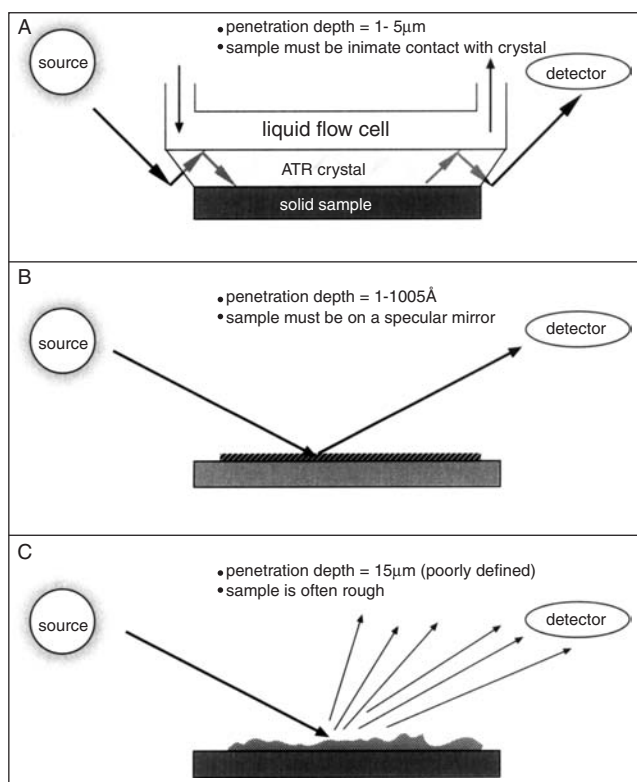

FIG. 12. Three surface-sensitive infrared sampling modes: (A) ATR-IR, (B) IRAS, (C) diffuse reflectance.

The attenuated total reflectance (ATR) mode of sampling has been used most often in biomaterials studies. The penetration depth into the sample is 1–5 μ m. Therefore, ATR is not highly surface sensitive, but observes a broad region near the surface. However, it does offer the wealth of rich structural information common to infrared spectra. With extremely high S/N FTIR instruments, ATR studies of proteins and polymers under water have been performed. In these experiments, the water signal (which is typically 99% or more of the total signal) is subtracted from the spectrum to leave only the surface material (e.g., adsorbed protein) under observation.

Another infrared method that has proven immensely valuable for observing extremely thin films on reflective surfaces is infrared reflection absorption spectroscopy (IRAS), Fig. 12. This method has been widely applied to self-assembled monolayers (SAMs), but is applicable to many surface films that are less than 10 nm in thickness. The surface upon which the thin film resides must be highly reflective and metal surfaces work best, though a silicon wafer can be used. IRAS gives information about composition, crystallinity and molecular orientation. Infrared spectroscopy is one member of a family of methods called vibrational spectroscopies. Two other vibrational spectroscopies, sum frequency generation and Raman, will be mentioned later in the section on newer methods.

Scanning Tunneling Microscopy, Atomic Force Microscopy, and the Scanning Probe Microscopies

In the 10 years since the first edition of this book, scanning tunneling microscopy (STM) and atomic force microscopy (AFM) have developed from novel research tools to key methods for biomaterials characterization. AFM has become more widely used than STM because oxide-free, electrically conductive surfaces are not needed with AFM. General review articles (Binnig and Rohrer, 1986; Avouris, 1990; Albrecht *et al.*, 1988) and articles oriented toward biological studies with these methods (Hansma *et al.*, 1988; Miles *et al.*, 1990; Rugar and Hansma, 1990; Jandt, 2001) are available.

The STM was invented in 1981 and led to a Nobel Prize for Binnig and Rohrer in 1986. The STM uses quantum tunneling to generate an atom-scale, electron density image of a surface. A metal tip terminating in a single atom is brought within 5–10 Å of an electrically conducting surface. At these distances, the electron cloud of the atom at the “tip of the tip” will significantly overlap the electron cloud of an atom on the surface. If a potential is applied between the tip and the surface, an electron tunneling current will be established whose magnitude, J , follows the proportionality:

$$J \propto e^{-Ak_0S}$$

where A is a constant, k_0 is an average inverse decay length (related to the electron affinity of the metals), and S is the separation distance in angstrom units. For most metals, a 1 Å change in the distance of the tip from the surface results in an order of magnitude change in tunneling current. Even though this current is small, it can be measured with good accuracy.

To image a surface, this quantum tunneling current is used in one of two ways. In constant current mode, a piezoelectric driver scans a tip over a surface. When the tip approaches an atom protruding above the plane of the surface, the current rapidly increases, and a feedback circuit moves the tip up to keep the current constant. Then, a plot is made of the tip height required to maintain constant current versus distance along the plane. In constant height mode, the tip is moved over the surface and the change in current with distance traveled along the plane of the surface is directly recorded. A schematic diagram of a scanning tunneling microscope is presented in Fig. 13. Two STM scanning modes are illustrated in Fig. 14.

The STM measures electrical current and therefore is well suited for conductive and semiconductive surfaces. However, biomolecules (even proteins) on conductive substrates appear amenable to imaging. It must be remembered that STM does not “see” atoms, but monitors electron density. The conductive and imaging mechanism for proteins is not well understood. Still, Fig. 15 suggests that valuable images of biomolecules on conductive surfaces can be obtained.

The AFM uses a similar piezo drive mechanism. However, instead of recording tunneling current, the deflection of a tip mounted on a flexible cantilever arm due to van der Waals and electrostatic repulsion and attraction between an atom at the tip and an atom on the surface is measured. Atomic-scale measurements of cantilever arm movements can be made by reflecting a laser beam off a mirror on the cantilever arm (an optical lever). A one-atom deflection of the cantilever arm can

FIG. 13. Schematic diagram illustrating the principle of the scanning tunneling microscope—a tip terminating in a single atom permits localized quantum tunneling current from surface features (or atoms) to tip. This tunneling current can be spatially reconstructed to form an image.

easily be magnified by monitoring the position of the laser reflection on a spatially resolved photosensitive detector. Other principles are also used to measure the deflection of the tip. These include capacitance measurements and interferometry. A diagram of a typical AFM is presented in Fig. 16.

Tips are important in AFM as the spatial resolution of the method is significantly associated with tip terminal diameter and shape. Tips are made from microlithographically fabricated silicon or silicon nitride. Also carbon whiskers, nanotubes, and a variety of nanospherical particles have been mounted on AFM tips to increase their sharpness or improve the ability to precisely define tip geometry. Tips are also surface-modified to alter the strength and types of interactions with surfaces (static SIMS can be used to image these surface modifications). Finally, cantilevers are sold in a range of stiffnesses so the analysis modes can be tuned to needs of the sample and the type of data being acquired. The forces associated with the interaction of an AFM tip with a surface as it approaches and is retracted are illustrated in Fig. 16. Since force is being measured and Hooke's law applies to the deformation of an elastic cantilever, the AFM can be used to quantify the forces between surface and tip. An exciting application of AFM is to measure the strength of interaction between two biomolecules (for example, biotin and streptavidin; see Chilkoti *et al.*, 1995).

AFM instruments are commonly applied to surface problems using one of two modes, contact mode and tapping mode. In contact mode, the tip is in contact with the surface (or at least the electron clouds of tip and surface essentially overlap). The pressures resulting from the force of the cantilever delivered through the extremely small surface area of the tip can be damaging to soft specimens (proteins, polymers, etc). However, for more rigid specimens, excellent topographical imaging can be achieved in contact mode. In tapping mode, the tip is oscillated at a frequency near the resonant frequency

FIG. 14. Scanning tunneling microscopy can be performed in two modes. In constant height mode, the tip is scanned a constant distance from the surface (typically 5–10 Å) and the change in tunneling current is recorded. In constant current mode, the tip height is adjusted so that the tunneling current is always constant, and the tip distance from the surface is recorded as a function of distance traveled in the plane of the surface.

FIG. 16. Schematic diagram illustrating the principle of the atomic force microscope.

TABLE 6 Scanning Probe Microscopy (SPM) Modes

Name	Acronym	Use
Contact mode	CM-AFM	Topographic imaging of harder specimens
Tapping (intermittent force) mode	IF-AFM	Imaging softer specimens
Noncontact mode	NCM-AFM	Imaging soft structures
Force modulation (allows slope of force–distance curve to be measured)	FM-AFM	Enhances image contrast based on surface mechanics
Scanning surface potential microscopy (Kelvin probe microscopy)	SSPM, KPM	Measures the spatial distribution of surface potential
Magnetic force microscopy	MFM	Maps the surface magnetic forces
Scanning thermal microscopy	SThM	Maps the thermal conductivity characteristics of a surface
Recognition force microscopy	RFM	Uses a biomolecule on a tip to probe for regions of specific biorecognition on a surface
Chemical force microscopy	CFM	A tip derivatized with a given chemistry is scanned on a surface to spatially measure differences of interaction strength
Lateral force microscopy	LFM	Maps frictional force on a surface
Electrochemical force microscopy	EFM	The tip is scanned under water and the electrochemical potential between tip and surface is spatially measured
Nearfield scanning optical microscopy	NSOM	A sharp optical fiber is scanned over a surface allowing optical microscopy or spectroscopy at 100-nm resolution
Electrostatic force microscopy	EFM	Surface electrostatic potentials are mapped
Scanning capacitance microscopy	SCM	Surface capacitance is mapped
Conductive atomic force microscopy	CAFM	Surface conductivity is mapped with an AFM instrument
Nanolithographic AFM		An AFM tip etches, oxidizes, or reacts a space permitting pattern fabrication at 10 nm or better resolution
Dip-pen nanolithography	DPN	An AFM tip, inked with a thiol or other molecule, writes on a surface at the nanometer scale

of the cantilever. The tip barely grazes the surface. The force interaction of tip and surface can affect the amplitude of oscillation and the oscillating frequency of the tip. In standard tapping mode, the amplitude change is translated into topographic spatial information. Many variants of tapping mode have been developed allowing imaging under different conditions and using the phase shift between the applied oscillation to the tip and the actual tip oscillation in the force field of the surface to provide information of the mechanical properties of the surface (in essence, the viscoelasticity of the surface can be appreciated).

The potential of the AFM to explore surface problems has been greatly expanded by ingenious variants of the technique. In fact, the term “atomic force microscopy” has been generalized to “scanning probe microscopy (SPM).” Table 6 lists many of these creative applications of the AFM/STM idea.

Since the AFM measures force, it can be used with both conductive and nonconductive specimens. Force must be applied to bend a cantilever, so AFM is subject to artifacts caused by damage to fragile structures on the surface. Both AFM and STM can function well for specimens under water, in air, or under vacuum. For exploring biomolecules or mobile organic surfaces, the “pushing around” of structures by the tip

is a significant concern. This surface artifact can be capitalized upon to write and fabricate surface structures at the nanometer scale (Fig. 17) (Boland *et al.*, 1998; Quate, 1997; Wilson *et al.*, 2001).

Newer Methods

There are many other surface characterization methods that have the potential to become important in future years. Some of these are listed in Table 7. A few of these evolving techniques that will be specifically mentioned here include sum frequency generation (SFG), Raman, and synchrotron methods.

SFG uses two high-intensity, pulsed laser beams, one in the visible range (frequency = ω_{visible}) and one in the infrared (frequency = ω_{ir}), to illuminate a specimen. The light emitted from the specimen by a non-linear optical process, $\omega_{\text{sum}} = \omega_{\text{visible}} + \omega_{\text{ir}}$, is detected and quantified (Fig. 18). The intensity of the light at ω_{sum} is proportional to the square of the sample’s second-order nonlinear susceptibility ($\chi^{(2)}$). The term susceptibility refers to the effect of the light field strength on the molecular polarizability. The ω_{sum} light intensity vanishes when a material has inversion symmetry, i.e., in the bulk of the material. At an interface, the inversion symmetry is broken and an SFG signal is generated. Thus, SFG is exquisitely sensitive

FIG. 17. An AFM tip, using relatively high force, was used to scratch a rectangular feature into a thin (70 Å) plasma deposited film. The AFM could also characterize the feature created.

TABLE 7 Methods that may have Applicability for the Surface Characterization of Biomaterials

Method	Information obtained
Second-harmonic generation (SHG)	Detect submonolayer amounts of adsorbate at any light-accessible interface (air–liquid, solid–liquid, solid–gas)
Surface-enhanced Raman spectroscopy (SERS)	High-sensitivity Raman at rough metal interfaces
Ion scattering spectroscopy (ISS)	Elastically reflected ions probe only the outermost atomic layer
Laser desorption mass spectrometry (LDMS)	Mass spectra of adsorbates at surfaces
Matrix assisted laser desorption ionization (MALDI)	Though generally a bulk mass spectrometry method, MALDI has been used to analyze large adsorbed proteins
IR photoacoustic spectroscopy (IR-PAS)	IR spectra of surfaces with no sample preparation based on wavelength-dependent thermal response
High-resolution electron energy loss spectroscopy (HREELS)	Vibrational spectroscopy of a highly surface-localized region, under ultrahigh vacuum
X-ray reflection	Structural information about order at surfaces and interfaces
Neutron reflection	Thickness and refractive index information about interfaces from scattered neutrons—where H and D are used, unique information on interface organization can be obtained
Extended X-ray absorption fine structure (EXAFS)	Atomic-level chemical and nearest-neighbor (morphological) information
Scanning Auger microprobe (SAM)	Spatially defined Auger analysis at the nanometer scale
Surface plasmon resonance (SPR)	Study aqueous adsorption events in real time by monitoring changes in surface refractive index
Rutherford backscattering spectroscopy (RBS)	Depth profiling of complex, multiplayer interfacial systems

to the plane of the interface. In practice, ω_{ir} is scanned over a vibrational frequency range—where vibrational interactions occur with interface molecules, then the SFG signal is resonantly enhanced and we see a vibrational spectrum. The advantages are the superb surface sensitivity, the cancellation of bulk spectral intensity (for example, this allows measurements at a water/solid interface), the richness of information

from vibrational spectra, and the ability to study molecular orientation due to the polarization of the light. SFG is not yet a routine method. The lasers and optical components are expensive and require precision alignment. Also, the range in the infrared over which lasers can scan is limited (though it has slowly expanded with improved equipment). However, the power of SFG for biomaterials studies has already been

FIG. 18. Schematic diagram of a sum frequency generation (SFG) apparatus (based upon a diagram developed by Polymer Technology Group, Inc.).

proven with studies on hydrated hydrogels, polyurethanes, surface active polymer additives, and proteins (Shen, 1989; Chen *et al.*, 2002).

In Raman spectroscopy a bright light is shined on a specimen. Most of the light scatters back at the same frequency as the incident beam. However, a tiny fraction of this light excites vibrations in the specimen and thereby loses or gains energy. The frequency shift of the light corresponds to vibrational bands indicative of the molecular structure of the specimen. The Raman spectroscopic technique has been severely limited for surface studies because of its low signal level. However, in recent years, great strides in detector sensitivity have allowed Raman to be applied for studying the minute mass of material at a surface. Also, surface enhanced Raman spectroscopy (SERS), Raman spectra taken from molecules on a roughened metal surface, can enhance Raman signal intensity by 10^6 or more. Raman spectra will be valuable for biomedical surface studies because water, which absorbs radiation very strongly in the infrared range, has little effect on Raman spectra that are often acquired with visible light (Storey *et al.*, 1995).

Synchrotron sources of energetic radiation that can be used to probe matter were originally confined to the physics community for fundamental studies. However, there are now more synchrotron sources, better instrumentation, and improved data interpretation. Synchrotron sources are typically national facilities costing $> \$100M$ and often occupying hundreds of acres (Fig. 19). By accelerating electrons to near the speed of light in a large, circular ring, energies covering a broad swath of the electromagnetic spectrum (IR to energetic X-rays) are emitted. A synchrotron source (and ancillary equipment) permits a desired energy of the probe beam to be “dialed in” or scanned through a frequency range. Other advantages include high source intensity (bright light) and polarized light. Some of the experimental methods that can be performed with great success at synchrotron sources include crystallography, scattering, spectroscopy, microimaging, and nanofabrication.

FIG. 19. The Advanced Photon Source, Argonne National Laboratories, a modern synchrotron source.

Specific surface spectroscopic methods include scanning photoemission microscopy (SPEM, 100 nm spatial resolution), ultraESCA (100 μm spatial resolution, high energy resolution), and near edge X-ray absorption spectrometry (NEXAFS).

STUDIES WITH SURFACE METHODS

Hundreds of studies have appeared in the literature in which surface methods have been used to enhance the understanding of biomaterial systems. A few studies that demonstrate the power of surface analytical methods for biomaterials science are briefly described here.

Platelet Consumption and Surface Composition

Using a baboon arteriovenous shunt model of platelet interaction with surfaces, a first-order rate constant of reaction of platelets with a series of polyurethanes was measured. This rate

constant, the platelet consumption by the material, correlated in an inverse linear fashion with the fraction of hydrocarbon-type groups in the ESCA C1s spectra of the polyurethanes (Hanson *et al.*, 1982). Thus, surface analysis revealed a chemical parameter about the surface that could be used to predict long-term biological reactivity of materials in a complex *ex vivo* environment.

Contact-Angle Correlations

The adhesion of a number of cell types, including bacteria, granulocytes, and erythrocytes, has been shown, under certain conditions, to correlate with solid-vapor surface tension as determined from contact-angle measurements. In addition, immunoglobulin G adsorption is related to ν_{sv} (Neumann *et al.*, 1983).

Contamination of Intraocular Lenses

Commercial intraocular lenses were examined by ESCA. The presence of sulfur, sodium, and excess hydrocarbon at their surfaces suggested contamination by sodium dodecyl sulfate (SDS) during the manufacture of the lenses (Ratner, 1983). A cleaning protocol was developed using ESCA to monitor results that produced a lens surface of clean PMMA.

Titanium

The discoloration sometimes observed on titanium implants after autoclaving was examined by ESCA and SIMS (Lausmaa *et al.*, 1985). The discoloration was found to be related to accelerated oxide growth, with oxide thicknesses to 650 Å. The oxide contained considerable fluorine, along with alkali metals and silicon. The source of the oxide was the cloth used to wrap the implant storage box during autoclaving. Since fluorine strongly affects oxide growth, and since the oxide layer has been associated with the biocompatibility of titanium implants, the authors advise avoiding fluorinated materials during sterilization of samples. A newer paper contains detailed surface characterization of titanium using a battery of surface methods and addresses surface preparation, contamination, and cleaning (Lausmaa, 1996).

SIMS for Adsorbed Protein Identification and Quantification

All proteins are made up of the same 20 amino acids and thus, on the average, are compositionally similar. Surface analysis methods have shown the ability to detect and quantify surface-bound protein, but biological tools have, until recently, been needed to identify specific proteins. Modern static SIMS instrumentation, using a multivariate statistical analysis of the data, has demonstrated the ability to distinguish between more than 13 different proteins adsorbed on surfaces (Wagner and Castner, 2001). Also, the limits of detection for adsorbed proteins on various surfaces were compared by ESCA and SIMS (Wagner *et al.*, 2002).

Poly(glycolic acid) Degradation Studied by SIMS

The degradation of an important polymer for tissue engineering, poly(glycolic acid), has been studied by static SIMS. As well as providing useful information on this degradation process, the study illustrates the power of SIMS for characterizing synthetic polymers and their molecular weight distributions (Chen *et al.*, 2000).

CONCLUSIONS

The instrumentation of surface analysis steadily advances and newer instruments and techniques can provide invaluable information about biomaterials and medical devices. The information obtained can be used to monitor contamination, ensure surface reproducibility, and explore fundamental aspects of the interaction of biological systems with living systems. Considering that biomedical experiments are typically expensive to perform, the costs for surface analysis are modest to ensure that the surface is as expected, stable and identical surface from experiment to experiment. Surface analysis can also contribute to the understanding of medical device failure (and success). Myriad applications for surface methods are found in device optimization, manufacture and quality control. Predicting biological reaction based on measured surface structure is a frontier area for surface analysis.

Acknowledgment

Support was received from the UWEB NSF Engineering Research Center and the NESAC/BIO National Resource, NIH grant EB-002027, during the preparation of this chapter and for some of the studies described herein.

QUESTIONS

1. Scan the table of contents and abstracts from the last three issues of the *Journal of Biomedical Materials Research* or *Biomaterials*. List all the surface analysis methods used in the articles therein and briefly describe what was learned by using them.
2. How is critical surface tension related to wettability? For the polymers in Table 2, draw the chemical formulas of the chain repeat units and attempt to relate the structures to the wettability. Where inconsistencies are noted, explain those inconsistencies using Table 3.
3. A titanium dental implant was manufactured by the Biomatter Company for the past 8 years. It performed well clinically. For economic reasons, manufacturing of the titanium device was outsourced to Metalsmed, Inc. Early clinical results on this Metalsmed implant, supposedly identical to the Biomatter implant, suggested increased inflammation. How would you compare the surface chemistry and structure of these two devices to see if a difference that might account for the difference in clinical performance could be identified?

1.5 ROLE OF WATER IN BIOMATERIALS

Erwin A. Vogler

The primary role water plays in biomaterials is as a solvent system. Water is the “universal ether” as it has been termed (Baier and Meyer, 1996), dissolving inorganic salts and large organic macromolecules such as proteins or carbohydrates (solutes) with nearly equal efficiency (Pain, 1982). Water suspends living cells, as in blood, for example, and is the principal constituent of the interstitial fluid that bathes tissues. Water is not just a bland, neutral carrier system for biochemical processes, however. Far from this, water is an active participant in biology, which simply could not and would not work the way it does without the special mediating properties of water. Moreover, it is widely believed that water is the first molecule to contact biomaterials in any clinical application (Andrade *et al.*, 1981; Baier, 1978). This is because water is the majority molecule in any biological mixture, constituting 70 wt % or more of most living organisms, and because water is such a small and agile molecule, only about 0.25 nm in the longest dimension. Consequently, behavior of water near surfaces and the role of water in biology are very important subjects in biomaterials science. Some of these important aspects of water are discussed in this chapter.

WATER SOLVENT PROPERTIES

Figures 1A–1D collect various diagrams of water illustrating the familiar atomic structure and how this arrangement leads

to the ability to form a network of self-associated molecules through hydrogen bonding. Self-association confers unique properties on water, many of which are still active areas of scientific investigation even after more than 200 years of chemical and physical research applied to water (Franks, 1972).

Hydrogen bonds in water are relatively weak 3–5 kcal/mole associations with little covalent character (Iassacs *et al.*, 1999; Marshall, 1999). As it turns out, hydrogen bond strength is approximately the same as the energy transferred from one molecule to another by collisions at room temperature (Vinogradov and Linnell, 1971). So hydrogen bonds are quite transient in nature, persisting only for a few tens of picoseconds (Berendsen, 1967; Luzar and Chandler, 1996). Modern molecular simulations suggest, however, that more than 75% of liquid-water molecules are interconnected in a three-dimensional (3D) network of three or four nearest neighbors at any particular instant in time (Robinson *et al.*, 1996). This stabilizing network of self-associated water formed from repeat units illustrated in Fig. 1D is so extensive, in fact, that it is frequently termed “water structure,” especially in the older literature (Narten and Levy, 1969). These somewhat dated water-structure concepts will not be discussed further here, other than to caution the reader that the transient nature of hydrogen bonding greatly weakens the notion of a “structure” as it might be practically applied by a chemist for example (Berendsen, 1967) and that reference to water structure near solutes and surfaces in terms of “icebergs” or “melting” should not be taken too literally, as will be discussed further subsequently.

A very important chemical outcome of this propensity of water to self-associate is the dramatic effect on water solvent properties. One view of self-association is from the standpoint of Lewis acidity and basicity. It may be recalled from general chemistry that a Lewis acid is a molecule that can accept electrons or, more generally, electron density from a molecular orbital of a donor molecule. An electron-density donor molecule is termed a Lewis base. Water is amphoteric in this sense because, as illustrated in Figs. 1A and 1D, it can simultaneously share and donate electron density. Hydrogen atoms (the Lewis acids) on one or more adjacent water molecules can accept electron density from the unshared electron pairs on the oxygen atom (the Lewis bases) of another water molecule. In this manner, water forms a 3D network through Lewis acid–base self-association reactions.

If the self-associated network is more complete than some arbitrary reference state, then there must be relatively fewer unmatched Lewis acid–base pairings than in this reference state. Conversely, in less-associated water, the network is relatively incomplete and there are more unmatched Lewis acid–base pairings than in the reference state. These unmatched pairings in less associated water are readily available to participate in other chemical reactions, such as dissolving a solute molecule or hydrating a water-contacting surface. Therefore, it can be generally concluded that less-associated water is a stronger solvent than more-associated water because it has a greater potential to engage in reactions other than self-association. In chemical terminology, less self-associated water has a greater chemical potential than more self-associated water. Interestingly, more self-associated water with

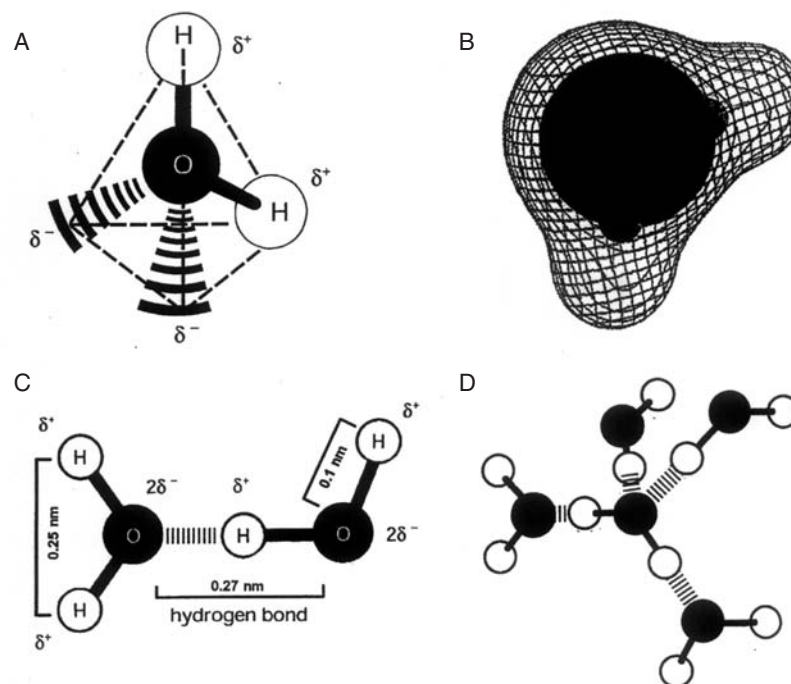

FIG. 1. Atomic structure of water illustrating (A) tetrahedral bonding arrangement wherein hydrogen atoms (H, light-colored spheres) are Lewis acid centers and the two lone-pair electrons on oxygen (O, dark-colored spheres) are Lewis base centers that permit water to hydrogen bond with four nearest-neighbor water molecules; (B) electron density map superimposed on an atomic-radius sphere model of water providing a more authentic representation of molecular water; (C) approximate molecular dimensions; and (D) five water molecules participating in a portion of a hydrogen-bond network.

a relatively more complete 3D network of hydrogen bonds must be less dense (greater partial molar volume) than less self-associated water because formation of linearly directed hydrogen bonds takes up space (Fig. 1C), increasing free volume in the liquid. This is why water ice with a complete crystalline network is less dense than liquid water and floats upon unfrozen water, a phenomenon with profound environmental impact. Thus, less associated water is not only more reactive but also more dense. These inferred relationships between water structure and reactivity are summarized in Table 1, which will be a useful aid to subsequent discussion.

A variety of lines of evidence ranging from molecular simulations (Lum *et al.*, 1999; Robinson *et al.*, 1996) to

experimental studies of water solvent properties in porous media (Qi and Soka, 1998; Wiggins, 1988) suggest that water expands and contracts in density (molar volume) with commensurate changes in chemical potential to accommodate presence of imposed solutes and surfaces. The word “imposed” is specifically chosen here to emphasize that a solute (e.g., an ion or a macromolecule) or an extended surface (e.g., the outer region of a biomaterial) must in some way interfere with self-association. Simply stated, the solute or surface gets in the way and water molecules must reorient to maintain as many hydrogen bonds with neighbors as is possible in this imposed presence of solute or surface. Water may not be able to maintain an extensive hydrogen-bond network in certain cases and this has important and measurable effects on water solvency. The next sections will first consider “hydrophobic” and “hydrophilic” solute molecules and then extend the discussion to hydrophobic and hydrophilic biomaterial surfaces, at least to the extent possible within the current scientific knowledge base.

TABLE 1 Relationships among Water Structure and Solvent Properties

Extent of water self-association	Density	Partial molar volume	Chemical potential (number of available hydrogen bonds)
More	Less	More	Less
Less	More	Less	More

THE HYDROPHOBIC EFFECT

The hydrophobic effect is related to the insolubility of hydrocarbons in water and is fundamental to the organization of lipids into bilayers, the structural elements of life as

we know it (Tanford, 1973). Clearly then, the hydrophobic effect is among the more fundamental, life-giving phenomena attributable to water. Hydrocarbons are sparingly soluble in water because of the strong self-association of water, not the strong self-association of hydrocarbons as is sometimes thought. Thus water structure is seen to be directly related to solvent properties in this very well-known case.

The so-called “entropy of hydrophobic hydration” (ΔS) has received a great deal of research attention from the molecular-simulation community because it dominates the overall (positive) free energy of hydrophobic hydration (ΔG) at ambient temperatures and pressures. The rather highly negative entropy of hydration of small hydrocarbons ($\Delta S \approx -20$ e.u.; see Kauzmann, 1959, for discussion related to lipids and proteins) turns out to be substantially due to constraints imposed on water-molecule orientation and translation as water attempts to maintain hydrogen-bond neighbors near the solute molecule (Paulaitis *et al.*, 1996). Apparently, there are no structural “icebergs” with enhanced self-association around small hydrocarbons (Besseling and Lyklema, 1995) as has been invoked in the past to account for ΔS (Berendsen, 1967). Instead, water surrounding small solutes such as methane or ethane may be viewed as spatially constrained by a “solute-straddling” effect that maximizes as many hydrogen-bonded neighbors as possible at the expense of orientational flexibility. Interestingly, while these constraints on water-molecule orientation do not significantly promote local self-association (i.e., increase structure), this lack of flexibility does have the effect of reducing repulsive, non-hydrogen-bonding interactions between water-molecule neighbors, accounting for a somewhat surprisingly exothermic (≈ -2 kcal/mol) enthalpy of hydration (ΔH) of small hydrocarbons (Besseling and Lyklema, 1995). The strong temperature sensitivities of these entropic and enthalpic effects are nearly equal and opposite and compensate in a way that causes the overall free energy of hydration ($\Delta G = \Delta H - T\Delta S$) to be essentially temperature insensitive. Increasing temperature expands the self-associated network of water, creating more space for a hydrophobic solute to occupy, and ΔS becomes more positive ($-T\Delta S$ more negative). On the other hand, nonbonding (repulsive) contacts between water molecules increase with temperature, causing ΔH to become more positive.

As one might imagine, difficulties in maintaining a hydrogen-bonded network are exacerbated near very large hydrophobic solutes where no orientations can prevent separation of water-molecule neighbors. Another water-driven mechanism comes into play in some of these cases wherein hydrophobic patches or domains on a solute such as a protein aggregate, exclude water, and participate in what has been termed “hydrophobic bonding” (DeVoe, 1969; Dunhill, 1965; Kauzmann, 1959; Tanford, 1966). This aspect of the hydrophobic effect is very important in biomaterials because it controls the folding of proteins and is thus involved in protein reactions at surfaces, especially denaturation of proteins at biomaterial surfaces induced by unfolding reactions in the adsorbed state. Water near large hydrophobic patches will be further considered in relation to hydrophobic surfaces that present analogous physical circumstances to water.

THE HYDROPHILIC EFFECT

There is no broadly recognized “hydrophilic effect” in science that is the antithesis to the well-known hydrophobic effect just discussed. But generally speaking, the behavior of water near hydrophilic solutes is so substantially different from that occurring near hydrophobic solutes that hydrophilicity may well be granted a distinguishing title of its own. The terms hydrophilic and hydrophobic are poorly defined in biomaterials and surface science (Hoffman, 1986; Oss and Giese, 1995; Vogler, 1998), requiring some clarification at this juncture since a distinction between hydrophilic and hydrophobic needs to be made. For the current purposes, let the term hydrophilic be applied to those solutes that compete with water for hydrogen bonds. That is to say, hydrophilic solutes exhibit Lewis acid or base strength comparable to or exceeding that of water, so that it is energetically favorable for water to donate electron density to or accept electron density from hydrophilic solutes instead of, or at least in competition with, other water molecules. For the sake of clarity, let it be added that there is no chemistry or other energetic reason for water to hydrogen bond with a hydrophobic solute as defined herein. Generally speaking, free energies of hydrophilic hydration are greater than that of hydrophobic hydration since acid–base chemistry is more energetic than the nonbonding “hydrophobic” reactions previously considered, and this frequently manifests itself in large enthalpic contributions to ΔG .

Familiar examples of hydrophilic solutes with biomedical relevance would include cations such as Na^+ , K^+ , Ca^{2+} , and Mg^{2+} or anions such as Cl^- , HCO_3^- and HPO_4^{2-} . These ions are surrounded by a hydration sphere of water directing oxygen atoms toward the cations or hydrogen atoms toward the anions. Water structuring near ions is induced by a strong electric field surrounding the ion that orients water dipole moments in a manner that depends on ionic size and extent of hydration (Marcus, 1985). Some ions are designated “structure promoting” and others “structure breaking.” Structure-promoting ions are those that impose more local order in surrounding water than occurs distant from the ion whereas structure-breaking or “chaotropic” ions increase local disorder and mobility of adjacent water molecules (Wiggins, 1971). Another feature of ion solvation important in biomaterials is that certain ions such as Ca^{2+} and Mg^{2+} are more hydrated (surrounded by more water molecules) than K^+ and Na^+ in the order of the so-called Hofmeister or lyotropic series. This implies that highly hydrated ions will partition into less associated water with more available hydrogen bonds for solvation (see Table 1) preferentially over more associated water with fewer available hydrogen bonds (Christenson *et al.*, 1990; Vogler, 1998; Wiggins, 1990; Wiggins and Ryn, 1990). This ion partitioning can have dramatic consequences on biology near surfaces since Ca^{2+} and Mg^{2+} have strong allosteric effects on enzyme reactions, a point that will be raised again in the final section of this chapter.

As in the hydrophobic effect, size plays a big role in the solvation of hydrophilic ions. Small inorganic ions are completely ionized and lead to separately hydrated ions in the

manner just discussed above. Hydration of a polyelectrolyte such as hyaluronic acid or a single strand of DNA is more complicated because a counterion "atmosphere" surrounds the dissolved polyelectrolyte. The countercharge distribution within this atmosphere is not uniform in space but instead diminishes in concentration with distance from the polyelectrolyte. This means that water in a hypothetical compartment near the polyelectrolyte is enriched in countercharges (higher ionic strength, lower water chemical potential) relative to that of an identical compartment distant from the polyelectrolyte (lower ionic strength, higher water chemical potential). Since concentration (chemical potential) gradients cannot persist at equilibrium, there must be some route to making chemical potentials uniform throughout solution. Wiggins has argued that the only means available to such a system of dissolved polyelectrolytes at constant temperature, pressure, and fixed composition (including water) is adjustment of water density or, more precisely, partial molar volume (Wiggins, 1990). That is to say, in order to increase water chemical potential in the near compartment relative to that of water in the distant compartment, water density must increase (see row 2 of Table 1, more molecules/unit volume available for chemical work). At the same time, in order to decrease water chemical potential in the distant compartment relative to that in the closer one; water density must decrease (see row 2 of Table 1, fewer molecules/unit volume available for chemical work). This thinking gives rise to the notion of contiguous regions of variable water density within a polyelectrolyte solution. Here again, it is evident that adjustment of water chemical potential to accommodate the presence of a large solute molecule appears to be a necessary mechanism to account for commonly observed hydration effects. The next section will explore how these same effects might account for surface wetting effects.

THE SURFACE WETTING EFFECT

It is a very common observation that water wets certain kinds of surfaces whereas water beads up on others, forming droplets with a finite "contact angle." This and related wetting phenomena have intrigued scientists for almost three centuries, and the molecular mechanisms of wetting are still an important area of research to this day. The reason for such continued interest is that wetting phenomena probe the various intermolecular forces and interactions responsible for much of the chemistry and physics of everyday life. Some of the remaining open questions are related to water structure and solvent properties near different kinds of surfaces.

Although surfaces on which water spreads are commonly termed hydrophilic and those on which water droplets form hydrophobic, the definitions employed in preceding sections based on presence or absence of Lewis acid/base groups that can hydrogen bond with water will continue to be used here, as this is a somewhat more precise way of categorizing biomaterials. Thus, hydrophobic surfaces are distinguished from hydrophilic by virtue of having no Lewis acid or base functional groups available for water interaction.

Water near hydrophobic surfaces finds itself in a predicament similar to that briefly mentioned in the preceding section

on the hydration of large hydrophobic solutes in that there are no configurational options available to water molecules closest to the surface that allow maintenance of nearest-neighbor hydrogen bonds. These surface-contacting water molecules are consequently in a less self-associated state and, according to row 2 of Table 1, must temporarily be in a state of higher chemical potential than bulk water. The key word here is temporarily, because chemical potential gradients cannot exist at equilibrium. At constant temperature and pressure, the only recourse available to the system toward establishment of equilibrium is decreasing local water density by increasing the extent of water self-association (row 1, Table 1). Thus it is reasoned that water in direct contact with a hydrophobic surface is less dense than bulk water some distance away from the hydrophobic surface.

This reasoning has been recently corroborated theoretically through molecular simulations of water near hydrophobic surfaces (Besseling and Lyklema, 1995; Lum *et al.*, 1999; Silverstein *et al.*, 1998) and experimentally by application of sophisticated vibrational spectroscopies (Du *et al.*, 1994; Gragson and Richmond, 1997). Although there is not precise uniformity among all investigators using a variety of different computational and experimental approaches, it appears that density variations propagate something of the order of 5 nm from a hydrophobic surface, or about 20 water layers.

There are at least two classes of hydrophilic surfaces that deserve separate mention here because these represent important categories of biomaterials as well (Hoffman, 1986). One class includes surfaces that adsorb water through the interaction with surface-resident Lewis acid or base groups. These water-surface interactions are constrained to the outermost surface layer, say the upper 1 nm or so. Examples of these biomaterials might include polymers that have been surface treated by exposure to gas discharges, use of flames, or reaction with oxidative reagents as well as ceramics, metals, and glass. Another category of hydrophilic surfaces embraces those that significantly absorb water. Examples here are hydrogel polymers such as poly(vinyl alcohol) (PVA), poly(ethylene oxide) (PEO), or hydroxyethylmethacrylate (HEMA) that can visibly swell or even go into water solution, depending on the molecular weight and extent of crosslinking. Modern surface engineering can create materials that fall somewhere between water-adsorbent and -absorbent by depositing very thin films using self-assembly techniques (P.-Grosdemange *et al.*, 1991; Prime and Whitesides, 1993), reactive gas plasma deposition (Lopez *et al.*, 1992), or radiation grafting (Hoffman and Harris, 1972; Hoffman and Kraft, 1972; Ratner and Hoffman, 1980) as examples. Here, oligomers that would otherwise dissolve in water form a thin-film surface that cannot swell in the usual, macroscopic application of the word. In all of the mentioned cases, however, water hydrogen bonds with functional groups that may be characterized as either Lewis acid or base. In the limit of very strong (energetic) surface acidity or basicity, water can become ionized through proton or hydroxyl abstraction.

The subject of water structure near hydrophilic surfaces is considerably more complex than water structuring at hydrophobic surfaces just discussed, which itself is no trivial matter. This extra complexity is due to three related features of hydrophilic surfaces. First, each hydrophilic surface is

a unique combination of both type and surface concentration of water-interactive Lewis acid or base functional groups (amine, carboxyl, ether, hydroxyl, etc.). Second, hydrophilic surfaces interact with water through both dispersion forces and Lewis acid–base interactions. This is to be contrasted to hydrophobic surfaces that interact with water only through dispersion forces (dispersion forces being a class of intermolecular interactions between the momentary dipoles in matter that arise from rapid fluctuations of electron density within molecular orbitals). Third, as a direct result of these two features, the number of possible water interactions and configurations is very large, especially if the hydrophilic surface is heterogeneous on a microscopic scale. These features make the problem of water behavior at hydrophilic surfaces both computationally and experimentally challenging.

In spite of this complexity, the reasoning and rationale applied to large polyelectrolytes in the preceding section should apply in an approximate way to extended hydrophilic surfaces, especially the more water-wettable types where acid–base interactions with water predominate over weaker dispersion interactions. This would suggest, then, that water near hydrophilic surfaces is more dense than bulk water, with a correspondingly less extensive self-associated water network (row 2, Table 1). There is some support for this general conclusion from simplified molecular models (Besseling, 1997; Silverstein *et al.*, 1998).

Thickness of this putative denser-water layer must depend in some way on the surface concentration (number) of Lewis acid/base sites and on whether the surface is predominately acid or predominately basic, but these relationships are far from worked out in detail. One set of experimental results suggesting that hydration layers near water-wettable surfaces can be quite thick comes from the rather startling finding by Pashley and Kitchener (1979) of 150-nm-thick, free-standing water films formed on fully water-wettable quartz surfaces from water vapor. These so-called condensate water films would comprise some 600 water molecules organized in a layer through unknown mechanisms. Perhaps these condensate films are formed from water-molecule layers with alternating oriented dipoles similar to the water layers around ions briefly discussed in the previous section. Note that this hypothetical arrangement defeats water self-association throughout the condensate-film layer in a manner consistent with the inferred less self-associated, high-density nature of water near hydrophilic surfaces.

Stepping back and viewing the full range of surface wetting behaviors discussed herein, it is apparent that water solvent properties (structure) near surfaces can be thought of as a sort of continuum or spectrum. At one end of the spectrum lie perfectly hydrophobic surfaces with no surface-resident Lewis acid or base sites. Water interacts with these hydrophobic surfaces only through dispersion forces mentioned above. At the other end of the spectrum, surfaces bear a sufficient surface concentration of Lewis sites to completely disrupt bulk water structure through a competition for hydrogen bonds, leading to complete water wetting (0° contact angle). Structure and solvent properties of water in contact with surfaces between these extremes must then exhibit some kind of graded properties associated with the graded wettability observed with contact angles. If the

surface region is composed of molecules that hydrate to a significant degree, as in the case of hydrogel materials, then the surface can adsorb water and swell or dissolve. At the extreme of water–surface interactions, surface acid or base groups can abstract hydroxyls or protons from water, respectively, leading to water ionization at the surface.

Finally, in closing this section on water properties near surfaces, it is worthwhile to note that whereas insights gained from computational models employing hypothetical surfaces and experimental systems using atomically smooth mica and highly polished semiconductor-grade silicon wafers provide very important scientific insights, these results have limited direct biomedical relevance because practical biomaterial surfaces are generally quite rough relative to the dimensions of water (Fig. 1C). At the 0.25-nm scale, water structure near a hydrophobic polymer such as polyethylene, for example, might better be envisioned as a result of hydrating molecular-scale domains where methyl- and methylene-group protrusions from a “fractal” surface solvate in water rather than a sea of close-packed groups disposed erectly on an infinitely flat plane that one might construct in molecular modeling. Surfaces of functionalized polymers such as poly(ethylene terephthalate) (PET) would be even more complex. Both surface topography and composition will play a role in determining water structure near surfaces.

WATER AND THE BIOLOGICAL RESPONSE TO MATERIALS

It has long been assumed that the observed biological response to materials is initiated or catalyzed by interactions with material residing in the same thin surface region that affects water wettability, arguably no thicker than about 1 nm. In particular, it is frequently assumed that biological responses begin with protein adsorption. These assumptions are based on the observations that cells and proteins interact only at the aqueous interface of a material, that this interaction seemingly does not depend on the macroscopic thickness of a rigid material, and that water does not penetrate deeply into the bulk of many materials (excluding those that absorb water). Thus, one may conclude that biology does not “sense” or “see” bulk properties of a contacting material, only the outermost molecular groups protruding from a surface. Over the past decade or so, the validity of this assumption seems to have been confirmed through numerous studies employing self-assembled monolayers (SAMs) supported on glass, gold, and silicon in which variation of the outermost surface functional groups exposed to blood plasma, purified proteins, and cells indeed induces different outcomes (Fagneto *et al.*, 1995; Liebmann-Vinson *et al.*, 1996; Margel *et al.*, 1993; Mooney *et al.*, 1996; Owens *et al.*, 1988; Petrash *et al.*, 1997; Prime and Whitesides, 1993; Scotchford *et al.*, 1998; Singhvi *et al.*, 1994; Sukenik *et al.*, 1990; Tidwell *et al.*, 1997; Vogler *et al.*, 1995a, b). But exactly how surfaces influence “biocompatibility” of a material is still not well understood.

Theories attempting to explain the role of surfaces in the biological response fall into two basic categories. One asserts

that surface energy is the primary correlating surface property (Akers *et al.*, 1977; Baier, 1972; Baier *et al.*, 1969), the other that water solvent properties near surfaces are the primary causative agent (Andrade *et al.*, 1981; Andrade and Hlady, 1986; Vogler, 1998). The former attempts to correlate surface energy factors such as critical surface energy σ_c or various interfacial tension components while the latter attempts correlations with water contact angle θ or some variant thereof such as water adhesion tension $\tau = \sigma_{lv} \cos \theta$, where σ_{lv} is the interfacial tension of water (see Chapter 1.4). Both approaches attempt to infer structure–property relationships between surface energy/wetting and some measure of the biological response. These two ideas would be functionally equivalent if water structure and solvent properties were directly related to surface energy in a straightforward way (e.g., linear), but this appears not to be the case (Vogler, 1998) because of water structuring in response to surface (adsorption) energetics, as described in preceding sections.

Both surface energy and water theories acknowledge that the principle interfacial events surfaces can promote or catalyze are adsorption and adhesion. Adsorption of proteins and/or adhesion of cells/tissues is known (or at least strongly suspected) to be involved in the primary interactions of biology with materials. Therefore, it is reasonable to anticipate that surfaces induce a biological response through adsorption and/or adhesion mechanisms. The surface energy theory acknowledges this connection by noting that surface energy is the engine that drives adsorption and adhesion. The water theory recognizes the same but in a quite different way. Instead, water theory asserts that surface energetics is the engine that drives adsorption of water and then, in subsequent steps, proteins and cells interact with the resulting hydrated interface either through or by displacing a so-called vicinal water layer that is more or less bound to the surface, depending on the energetics of the original water–surface interaction. Furthermore, water theory suggests that the ionic composition of vicinal water may be quite different than that of bulk water, with highly hydrated ions such as Ca^{2+} and Mg^{2+} preferentially concentrating in water near hydrophilic surfaces and less hydrated ions such as Na^+ and K^+ preferentially concentrating in water near hydrophobic surfaces. It is possible that the ionic composition of vicinal water layers further accounts for differences in the biological response to hydrophilic and hydrophobic materials on the basis that divalent ions have allosteric effects on enzyme reactions and participate in adhesion through divalent ion bridging.

Water is a very small, but very special, molecule. Properties of this universal biological solvent, this essential medium of life as we understand it, remain more mysterious in this century of science than those of the very atoms that compose it. Self-association of water through hydrogen bonding is the essential mechanism behind water solvent properties, and understanding self-association effects near surfaces is a key to understanding water properties in contact with biomaterials. It seems safe to conclude that no theory explaining the biological response to materials can be complete without accounting for water properties near surfaces and that this remains an exciting topic in biomaterials surface science.

Acknowledgments

The author is indebted to the editors for helpful and detailed discussion of the manuscript and to Professor J. Kubicki for molecular models used in construction of figures. Mr. Brian J. Mulhollem is thanked for reading the manuscript for typographical errors.

2.1 INTRODUCTION

Allan S. Hoffman

Biomaterials can be divided into four major classes of materials: polymers, metals, ceramics (including carbons, glass-ceramics, and glasses), and natural materials (including those from both plants and animals). Sometimes two different classes of materials are combined together into a composite material, such as silica-reinforced silicone rubber or carbon fiber- or hydroxyapatite particle-reinforced poly (lactic acid). Such composites are a fifth class of biomaterials. What is the history behind the development and application of such diverse materials for implants and medical devices, what are the compositions and properties of these materials, and what are the principles governing their many uses as components of implants and medical devices? This chapter critically reviews this important literature of biomaterials.

The wide diversity and sophistication of materials currently used in medicine and biotechnology is testimony to the significant scientific and technological advances that have occurred over the past 50 years. From World War II to the early 1960s, relatively few pioneering surgeons were taking commercially available polymers and metals, fabricating implants and components of medical devices from them, and applying them clinically. There was little government regulation of this activity, and yet these earliest implants and devices had a remarkable success. However, there were also some dramatic failures. This led the surgeons to enlist the aid of physical, biological, and materials scientists and engineers, and the earliest interdisciplinary “bioengineering” collaborations were born.

These teams of physicians and scientists and engineers not only recognized the need to control the composition, purity, and physical properties of the materials they were using, but they also recognized the need for new materials with new and special properties. This stimulated the development of many new materials in the 1970s. New materials were designed *de novo* specifically for medical use, such as biodegradable polymers and bioactive ceramics. Some were derived from

existing materials fabricated with new technologies, such as polyester fibers that were knit or woven in the form of tubes for use as vascular grafts, or cellulose acetate plastic that was processed as bundles of hollow fibers for use in artificial kidney dialysers. Some materials were “borrowed” from unexpected sources such as pyrolytic carbons or titanium alloys that had been developed for use in air and space technology. And other materials were modified to provide special biological properties, such as immobilization of heparin for anti-coagulant surfaces. More recently biomaterials scientists and engineers have developed a growing interest in natural tissues and polymers in combination with living cells. This is particularly evident in the field of tissue engineering, which focuses on the repair or regeneration of natural tissues and organs. This interest has stimulated the isolation, purification, and application of many different natural materials. The principles and applications of all of these biomaterials and modified biomaterials are critically reviewed in this chapter.

2.2 POLYMERS

*Stuart L. Cooper, Susan A. Visser,
Robert W. Hergenrother, and Nina M. K. Lamba*

Many types of polymers are widely used in biomedical devices that include orthopedic, dental, soft tissue, and cardiovascular implants. Polymers represent the largest class of biomaterials. In this section, we will consider the main types of polymers, their characterization, and common medical applications. Polymers may be derived from natural sources, or from synthetic organic processes.

The wide variety of natural polymers relevant to the field of biomaterials includes plant materials such as cellulose, sodium alginate, and natural rubber, animal materials such as tissue-based heart valves and sutures, collagen, glycosaminoglycans (GAGs), heparin, and hyaluronic acid, and other natural materials such as deoxyribonucleic acid (DNA), the genetic material of all living creatures. Although these polymers are undoubtedly important and have seen widespread

use in numerous applications, they are sometimes eclipsed by the seemingly endless variety of synthetic polymers that are available today. Synthetic polymeric biomaterials range from hydrophobic, non-water-absorbing materials such as silicone rubber (SR), polyethylene (PE), polypropylene (PP), poly(ethylene terephthalate) (PET), polytetrafluoroethylene (PTFE), and poly(methyl methacrylate) (PMMA) to somewhat more polar materials such as poly(vinyl chloride) (PVC), copoly(lactic–glycolic acid) (PLGA), and nylons, to water-swelling materials such as poly(hydroxyethyl methacrylate) (PHEMA) and beyond, to water-soluble materials such as poly(ethylene glycol) (PEG or PEO). Some are hydrolytically unstable and degrade in the body while others may remain essentially unchanged for the lifetime of the patient.

Both natural and synthetic polymers are long-chain molecules that consist of a large number of small repeating units. In synthetic polymers, the chemistry of the repeat units differs from the small molecules (monomers) that were used in the original synthesis procedures, resulting from either a loss of unsaturation or the elimination of a small molecule such as water or HCl during polymerization. The exact difference between the monomer and the repeat unit depends on the mode of polymerization, as discussed later.

The task of the biomedical engineer is to select a biomaterial with properties that most closely match those required for a particular application. Because polymers are long-chain molecules, their properties tend to be more complex than those of their short-chain precursors. Thus, in order to choose a polymer type for a particular application, the unusual properties of polymers must be understood.

This chapter introduces the concepts of polymer synthesis, characterization, and property testing as they are relevant to the eventual application of a polymer as a biomaterial. Following this, examples of polymeric biomaterials currently used by the medical community are cited and their properties and uses are discussed.

MOLECULAR WEIGHT

In polymer synthesis, a polymer is usually produced with a distribution of molecular weights. To compare the molecular weights of two different batches of polymer, it is useful to define an average molecular weight. Two statistically useful definitions of molecular weight are the number average and weight average molecular weights. The number average molecular weight (M_n) is the first moment of the molecular weight distribution and is an average over the number of molecules. The weight average molecular weight (M_w) is the second moment of the molecular weight distribution and is an average over the weight of each polymer chain. Equations 1 and 2 define the two averages:

$$M_n = \frac{\sum N_i M_i}{\sum N_i} \quad (1)$$

$$M_w = \frac{\sum N_i M_i^2}{\sum N_i M_i} \quad (2)$$

FIG. 1. Typical molecular weight distribution of a polymer.

where N_i is the number of moles of species i , and M_i is the molecular weight of species i .

The ratio of M_w to M_n is known as the polydispersity index (PI) and is used as a measure of the breadth of the molecular weight distribution. Typical commercial polymers have polydispersity indices of 1.5–5.0, although polymers with polydispersity indices of less than 1.1 can be synthesized with special techniques. A molecular weight distribution for a typical polymer is shown in Fig. 1.

Linear polymers used for biomedical applications generally have M_n in the range of 25,000 to 100,000 and M_w from 50,000 to 300,000, and in exceptional cases, such as the PE used in the hip joint, the M_w may range up to a million. Higher or lower molecular weights may be necessary, depending on the ability of the polymer chains to crystallize or to exhibit secondary interactions such as hydrogen bonding. The crystallinity and secondary interactions can give polymers additional strength. In general, increasing molecular weight corresponds to increasing physical properties; however, since melt viscosity also increases with molecular weight, processability will decrease and an upper limit of useful molecular weights is usually reached. Mechanical properties of some polymeric biomaterials are presented in Table 1.

SYNTHESIS

Methods of synthetic polymer preparation fall into two categories: addition polymerization (chain reaction) and condensation polymerization (stepwise growth) (Fig. 2). (Ring opening is another type of polymerization and is discussed in more detail later in the section on degradable polymers.) In addition polymerization, unsaturated monomers react through the stages of initiation, propagation, and termination to give the final polymer product. The initiators can be free radicals, cations, anions, or stereospecific catalysts. The initiator opens the double bond of the monomer, presenting another “initiation” site on the opposite side of the monomer bond for continuing growth. Rapid chain growth ensues during the propagation step until the reaction is terminated by reaction with another radical, a solvent molecule, another polymer molecule, an initiator, or an added chain transfer agent. PVC, PE, and PMMA are

FIG. 3. Polymer arrangements. (From F. Rodriguez, *Principles of Polymer Systems*, Hemisphere Publ., 1982, p. 21, with permission.)

of living free radical polymerizations called ATRP and RAFT may also yield low PIs.

Polymers produced by addition polymerization can be homopolymers, i.e., polymers containing only one type of repeat unit, or copolymers with two or more types of repeat units. Depending on the reaction conditions and the reactivity of each monomer type, the copolymers can be random, alternating, graft, or block copolymers, as illustrated in Fig. 4. Random copolymers exhibit properties that approximate the weighted average of those of the two types of monomer units, whereas block copolymers tend to phase separate into a monomer-A-rich phase and a monomer-B-rich phase, displaying properties unique to each of the homopolymers. Figure 5 shows the repeat units of many of the homopolymers used in medicine.

Condensation polymerization can also result in copolymer formation. The properties of the condensation copolymer depend on three factors: the chemistry of monomer units; the molecular weight of the polymer product, which can be controlled by the ratio of one reactant to another and by the time

FIG. 4. Possible structures of polymer chains.

of polymerization; and the final distribution of the molecular weight of the copolymer chains. The use of bifunctional monomers gives rise to linear polymers, while multifunctional monomers may be used to form covalently cross-linked networks. Figure 6 shows the reactant monomers and polymer products of some biomedical copolymers.

Postpolymerization cross-linking of addition or condensation polymers is also possible. Natural rubber, for example, consists mostly of linear molecules that can be cross-linked to a loose network with 1–3% sulfur (vulcanization) or to a hard rubber with 40–50% sulfur (Fig. 3). In addition, physical, rather than chemical, cross-linking of polymers can occur in microcrystalline regions, that are present in nylon (Fig. 7A). Alternatively, physical cross-linking can be achieved through incorporation of ionic groups in the polymer (Fig. 7B). This is used in acrylic acid cement systems (e.g., for dental cements) where divalent cations such as zinc and calcium are incorporated into the formulation and interact with the carboxyl groups to produce a strong, hard material. The alginates, which are polysaccharides derived from brown seaweed, also contain anionic residues that will interact with cations and water to form a gel. The alginates are used successfully to dress deep wounds and are also being studied as tissue engineering matrices.

THE SOLID STATE

Tacticity

Polymers are long-chain molecules and, as such, are capable of assuming many conformations through rotation of valence bonds. The extended chain or planar zigzag conformation of PP is shown in Fig. 8. This figure illustrates the concept of tacticity. Tacticity refers to the arrangement of substituents (methyl groups in the case of polypropylene) around the extended polymer chain. Chains in which all substituents are located on the same side of the zigzag plane are isotactic, whereas syndiotactic chains have substituents alternating from side to side. In the atactic arrangement, the substituent groups appear at random on either side of the extended chain backbone.

FIG. 8. Schematic of stereoisomers of polypropylene. (From F. Rodriguez, *Principles of Polymer Systems*, Hemisphere Publ., 1982, p. 22, with permission.)

Atactic polymers usually cannot crystallize, and an amorphous polymer results. Isotactic and syndiotactic polymers may crystallize if conditions are favorable. PP is an isotactic crystalline polymer used as sutures. Crystalline polymers, such as PE, also possess a higher level of structure characterized by folded chain lamellar growth that results in the formation of spherulites. These structures can be visualized in a polarized light microscope.

Crystallinity

Polymers can be either amorphous or semicrystalline. They can never be completely crystalline owing to lattice defects that form disordered, amorphous regions. The tendency of a polymer to crystallize is enhanced by the small side groups and chain regularity. The presence of crystallites in the polymer usually leads to enhanced mechanical properties, unique thermal behavior, and increased fatigue strength. These properties make semicrystalline polymers (often referred to simply as crystalline polymers) desirable materials for biomedical applications. Examples of crystalline polymers used as biomaterials are PE, PP, PTFE, and PET.

Mechanical Properties

The tensile properties of polymers can be characterized by their deformation behavior (stress-strain response (Fig. 9)). Amorphous, rubbery polymers are soft and reversibly extensible. The freedom of motion of the polymer chain is retained at a local level while a network structure resulting from chemical cross-links and chain entanglements prevents large-scale movement or flow. Thus, rubbery polymers tend to exhibit a lower modulus, or stiffness, and extensibilities of several hundred percent, as shown in Table 1. Rubbery materials may also exhibit an increase of stress prior to breakage as a result of strain-induced crystallization assisted by molecular orientation in the

FIG. 9. Tensile properties of polymers.

direction of stress. Glassy and semicrystalline polymers have higher moduli and lower extensibilities.

The ultimate mechanical properties of polymers at large deformations are important in selecting particular polymers for biomedical applications. The ultimate strength of polymers is the stress at or near failure. For most materials, failure is catastrophic (complete breakage). However, for some semicrystalline materials, the failure point may be defined by the stress point where large inelastic deformation starts (yielding). The toughness of a polymer is related to the energy absorbed at failure and is proportional to the area under the stress-strain curve.

The fatigue behavior of polymers is also important in evaluating materials for applications where dynamic strain is applied. For example, polymers that are used in the artificial heart must be able to withstand many cycles of pulsating motion. Samples that are subjected to repeated cycles of stress and release, as in a flexing test, fail (break) after a certain number of cycles. The number of cycles to failure decreases as the applied stress level is increased, as shown in Fig. 10 (see also Chapter 6.4). For some materials, a minimum stress exists below which failure does not occur in a measurable number of cycles.

FIG. 10. Fatigue properties of polymers.

Thermal Properties

In the liquid or melt state, a noncrystalline polymer possesses enough thermal energy for long segments of each polymer to move randomly (Brownian motion). As the melt is cooled, a temperature is eventually reached at which all long-range segmental motions cease. This is the glass transition temperature (T_g), and it varies from polymer to polymer. Polymers used below their T_g , such as PMMA, tend to be hard and glassy, while polymers used above their T_g , such as SR, are rubbery. Polymers with any crystallinity will also exhibit a melting temperature (T_m) owing to melting of the crystalline phase. These polymers, such as PET, PP, and nylon, will be relatively hard and strong below T_g , and tough and strong above T_g . Thermal transitions in polymers can be measured by differential scanning calorimetry (DSC), as discussed in the section on characterization techniques. All polymers have a T_g , but only polymers with regular chain architecture can pack well, crystallize, and exhibit a T_m . The T_g is always below the T_m .

The viscoelastic responses of polymers can also be used to classify their thermal behavior. The modulus versus temperature curves shown in Fig. 11 illustrate behaviors typical of linear amorphous, cross-linked, and semicrystalline polymers. The response curves are characterized by a glassy modulus below T_g of approximately 3×10^9 Pa. For linear amorphous polymers, increasing temperature induces the onset of the glass transition region where, in a 5–10°C temperature span (depending on heating rate), the modulus drops by three orders of magnitude, and the polymer is transformed from a stiff glass to a leathery material. The relatively constant modulus region above T_g is the rubbery plateau region where long-range segmental motion is occurring but thermal energy is insufficient to overcome entanglement interactions that inhibit flow. This is the target region for many biomedical applications. Finally, at high enough temperatures, the polymer begins to flow, and a sharp decrease in modulus is seen over a narrow temperature range. This is the region where polymers are processed into various shapes, depending on their end use.

FIG. 11. Dynamic mechanical behavior of polymers.

Crystalline polymers exhibit the same general features in modulus versus temperature curves as amorphous polymers; however, crystalline polymers possess a higher plateau modulus owing to the reinforcing effect of the crystallites. Crystalline polymers tend to be tough, ductile plastics whose properties are sensitive to processing history. When heated above their flow point, they can be melt processed and will crystallize and become rigid again upon cooling.

Chemically cross-linked polymers exhibit modulus versus temperature behavior analogous to that of linear amorphous polymers until the flow regime is approached. Unlike linear polymers, chemically cross-linked polymers do not display flow behavior; the cross links inhibit flow at all temperatures below the degradation temperature. Thus, chemically cross-linked polymers cannot be melt processed. Instead, these materials are processed as reactive liquids or high-molecular-weight amorphous gums that are cross-linked during molding to give the desired product. SR is an example of this type of polymer. Some cross-linked polymers are formed as networks during polymerization, and then must be machined to be formed into useful shapes. The soft contact lens, poly(hydroxyethyl methacrylate) or polyHEMA, is an example of this type of network polymer; it is shaped in the dry state, and used when swollen with water.

Copolymers

In contrast to the thermal behavior of homopolymers discussed earlier, copolymers can exhibit a number of additional thermal transitions. If the copolymer is random, it will exhibit a T_g that approximates the weighted average of the T_g values of the two homopolymers. Block copolymers of sufficient size and incompatible block types, such as the polyurethanes, will exhibit two individual transitions, each one characteristic of the homopolymer of one of the component blocks (in addition to other thermal transitions) but slightly shifted owing to incomplete phase separation.

CHARACTERIZATION TECHNIQUES

Determination of Molecular Weight

Gel permeation chromatography (GPC), a type of size exclusion chromatography, involves passage of a dilute polymer solution over a column of porous beads. High-molecular-weight polymers are excluded from the beads and elute first, whereas lower molecular-weight molecules pass through the pores of the bead, increasing their elution time. By monitoring the effluent of the column as a function of time using an ultraviolet or refractive index detector, the amount of polymer eluted during each time interval can be determined. Comparison of the elution time of the samples with those of monodisperse samples of known molecular weight allows the entire molecular weight distribution to be determined. A typical GPC trace is shown in Fig. 12.

Osmotic pressure measurements can be used to measure M_n . A semipermeable membrane is placed between two chambers.

FIG. 12. A typical trace from a gel permeation chromatography run for a poly(tetramethylene oxide)/toluene diisocyanate-based polyurethane. The response of the ultraviolet detector is directly proportional to the amount of polymer eluted at each time point.

Only solvent molecules flow freely through the membrane. Pure solvent is placed in one chamber, and a dilute polymer solution of known concentration is placed in the other chamber. The lowering of the activity of the solvent in solution with respect to that of the pure solvent is compensated by applying a pressure π on the solution. π is the osmotic pressure and is related to M_n by:

$$\frac{\pi}{c} = RT \left[\frac{1}{M_n} + A_2c + A_3c^2 + \dots \right] \quad (3)$$

where c is the concentration of the polymer in solution, R is the gas constant, T is temperature, and A_2 and A_3 are virial coefficients relating to pairwise and triplet interactions of the molecules in solution. In general, a number of polymer solutions of decreasing concentration are prepared, and the osmotic pressure is extrapolated to zero:

$$\lim_{c \rightarrow 0} \frac{\pi}{c} = \frac{RT}{M_n} \quad (4)$$

A plot of π/c versus c then gives as its intercept the number average molecular weight.

A number of other techniques, including vapor pressure osmometry, ebulliometry, cryoscopy, and end-group analysis, can be used to determine the M_n of polymers up to molecular weights of about 40,000.

Light-scattering techniques are used to determine M_w . In dilute solution, the scattering of light is directly proportional to the number of molecules. The scattered intensity is observed at a distance r and an angle θ from the incident beam I_o is characterized by Rayleigh's ratio R_θ :

$$R_\theta = \frac{i_o r^2}{I_o} \quad (5)$$

The Rayleigh ratio is related to M_w by:

$$\frac{K_c}{R_\theta} = \frac{1}{M_w} + 2 A_2c + 3 A_2c^2 + \dots \quad (6)$$

A number of solutions of varying concentrations are measured, and the data are extrapolated to zero concentration to determine M_w .

Determination of Structure

Infrared (IR) spectroscopy is often used to characterize the chemical structure of polymers. Infrared spectra are obtained by passing infrared radiation through the sample of interest and observing the wavelength of the absorption peaks. These peaks are caused by the absorption of the radiation and its conversion into specific motions, such as C–H stretching. The infrared spectrum of a polyurethane is shown in Fig. 13, with a few of the bands of interest marked.

Nuclear magnetic resonance (NMR), in which the magnetic spin energy levels of nuclei of spin 1/2 or greater are probed, may also be used to analyze chemical composition. ^1H and ^{13}C NMR are the most frequently studied isotopes. Polymer chemistry can be determined in solution or in the solid state. Figure 14 shows a ^{13}C NMR spectrum of a polyurethane with a table assigning the peaks to specific chemical groups. NMR is also used in a number of more specialized applications relating to local motions and intermolecular interactions of polymers.

Wide-angle X-ray scattering (WAXS) techniques are useful for probing the local structure of a semicrystalline polymeric solid. Under appropriate conditions, crystalline materials diffract X-rays, giving rise to spots or rings. According to Bragg's law, these can be interpreted as interplanar spacings. The interplanar spacings can be used without further manipulation or the data can be fit to a model such as a disordered helix or an extended chain. The crystalline chain conformation and atomic placements can then be accurately inferred.

Small-angle X-ray scattering (SAXS) is used in determining the structure of many multiphase materials. This technique requires an electron density difference to be present between two components in the solid and has been widely applied to morphological studies of copolymers and ionomers. It can probe features of 10–1000 Å in size. With appropriate modeling of the data, SAXS can give detailed structural information unavailable with other techniques.

Electron microscopy of thin sections of a polymeric solid can also give direct morphological data on a polymer of interest, assuming that (1) the polymer possesses sufficient electron density contrast or can be appropriately stained without changing the morphology and (2) the structures of interest are sufficiently large.

Mechanical and Thermal Property Studies

In stress-strain or tensile testing, a dog-bone-shaped polymer sample is subjected to a constant elongation, or strain, rate, and the force required to maintain the constant elongation rate is monitored. As discussed earlier, tensile testing gives information about modulus, yield point, and ultimate strength of the sample of interest.

Dynamic mechanical analysis (DMA) provides information about the small deformation behavior of polymers. Samples are subjected to cyclic deformation at a fixed frequency in the range of 1–1000 Hz. The stress response is measured while the cyclic strain is applied and the temperature is slowly increased (typically at 2–3 degrees/min). If the strain is a sinusoidal function of time given by:

$$\varepsilon(\omega) = \varepsilon_o \sin(\omega t) \quad (7)$$

where ε is the time-dependent strain, ε_o is the strain amplitude, ω is the frequency of oscillation, and t is time, the resulting stress can be expressed by:

$$\sigma(\omega) = \sigma_o \sin(\omega t + \delta) \quad (8)$$

where σ is the time-dependent stress, σ_o is the amplitude of stress response, and δ is the phase angle between stress and strain. For Hookean solids, the stress and strain are completely in phase ($\delta = 0$), while for purely viscous liquids, the stress response lags by 90° . Real materials demonstrate viscoelastic behavior where δ has a value between 0° and 90° .

A typical plot of $\tan \delta$ versus temperature will display maxima at T_g and at lower temperatures where small-scale motions (secondary relaxations) can occur. Additional peaks above T_g , corresponding to motions in the crystalline phase and melting, are seen in semicrystalline materials. DMA is a sensitive tool for characterizing polymers of similar chemical composition or for detecting the presence of moderate quantities of additives.

Differential scanning calorimetry is another method for probing thermal transitions of polymers. A sample cell and a reference cell are supplied energy at varying rates so that the temperatures of the two cells remain equal. The temperature is increased, typically at a rate of 10–20 degrees/min over the range of interest, and the energy input required to maintain equality of temperature in the two cells is recorded. Plots of energy supplied versus average temperature allow determination of T_g , crystallization temperature (T_c), and T_m . T_g is taken as the temperature at which one half the change in heat capacity, ΔC_p , has occurred. The T_c and T_m are easily identified, as shown in Fig. 15. The areas under the peaks can be quantitatively related to enthalpic changes.

Surface Characterization

Surface characteristics of polymers for biomedical applications are critically important. The surface composition is inevitably different from the bulk, and the surface of the material is generally all that is contacted by the body. The main surface characterization techniques for polymers are X-ray photoelectron spectroscopy (XPS), contact angle measurements, attenuated total reflectance Fourier transform infrared (ATR-FTIR) spectroscopy, and scanning electron microscopy (SEM). The techniques are discussed in detail in Chapter 1.4.

FIG. 15. Differential scanning calorimetry thermogram of a semicrystalline polymer, showing the glass transition temperature (T_g), the crystallization temperature (T_c), and the melting temperature (T_m) of the polymer sample.

FABRICATION AND PROCESSING

Before a polymer can be employed usefully in a medical device, the material must be manipulated physically, thermally, or mechanically into the desired shape. This can be achieved using the high-molecular-weight polymer at the start of the process and may require additives in the material to aid processing, or the end use. Such additives can include antioxidants, UV stabilizers, reinforcing fillers, lubricants, mold release agents, and plasticizers.

Alternatively, polymer products can be fabricated into end-use shapes starting from the monomers or low-molecular-weight prepolymers. In such processes, the final polymerization step is carried out once the precursors are in a casting or molding device, yielding a solid, shaped end product. A typical example is PMMA dental or bone cement, which is cured *in situ* in the body. Polymers can be fabricated into sheets, films, rods, tubes, and fibers, as coatings on another substrate, and into more complex geometries and foams.

It is important to realize that the presence of processing and functional aids can affect other properties of a polymer. For example, plasticisers are added to rigid PVC to produce a softer material, e.g., for use as dialysis tubing and blood storage bags. But additives such as plasticizers and mold release agents may alter the surface properties of the material, where the tissues come into contact with the polymer, and may also be extracted into body fluids.

Prior to use, materials must also be sterilized. Agents used to reduce the chances of clinical infection include, steam, dry heat, chemicals, and irradiation. Exposing polymers to heat or ionizing radiation may affect the properties of the polymer, by chain scission or creating cross-links. Chemical agents such as ethylene oxide may also be absorbed by a material and later could be released into the body. Therefore, devices sterilized with ethylene oxide require a period of time following sterilization for any residues to be released before use.

POLYMERIC BIOMATERIALS

PMMA is a hydrophobic, linear chain polymer that is transparent, amorphous, and glassy at room temperature and may be more easily recognized by such trade names as Lucite or Plexiglas. It is a major ingredient in bone cement for orthopedic implants. In addition to toughness and stability, it has excellent light transmittance, making it a good material for intraocular lenses (IOLs) and hard contact lenses. The monomers are polymerized in the shape of a rod from which buttons are cut. The button or disk is then mounted on a lathe, and the posterior and anterior surfaces machined to produce a lens with defined optical power. Lenses can also be fabricated by melt processing, compression molding, or casting, but lathe machining methods are most commonly used.

Soft contact lenses are made from the same methacrylate family of polymers. The substitution of the methyl ester group in methylmethacrylate with a hydroxyethyl group (2-hydroxyethyl methacrylate or HEMA) produces a very hydrophilic polymer. For soft contact lenses, the poly(HEMA) is slightly cross-linked with ethylene glycol dimethacrylate (EGDMA) to retain dimensional stability for its use as a lens. Fully hydrated, it is a swollen hydrogel. PHEMA is glassy when dried, and therefore, soft lenses are manufactured in the same way as hard lenses; however, for the soft lens a swelling factor must be included when defining the optical specifications. This class of hydrogel polymers is discussed in more detail in Chapter 2.5.

Polyacrylamide is another hydrogel polymer that is used in biomedical separations (e.g., polyacrylamide gel electrophoresis, or PAGE). The mechanical properties and the degree of swelling can be controlled by cross-linking with methylene-bis-acrylamide (MBA). Poly(*N*-alkylacrylamides) are environmentally sensitive, and the degree of swelling can be altered by changes in temperature and acidity. These polymers are discussed in more detail in Chapters 2.6 and 7.14; see also Hoffman (1997).

Polyacrylic acids also have applications in medicine. They are used as dental cements, e.g., as glass ionomers. In this use, they are usually mixed with inorganic salts, where the cation interacts with the carboxyl groups of the acid to form physical cross-links. Polyacrylic acid is also used in a covalently cross-linked form as a mucoadhesive additive to mucosal drug delivery formulations (See Chapter 7.14). Polymethacrylic acid may also be incorporated in small quantities into contact lens polymer formulations to improve wettability.

PE is used in its high-density form in biomedical applications because low-density material cannot withstand sterilization temperatures. It is used as tubing for drains and catheters, and in ultrahigh-MW form as the acetabular component in artificial hips and other prosthetic joints. The material has good toughness and wear resistance and is also resistant to lipid absorption. Radiation sterilization in an inert atmosphere may also provide some covalent cross-linking that strengthens the PE.

PP is an isotactic crystalline polymer with high rigidity, good chemical resistance, and good tensile strength. Its stress cracking resistance is excellent, and it is used for sutures and hernia repair.

PTFE, also known as PTFE Teflon, has the same structure as PE, except that the four hydrogens in the repeat unit of PE are replaced by fluorines. PTFE is a very high melting polymer ($T_m = 327^\circ\text{C}$) and as a result it is very difficult to process. It is very hydrophobic, has excellent lubricity, and is used to make catheters. In microporous form, known generically as e-PTFE or most commonly as the commercial product Gore-Tex, it is used in vascular grafts. Because of its low friction, it was the original choice by Dr. John Charnley for the acetabular component of the first hip joint prosthesis, but it failed because of its low wear resistance and the resultant inflammation caused by the PTFE wear particles.

PVC is used mainly as tubing and blood storage bags in biomedical applications. Typical tubing uses include blood transfusion, feeding, and dialysis. Pure PVC is a hard, brittle material, but with the addition of plasticizers, it can be made flexible and soft. PVC can pose problems for long-term applications because the plasticizers can be extracted by the body. While these plasticizers have low toxicities, their loss also makes the PVC less flexible.

Poly(dimethyl siloxane) (PDMS) or SR is an extremely versatile polymer, although its use is often limited by its relatively poor mechanical strength. It is unique in that it has a silicon-oxygen backbone instead of a carbon backbone. Its properties are less temperature sensitive than other rubbers because of its very low T_g . In order to improve mechanical properties, SR is usually formulated with reinforcing silica filler, and sometimes the polysiloxane backbone is also modified with aromatic rings that can toughen it. Because of its excellent flexibility and stability, SR is used in a variety of prostheses such as finger joints, heart valves, and breast implants, and in ear, chin, and nose reconstruction. It is also used as catheter and drainage tubing and in insulation for pacemaker leads. It has also been used in membrane oxygenators because of its high oxygen permeability, although porous polypropylene or polysulfone polymers have recently become more used as oxygenator membranes. Silicones are so important in medicine that details on their chemistry are provided in Chapter 2.3 and their medical applications are discussed in Chapter 7.19.

PET is one of the highest volume polymeric biomaterials. It is a polyester, containing rigid aromatic rings in a "regular" polymer backbone, which produces a high-melting ($T_m = 267^\circ\text{C}$) crystalline polymer with very high tensile strength. It may be fabricated in the forms of knit, velour, or woven fabrics and fabric tubes, and also as nonwoven felts. Dacron is a common commercial form of PET used in large-diameter knit, velour, or woven arterial grafts. Other uses of PET fabrics are for the fixation of implants and hernia repair. PET can also be used in ligament reconstruction and as a reinforcing fabric for tissue reconstruction with soft polymers such as SR. It is used in a nonwoven felt coating on the peritoneal dialysis shunt (where it enters the body and traverses the skin) to enhance ingrowth and thereby reduce the possibility of infection.

PEG is used in drug delivery as conjugates with low solubility drugs and with immunogenic or fairly unstable protein drugs, to enhance the circulation times and stabilities of the drugs. It is also used as PEG-phospholipid conjugates to enhance the stability and circulation time of drug-containing

liposomes. In both cases it serves to “hide” the circulating drug system from immune recognition, especially in the liver (See Chapter 7.14). PEG has also been immobilized on polymeric biomaterial surfaces to make them “nonfouling.” PEGs usually exist in a highly hydrated state on the polymer surfaces, where they can exhibit steric repulsion based on an osmotic or entropic mechanism. This phenomenon contributes to the protein- and cell-resistant properties of surfaces containing PEGs (See Chapter 2.13).

Regenerated cellulose, for many years, was the most widely used dialysis membrane. Derivatives of cellulose, such as cellulose acetate (CA), are also used, since CA can be melt processed as hollow fibers for the hollow fiber kidney dialyser. CA is also used in osmotic drug delivery devices (See Chapter 7.14).

Polymerization of bisphenol A and phosgene produces polycarbonate, a clear, tough material. Its high impact strength dictates its use as lenses for eyeglasses and safety glasses, and housings for oxygenators and heart–lung bypass machine. Polycarbonate macrodiols have also been used to prepare copolymers such as polyurethanes. Polycarbonate segments may confer enhanced biological stability to a material.

Nylon is the name originally given by Du Pont to a family of polyamides; the name is now generic, and many other companies make nylons. Nylons are formed by the reaction of diamines with dibasic acids or by the ring opening polymerization of lactams. Nylons are used as surgical sutures (see also Chapter 2.4).

Biodegradable Polymers

PLGA is a random copolymer used in resorbable surgical sutures, drug delivery systems, and orthopedic appliances such as fixation devices. The degradation products are endogenous compounds (lactic and glycolic acids) and as such are nontoxic. PLGA polymerization occurs via a ring-opening reaction of a glycolide and a lactide, as illustrated in Fig. 6. The presence of ester linkages in the polymer backbone allows gradual hydrolytic degradation (resorption). The rate of degradation can be controlled by the ratio of polyglycolic acid to polylactic acid (See Chapter 7.14).

Copolymers

Copolymers are another important class of biomedical materials. A copolymer of tetrafluoroethylene with a small amount of hexafluoropropylene (FEP Teflon) is used as a tubing connector and catheter. FEP has a crystalline melting point near 265°C compared with 327°C for PTFE. This enhances the processability of FEP compared with PTFE while maintaining the excellent chemical inertness and low friction characteristic of PTFE.

Polyurethanes are block copolymers containing “hard” and “soft” blocks. The “hard” blocks, having T_g values above room temperature and acting as glassy or semicrystalline reinforcing blocks, are composed of a diisocyanate and a chain extender. The diisocyanates most commonly used are 2,4-toluene diisocyanate (TDI) and methylene

di(4-phenyl isocyanate) (MDI), with MDI being used in most biomaterials. The chain extenders are usually shorter aliphatic glycol or diamine materials with two to six carbon atoms. The “soft” blocks in polyurethanes are typically polyether or polyester polyols whose T_g values are much lower than room temperature, allowing them to give a rubbery character to the materials. Polyether polyols are more commonly used for implantable devices because they are stable to hydrolysis. The polyol molecular weights tend to be on the order of 1000 to 2000.

Polyurethanes are tough elastomers with good fatigue and blood-containing properties. They are used in pacemaker lead insulation, catheters, vascular grafts, heart assist balloon pumps, artificial heart bladders, and wound dressings.

FINAL REMARKS

The chemistry, physics, and mechanics of polymeric materials are highly relevant to the performance of many devices employed in the clinic today. Polymers represent a broad, diverse family of materials, with mechanical properties that make them useful in applications relating to both soft and hard tissues. The presence of functional groups on the backbone or side chains of a polymer also means that they are readily modified chemically or biochemically, especially at their surfaces. Many researchers have successfully altered the chemical and biological properties of polymers, by immobilizing anticoagulants such as heparin, proteins such as albumin for passivation and fibronectin for cell adhesion, and cell-receptor peptide ligands to enhance cell adhesion, greatly expanding their range of applications (See Chapter 2.16).

2.3 SILICONE BIOMATERIALS: HISTORY AND CHEMISTRY

André Colas and Jim Curtis

CHEMICAL STRUCTURE AND NOMENCLATURE

Silicones are a general category of synthetic polymers whose backbone is made of repeating silicon to oxygen bonds. In addition to their links to oxygen to form the polymeric chain, the silicon atoms are also bonded to organic groups, typically methyl groups. This is the basis for the name “silicones,” which was assigned by Kipping based on their similarity with ketones, because in most cases, there is on average one silicone atom for one oxygen and two methyl groups (Kipping, 1904). Later, as these materials and their applications flourished, more specific nomenclature was developed. The basic repeating unit became known as “siloxane” and the most common silicone is polydimethylsiloxane, abbreviated as PDMS.

Many other groups, e.g., phenyl, vinyl and trifluoropropyl, can be substituted for the methyl groups along the chain. The simultaneous presence of “organic” groups attached to an “inorganic” backbone gives silicones a combination of unique properties, making possible their use as fluids, emulsions, compounds, resins, and elastomers in numerous applications and diverse fields. For example, silicones are common in the aerospace industry, due principally to their low and high temperature performance. In the electronics field, silicones are used as electrical insulation, potting compounds and other applications specific to semiconductor manufacture. Their long-term durability has made silicone sealants, adhesives and waterproof coatings commonplace in the construction industry. Their excellent biocompatibility makes many silicones well suited for use in numerous personal care, pharmaceutical, and medical device applications.

Historical Milestones in Silicone Chemistry

Key milestones in the development of silicone chemistry—thoroughly described elsewhere by Lane and Burns (1996), Rochow (1987), and Noll (1968)—are summarized in Table 1.

Nomenclature

The most common silicones are the polydimethylsiloxanes trimethylsilyloxy terminated, with the following structure:

These are linear polymers and liquids, even for large values of n . The main chain unit, $-(\text{Si}(\text{CH}_3)_2\text{O})_n-$, is often represented by the letter D because, as the silicon atom is connected with two oxygen atoms, this unit is capable of expanding within the polymer in two directions. M, T and Q units are defined in a similar manner, as shown in Table 2.

The system is sometimes modified by the use of superscript letters designating nonmethyl substituents, for example, $\text{D}^{\text{H}} = \text{H}(\text{CH}_3)\text{SiO}_{2/2}$ and $\text{M}^{\text{P}} = \text{M}^{\text{Ph}} = (\text{CH}_3)_2(\text{C}_6\text{H}_5)\text{SiO}_{1/2}$ (Smith, 1991). Further examples are shown in Table 3.

Preparation

Silicone Polymers

The modern synthesis of silicone polymers is multifaceted. It usually involves the four basic steps described in Table 4. Only step 4 in this table will be elaborated upon here.

Polymerization and Polycondensation. The linear [4] and cyclic [5] oligomers resulting from dimethyldichlorosilane hydrolysis have chain lengths too short for most applications. The cyclics must be polymerized, and the linears condensed, to give macromolecules of sufficient length (Noll, 1968).

Catalyzed by acids or bases, cyclosiloxanes $(\text{R}_2\text{SiO})_m$ are ring-opened and polymerized to form long linear chains.

TABLE 1 Key Milestones in the Development of Silicone Chemistry

1824	Berzelius discovers silicon by the reduction of potassium fluorosilicate with potassium: $4\text{K} + \text{K}_2\text{SiF}_6 \rightarrow \text{Si} + 6\text{KF}$. Reacting silicon with chlorine gives a volatile compound later identified as tetrachlorosilane, SiCl_4 : $\text{Si} + 2\text{Cl}_2 \rightarrow \text{SiCl}_4$.
1863	Friedel and Craft synthesize the first silicon organic compound, tetraethylsilane: $2\text{Zn}(\text{C}_2\text{H}_5)_2 + \text{SiCl}_4 \rightarrow \text{Si}(\text{C}_2\text{H}_5)_4 + 2\text{ZnCl}_2$.
1871	Ladenburg observes that diethyldioxyasilane, $(\text{C}_2\text{H}_5)_2\text{Si}(\text{OC}_2\text{H}_5)_2$, in the presence of a diluted acid gives an oil that decomposes only at a “very high temperature.”
1901–1930s	Kipping lays the foundation of organosilicon chemistry with the preparation of various silanes by means of Grignard reactions and the hydrolysis of chlorosilanes to yield “large molecules.” The polymeric nature of the silicones is confirmed by the work of Stock.
1940s	In the 1940s, silicones become commercial materials after Hyde of Dow Corning demonstrates the thermal stability and high electrical resistance of silicone resins, and Rochow of General Electric finds a direct method to prepare silicones from silicon and methylchloride.

TABLE 4 The Basic Steps in Silicone Polymer Synthesis

1. Silica reduction to silicon	$\text{SiO}_2 + 2\text{C} \rightarrow \text{Si} + 2\text{CO}$
2. Chlorosilanes synthesis	$\text{Si} + 2\text{CH}_3\text{Cl} \rightarrow (\text{CH}_3)_2\text{SiCl}_2 + \text{CH}_3\text{SiCl}_3 + (\text{CH}_3)_3\text{SiCl} + \text{CH}_3\text{HSiCl}_2 + \dots$ [1] [2] [3]
3. Chlorosilanes hydrolysis	$\text{Cl} - \begin{array}{c} \text{CH}_3 \\ \\ \text{Si} - \text{Cl} \\ \\ \text{CH}_3 \end{array} + 2\text{H}_2\text{O} \rightarrow \text{HO} - \left(\begin{array}{c} \text{CH}_3 \\ \\ \text{Si} - \text{O} - \\ \\ \text{CH}_3 \end{array} \right)_x - \text{H} + \left(\begin{array}{c} \text{CH}_3 \\ \\ \text{Si} - \text{O} \\ \\ \text{CH}_3 \end{array} \right)_{3,4,5} + \text{HCl}$ [1] [4] [5]
4. Polymerization and polycondensation	$\left(\begin{array}{c} \text{CH}_3 \\ \\ \text{Si} - \text{O} \\ \\ \text{CH}_3 \end{array} \right)_{3,4,5} \rightarrow \left(\begin{array}{c} \text{CH}_3 \\ \\ \text{Si} - \text{O} - \\ \\ \text{CH}_3 \end{array} \right)_y$ [5] [4] $\text{HO} - \left(\begin{array}{c} \text{CH}_3 \\ \\ \text{Si} - \text{O} - \\ \\ \text{CH}_3 \end{array} \right)_x - \text{H} \rightarrow \left(\begin{array}{c} \text{CH}_3 \\ \\ \text{Si} - \text{O} - \\ \\ \text{CH}_3 \end{array} \right)_z + z\text{H}_2\text{O}$ [4]

In this way, catalyst neutralization or filtration can be avoided (Noll, 1968).

The cyclic trimer $(\text{Me}_2\text{SiO})_3$ has an internal ring tension and can be polymerized without reequilibration of the resulting polymers. With this cyclic, polymers with narrow molecular-weight distribution can be prepared, but also polymers only carrying one terminal reactive function (living polymerization). Starting from a mixture of different “tense” cyclics also allows the preparation of block or sequential polymers (Noll, 1968).

Linears can combine when catalyzed by many acids or bases to give long chains by intermolecular condensation of silanol terminals (Noll, 1968; Stark *et al.*, 1982).

A distribution of chain lengths is obtained. Longer chains are favored when working under vacuum and/or at elevated temperatures to reduce the residual water concentration. In addition to the polymers described above, reactive polymers can also be prepared. This can be achieved when reequilibrating oligomers or existing polymers to obtain a polydimethylmethylhydrogenosiloxane, $\text{MD}_z\text{D}_w^{\text{HM}}$.

[6]

Additional functional groups can be attached to this polymer using an addition reaction.

The polymers shown are all linear or cyclic, comprising difunctional units, D. In addition to these, branched polymers or resins can be prepared if, during hydrolysis, a certain amount of T or Q units are included, which will allow molecular expansion, in three or four directions, as opposed to just two. For example, consider the hydrolysis of methyltrichlorosilane in the presence of trimethylchlorosilane, which leads to a branched polymer as shown next:

The resulting polymer can be described as $(\text{Me}_3\text{SiO}_{1/2})_x$ $(\text{MeSiO}_{3/2})_y$ or M_xT_y , using shorthand notation. The formation of three silanols on the MeSiCl_3 by hydrolysis yields a three-dimensional structure or resin, rather than a linear polymer. The average molecular weight depends upon the number of M units that come from the trimethylchlorosilane, which limits the growth of the resin molecule. Most of these resins are prepared in a solvent and usually contain some residual hydroxyl groups. These could subsequently be used to cross-link the resin and form a continuous network.

Silicone Elastomers

Silicone polymers can be easily transformed into a three-dimensional network by way of a cross-linking reaction, which allows the formation of chemical bonds between adjacent chains. The majority of silicone elastomers are cross-linked according to one of the following three reactions.

1. Cross-Linking with Radicals Efficient cross-linking with radicals is only achieved when some vinyl groups are present on the polymer chains. The following mechanism has been proposed for the cross-linking reaction associated with radicals generated from an organic peroxide (Stark, 1982):

where \equiv represents two methyl groups and the rest of the polymer chain.

This reaction has been used for high-consistency silicone rubbers (HCRs) such as those used in extrusion or injection molding, as well as those that are cross-linked at elevated temperatures. The peroxide is added before processing. During cure, some precautions are needed to avoid the formation of voids by the peroxide's volatile residues. Postcure may also be necessary to remove these volatiles, which can catalyze depolymerization at high temperatures.

2. Cross-Linking by Condensation Although mostly used in silicone caulks and sealants for the construction industry and do-it-yourselfer, this method has also found utility for medical devices as silicone adhesives facilitating the adherence of materials to silicone elastomers, as an encapsulant and as sealants such as around the connection of a pacemaker lead to the pulse generator (Fig. 1 shows Silastic Medical Adhesive, type A).

These products are ready to apply and require no mixing. Cross-linking starts when the product is squeezed from the cartridge or tube and comes into contact with moisture,

FIG. 1. RTV silicone adhesive.

typically from humidity in the ambient air. These materials are formulated from a reactive polymer prepared from a hydroxy end-blocked polydimethylsiloxane and a large excess of methyltriacetoxysilane.

where $\text{Ac} = \text{---C} = \text{O}$

Because a large excess of silane is used, the probability of two different chains reacting with the same silane molecule is remote. Consequently, all the chains are end-blocked with two acetoxy functional groups. The resulting product is still liquid and can be packaged in sealed tubes and cartridges. Upon opening the acetoxy groups are hydrolyzed by the ambient moisture to give silanols, which allow further condensation to occur.

In this way, two chains have been linked, and the reaction will proceed further from the remaining acetoxy groups. An organometallic tin catalyst is normally used. The cross-linking reaction requires moisture to diffuse into the material. Accordingly cure will proceed from the outside surface inward. These materials are called one-part RTV (room temperature vulcanization) sealants, but actually require moisture as a second component. Acetic acid is released as a by-product of the reaction. Problems resulting from the acid can be overcome using other cure (cross-linking) systems that have been developed by replacing the acetoxy silane $\text{RSi}(\text{OAc})_3$ with oximosilane $\text{RSi}(\text{ON}=\text{CR}'_2)_3$ or alkoxy silane $\text{RSi}(\text{OR}')_3$.

Condensation curing is also used in some two-part systems where cross-linking starts upon mixing the two components, e.g., a hydroxy end-blocked polymer and an alkoxy silane such as tetra-*n*-propoxysilane (Noll, 1968):

Here, no atmospheric moisture is needed. Usually an organotin salt is used as catalyst, but it also limits the stability of the resulting elastomer at high temperatures. Alcohol is released as a by-product of the reaction, leading to a slight shrinkage upon cure (0.5 to 1% linear shrinkage). Silicones with this cure system are therefore not suitable for the fabrication of parts with precise tolerances.

3. Cross-linking by Addition Use of an addition-cure reaction for cross-linking can eliminate the shrinkage problem

mentioned above. In addition cure, cross-linking is achieved by reacting vinyl endblocked polymers with Si-H groups carried by a functional oligomer such as described above [6]. A few polymers can be bonded to this functional oligomer [6], as follows (Stark, 1982):

where \equiv represents the remaining valences of the Si in [6].

The addition occurs mainly on the terminal carbon and is catalyzed by Pt or Rh metal complexes, preferably as organometallic compounds to enhance their compatibility. The following mechanism has been proposed (oxidative addition of the $\equiv\text{Si}$ to the Pt, H transfer to the double bond, and reductive elimination of the product):

where, to simplify, other Pt ligands and other Si substituents are omitted.

There are no by-products with this reaction. Molded pieces made with silicone using this addition-cure mechanism are very accurate (no shrinkage). However, handling these two-part products (i.e., polymer and Pt catalyst in one component, SiH oligomer in the other) requires some precautions. The Pt in the complex is easily bonded to electron-donating substances such as amine or organosulfur compounds to form stable complexes with these "poisons," rendering the catalyst inactive and inhibiting the cure.

The preferred cure system can vary by application. For example, silicone-to-silicone medical adhesives use acetoxy cure (condensation cross-linking), and platinum cure (cross-linking by addition) is used for precise silicone parts with no by-products.

4. Elastomer Filler In addition to the silicone polymers described above, the majority of silicone elastomers incorporate "filler." Besides acting as a material extender, as the name implies, filler acts to reinforce the cross-linked matrix. The strength of silicone polymers without filler is generally unsatisfactory for most applications (Noll, 1968). Like most other noncrystallizing synthetic elastomers, the addition of reinforcing fillers reduces silicone's stickiness, increases its hardness and enhances its mechanical strength. Fillers might also be employed to affect other properties; for example, carbon black is added for electrical conductivity, titanium dioxide improves the dielectric constant, and barium sulfate increases radiopacity. These and other materials are used to pigment the

otherwise colorless elastomer; however, care must be taken to select only pigments suitable for the processing temperatures and end-use application.

Generally, the most favorable reinforcement is obtained using fumed silica, such as Cab-O-Sil, Aerosil, or Wacker HDK. Fumed silica is produced by the hydrolysis of silicon tetrachloride vapor in a hydrogen flame:

Unlike many naturally occurring forms of crystalline silica, fumed silica is amorphous. The very small spheroid silica particles (on the order of 10 nm diameter) fuse irreversibly while still semimolten, creating aggregates. When cool, these aggregates become physically entangled to form agglomerates. Silica produced in this way possesses remarkably high surface area, 100 to 400 m²/g as measured by the BET method developed by Brunauer, Emmett, and Teller (Brunauer *et al.*, 1938; Noll, 1968; Cabot Corporation, 1990).

The incorporation of silica filler into silicone polymers is called “compounding.” This is accomplished prior to cross-linking, by mixing the silica into the silicone polymers on a two-roll mill, in a twin-screw extruder, or in a Z-blade mixer capable of processing materials with this rheology.

Reinforcement occurs with polymer adsorption encouraged by the silica’s large surface area and when hydroxyl groups on the filler’s surface lead to hydrogen bonds between the filler and the silicone polymer, thereby contributing to the production of silicone rubbers with high tensile strength and elongation capability (Lynch, 1978). The addition of filler increases the polymer’s already high viscosity. Chemical treatment of the silica filler with silanes further enhances its incorporation in, and reinforcement of, the silicone elastomer, resulting in increased material strength and tear resistance (Lane and Burns, 1996) (Fig. 2).

Silicone elastomers for medical applications normally utilize only fillers of fumed silica, and occasionally appropriate pigments or barium sulfate. Because of their low glass transition temperature, these compounded and cured silicone materials are elastomeric at room and body temperatures without the use of any plasticizers—unlike other medical materials such as PVC, which might contain phthalate additives.

FIG. 2. Silicone elastomer matrix.

Physicochemical Properties

Silicon’s position just under carbon in the periodic table led to a belief in the existence of analog compounds where silicon would replace carbon. Most of these analog compounds do not exist, or behave very differently. There are few similarities between Si–X bonds in silicones and C–X bonds (Corey, 1989; Hardman, 1989; Lane and Burns, 1996; Stark, 1982).

Between any given element and Si, bond lengths are longer than for C with this element. The lower electronegativity of silicon ($\chi^{\text{Si}} \approx 1.80$, $\chi^{\text{C}} \approx 2.55$) leads to more polar bonds compared to carbon. This bond polarity also contributes to strong silicon bonding; for example, the Si–O bond is highly ionic and has large bond energy. To some extent, these values explain the stability of silicones. The Si–O bond is highly resistant to homolytic scission. On the other hand, heterolytic scissions are easy, as demonstrated by the reequilibration reactions occurring during polymerizations catalyzed by acids or bases (see earlier discussion).

Silicones exhibit the unusual combination of an inorganic chain similar to silicates and often associated with high surface energy, but with side methyl groups that are very organic and often associated with low surface energy (Owen, 1981). The Si–O bonds are quite polar and without protection would lead to strong intermolecular interactions (Stark, 1982). Yet, the methyl groups, only weakly interacting with each other, shield the main chain (see Fig. 3).

FIG. 3. Three-dimensional representation of dodecamethylpentasiloxane, Me₃SiO-(SiMe₂O)₃SiMe₃ or MD₃M. (Courtesy S. Grigoras, Dow Corning.)

This is made easier by the high flexibility of the siloxane chain. Barriers to rotation are low and the siloxane chain can adopt many configurations. Rotation energy around a $\text{H}_2\text{C}-\text{CH}_2$ bond in polyethylene is 13.8 kJ/mol but only 3.3 kJ/mol around a $\text{Me}_2\text{Si}-\text{O}$ bond, corresponding to a nearly free rotation. In general, the siloxane chain adopts a configuration such that the chain exposes a maximum number of methyl groups to the outside, whereas in hydrocarbon polymers, the relative rigidity of the polymer backbone does not allow a "selective" exposure of the most organic or hydrophobic methyl groups. Chain-to-chain interactions are low, and the distance between adjacent chains is also greater in silicones. Despite a very polar chain, silicones can be compared to paraffin, with a low critical surface tension of wetting (Owen, 1981).

The surface activity of silicones is evident in many ways (Owen, 1981):

- The polydimethylsiloxanes have a low surface tension (20.4 mN/m) and are capable of wetting most surfaces. With the methyl groups pointing to the outside, this gives very hydrophobic films and a surface with good release properties, particularly if the film is cured after application. Silicone surface tension is also in the most promising range considered for biocompatible elastomers (20 to 30 mN/m).
- Silicones have a critical surface tension of wetting (24 mN/m) higher than their own surface tension. This means that silicones are capable of wetting themselves, which promotes good film formation and good surface covering.
- Silicone organic copolymers can be prepared with surfactant properties, with the silicone as the hydrophobic part, e.g., in silicone glycols copolymers.

The low intermolecular interactions in silicones have other consequences (Owen, 1981):

- Glass transition temperatures are very low, e.g., 146 K for a polydimethylsiloxane compared to 200 K for polyisobutylene, the analog hydrocarbon.
- The presence of a high free volume compared to hydrocarbons explains the high solubility and high diffusion coefficient of gas into silicones. Silicones have a high permeability to oxygen, nitrogen, or water vapor, even though liquid water is not capable of wetting a silicone surface. As expected, silicone compressibility is also high.
- The viscous movement activation energy is very low for silicones, and their viscosity is less dependent on temperature compared to hydrocarbon polymers. Furthermore, chain entanglements are involved at higher temperature and contribute to limit the viscosity reduction (Stark, 1982).

CONCLUSION

Polydimethylsiloxanes are often referred to as silicones. They are used in many applications because of their stability, low surface tension, and lack of toxicity. Methyl group substitution or introduction of tri- or tetra-functional siloxane units leads to a wide range of structures. Polymers are easily

cross-linked at room or elevated temperature to elastomers, without losing the above properties.

2.4 MEDICAL FIBERS AND BIOTEXTILES

Steven Weinberg and Martin W. King

The term "medical textiles" encompasses medical products and devices ranging from wound dressings and bandages to high-technology applications such as biotextiles, tissue engineered scaffolds, and vascular implants (King, 1991). The use of textiles in medicine goes back to the Egyptians and the Native Americans who used textiles as bandages to cover and draw wound edges together after injury (Shalaby, 1985). Over the past several decades, the use of fibers and textiles in medicine has grown dramatically as new and innovative fibers, structures, and therapies have been developed. Advances in fabrication techniques, fiber technology, and composition have led to numerous new concepts for both products and therapies, some of which are still in development or in clinical trials. In this chapter, an introduction to fiber and textile fabric technology will be presented along with discussion of

TABLE 1 Textile Structures and Applications (Ko, 1990)

Application	Material	Yarn structure	Fabric structure
Arteries	Dacron T56	Textured	Weft/warp knit
	Teflon	Multifilament	Straight/ bifurcations Woven/non-woven
Tendons	Dacron T56 Dacron T55 Kevlar	Low-twist filament Multifilament	Coated woven tape
Hernia repair	Polypropylene	Monofilament	Tricot knit
Esophagus	Regenerated collagen	Monofilament	Plain weave Knit
Patches	Dacron T56	Monofilament Multifilament	Woven Knit/knit velour
Sutures	Polyester	Monofilament	Braid
	Nylon	Multifilament	Woven tapes
	Regenerated collagen		
	Silk		
Ligaments	Polyester	Monofilament	Braid

Bones and joints	Carbon in thermoset or thermoplastic Matrix	Monofilament	Woven tapes Knits/braids

both old and new application areas. Traditional and nontraditional fiber and fabric constructions, processing issues, and fabric testing will be included in order to offer an overview of the technology associated with the use of textiles in medicine. Table 1 illustrates some of the more common application areas for textiles in medicine. As can be seen from this table, the products range from the simplest products (i.e., gauze bandages) to the most complex textile products such as vascular grafts and tissue scaffolds.

MEDICAL FIBERS

All textile-based medical devices are composed of structures fabricated from monofilament; multifilaments; or staple fibers formulated from synthetic polymers, natural polymers (biopolymers), or genetically engineered polymers. When choosing the appropriate fiber configuration and polymer for a specific application, consideration must be given to the device design requirements and the manner in which the fiber is to be used. For example, collagen-based implantable hemostatic wound dressings are available in multiple configurations including loose powder (Avitine), nonwoven mats (Helistat and Surgicel Fibrillar Hemostat), and knitted collagen fibrils (Surgicel Nu-Knit). In addition, other materials are also available for the same purpose (e.g., Surgicel Absorbable Hemostat is knitted from regenerated cellulose). Fibers can be fabricated from nonabsorbable synthetic polymers such as

poly(ethylene terephthalate) or polyester (e.g., Dacron) and polytetrafluoroethylene (e.g., Teflon), or absorbable synthetic materials such as polylactide (PLA) and polyglycolide (PGA) (Hoffman, 1977). Natural materials (biopolymers), such as collagen or polysaccharides like alginates, have also been used to fabricate medical devices (Keys, 1996). And there are recent reports that biomimetic polymers have been synthesized in experimental quantities by genetic engineering of peptide sequences from elastin, collagen, and spider dragline silk protein, and expressed in *Escherichia coli* and yeast using plasmid vectors (Huang, 2000; Teule, 2003).

Cotton was and still is commonly being used for bandages, surgical sponges, drapes, and surgical apparel, and in surgical gowns. In current practice, cotton has been replaced in many applications by coated nonwoven disposable fabrics, especially in cases when nonabsorbency is critical.

It is important to note that most synthetic polymers currently used in medicine were originally developed as commercial polymers for nonmedical applications and usually contain additives such as dyes, delustrants, stabilizers, antioxidants, and antistatic agents. Some of these chemicals may not be desirable for medical applications, and so must be removed prior to use. To illustrate this point, poly(ethylene terephthalate) (PET), formerly Dacron, which at present is the material of choice for most large-caliber textile vascular grafts, was originally developed for apparel use. A complex cleaning process is required before the material can be used in an implant application. Additional reading relating to this point can be found in Goswami *et al.* (1977) and Piller (1973).

Synthetic Fibers

Various synthetic fibers have been used to fabricate medical devices over the past 25 years. Starting in the 1950s, various materials were evaluated for use in vascular grafts, such as Vinyon (PVC copolymer), acrylic polymers, poly(vinyl alcohol), nylon, polytetrafluoroethylene, and polyester (PET) (King, 1983). Today, only PTFE and PET are still used for vascular graft applications since they are reasonably inert, flexible, resilient, durable, and resistant to biological degradation. They have withstood the test of time, whereas other materials have not proven to be durable when used in an implant application. Table 2 shows a partial list of synthetic polymers that have been prepared as fibers, their method of fabrication, and how they are used in the medical field.

Most synthetic fibers are formed either by a melt spinning or a wet spinning process.

Melt Spinning

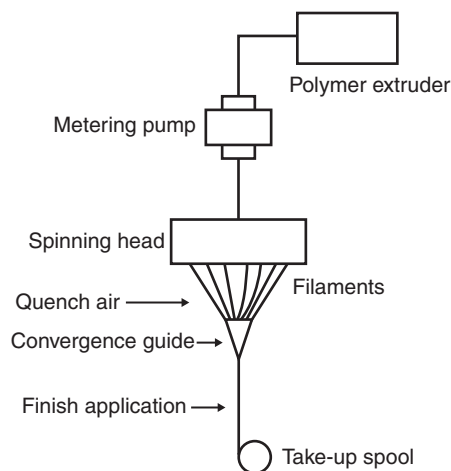

With melt spinning the polymer resin is heated above its melting temperature and extruded through a spinneret. The number of holes in the spinneret defines the number of filaments in the fiber being produced. For example, a spinneret for a monofilament fiber contains one hole, whereas 54 holes are required to produce the 54-multifilament yarn that is commonly used in vascular graft construction. Once the monofilament or multifilament yarn is extruded, it is then drawn and cooled prior to being wound onto spools. The yarn can also be further processed to form the final configuration. For example,

TABLE 2 Synthetic Polymers (Shalaby, 1996)

Type	Chemical and physical aspects	Construction/useful forms	Comments/applications
Polyethylene (PE)	High-density PE (HDPE): melting temperature $T_m = 125^\circ\text{C}$ Low-density PE (LDPE): $T_m = 110^\circ\text{C}$, Linear low-density (LLDPE) Ultrahigh molecular weight PE (UHMWPE) ($T_m = 140\text{--}150^\circ\text{C}$), exceptional tensile strength and modulus	Melt spun into continuous yarns for woven fabric and/or melt blown onto nonwoven fabric Converted to very high tenacity yarn by gel spinning	The HDPE, LDPE and LLDP are used in a broad range of health care products Used experimentally as reinforced fabrics in lightweight orthopedic casts, ligament prostheses, and load-bearing composites
Polypropylene (PP)	Predominantly isotactic, $T_m = 165\text{--}175^\circ\text{C}$; higher fracture toughness than HDPE	Melt spun to monofilaments and melt blown to nonwoven fabrics Hollow fibers	Sutures, hernia repair meshes, surgical drapes, and gowns Plasma filtration
Poly(tetrafluoroethylene) (PTFE)	High melting ($T_m = 325^\circ\text{C}$) and high crystallinity polymer (50–75% for processed material)	Melt extruded	Vascular fabrics, heart valve sewing rings, orthopedic ligaments
Nylon 6	$T_g = 45^\circ\text{C}$, $T_m = 220^\circ\text{C}$, thermoplastic, hydrophilic	Monofilaments, braids	Sutures
Nylon 66	$T_g = 50^\circ\text{C}$, $T_m = 265^\circ\text{C}$, thermoplastic, hydrophilic	Monofilaments, braids	Sutures
Poly(ethylene terephthalate) (PET)	Excellent fiber-forming properties, $T_m = 265^\circ\text{C}$, $T_g = 65\text{--}105^\circ\text{C}$	Multifilament yarn for weaving, knitting, and braiding	Sutures, hernia repair meshes, and vascular grafts

most yarns used for application in vascular grafts are texturized to improve the handling characterizes of the final product. In contrast to flat or untexturized yarn, texturization results in a yarn that imparts bulk to the fabric for improved “hand” or feel, flexibility, ease of handling and suturing, and more pores for tissue ingrowth. Melt spinning is typically used with thermoplastic polymers that are not affected by the elevated temperatures required in the melt spinning process. Figure 1 is a schematic representation of a melt spinning process.

In this process, the molten resin is extruded through the spinning head containing one (monofilament) or multiple

**FIG. 1.** Melt spinning process.

holes (multifilament). Air is typically used to cool and solidify the continuous threadline prior to lubricating, twisting, and winding up on a bobbin.

Wet Spinning

If the polymer system experiences thermal degradation at elevated temperatures, as is the case with a polymer containing a drug, a low-temperature wet solution spinning process can be used. In this process the polymer is dissolved in a solvent and then extruded through a spinneret into a nonsolvent in a spin bath. Because the solvent is soluble in the spin bath, but the polymer is not, the continuous polymer stream precipitates into a solid filament, which is then washed to remove all solvents and nonsolvents, drawn, and dried before winding up (Adanur, 1995). Figure 2 presents a schematic of a typical wet solution spinning process.

Electrospinning

The diameters of fibers spun by melt spinning and wet solution spinning are controlled by the size of the hole in the spinneret and the amount of draw or stretch applied to the filament prior to wind-up. So the diameters of conventional spun fibers fall in a range from about 10 μm for multifilament yarns to 500 μm or thicker for monofilaments. To obtain finer fiber diameters it is necessary to employ alternative spinning technologies such as the bicomponent fiber (BCF) approach (see later section entitled “Hybrid Bicomponent Fibers”), or an electrospinning technique. This method of manufacturing microfibers and nanofibers has been known since 1934 when the first patent was filed (Formhals, 1934). Since then

FIG. 2. Wet solution spinning process.

Freudenberg Inc. has used this process for the commercial production of ultrahigh-efficiency filters (Groitzsch, 1986).

Electrospinning occurs when a polymer solution or melt is exposed to an electrostatic field by the application of a high voltage (5–30 kV), which overcomes the surface tension of the polymer and accelerates fine jets of the liquid polymer towards a grounded target (Reneker *et al.*, 2000). As the polymer jets cool or lose solvent they are drawn in a series of unstable loops, solidified, and collected as an interconnected web of fine fibers on a grounded rotating drum or other specially shaped target (Fig. 3).

The fineness of the fibers produced depends on the polymer chemistry, its solution or melt viscosity, the strength and uniformity of the applied electric field, and the geometry and operating conditions of the spinning system. Fiber diameters in the range of 1 μm down to 100 nm or less have been reported.

In addition to being used to fabricate ultrathin filtration membranes, electrospinning techniques have also been applied to the production of nonwoven mats for wound dressings (Martin *et al.*, 1977), and there is currently much interest in making scaffolds for tissue engineering applications. Nonwoven scaffolds spun from Type I collagen and synthetic polymers such as poly(L-lactide), poly(lactide-co-glycolide), poly(vinyl alcohol), poly(ethylene-co-vinyl acetate), poly(ethylene oxide), polyurethanes, and polycarbonates have been reported (Stitzel *et al.*, 2001; Matthews *et al.*, 2002; Kenawy *et al.*, 2002; Theron *et al.*, 2001; Schreuder-Gibson *et al.*, 2002). In addition genetic engineering has been used to synthesize an elastin-biomimetic peptide polymer based on the elastomeric peptide sequence of elastin and expressed from recombinant plasmid pRAM1 in *Escherichia coli*. The protein has been electrospun into fibers with diameters varying between 3 nm and 200 nm (Huang *et al.*, 2000) (Fig. 4).

Polymer and Fiber Selection

When deciding on a polymer and fiber structure to be incorporated into the construction of a medical fabric, careful

FIG. 3. Electrospinning system.

consideration of the end use is necessary. Issues such as the duration of body contact, device mechanical properties, fabrication restrictions, and sterilization methods must be considered. To illustrate this point, polypropylene has been successfully used in many implantable applications such as a support mesh for hernia repair. Experience has shown that polypropylene has excellent characteristics in terms of tissue compatibility and can be fabricated into a graft material with adequate mechanical strength. A critical question remaining

A

B

FIG. 4. Electrospun fibers from biomimetic-elastin peptide.

is whether the graft will remain stable and survive as a long-term implant. Figure 5 demonstrates the creep characteristics of grafts fabricated from expanded polytetrafluoroethylene (e-PTFE), polyester, and a bicomponent fiber (BCF) containing polypropylene yarns. In the case of the first BCF design (see later section), the polypropylene was used as the nonabsorbable core material and the main structural component of the fiber. Figure 5 represents the outer diameter of a series of pressurized graft materials as a function of time. Classical graft materials such as PET and e-PTFE show no creep over time, whereas the polypropylene-based materials continue to creep over time, making them unacceptable for long-term vascular implants. However, in other applications such as for hernia repair meshes and sutures, polypropylene has been used very successfully. It should be noted that in the second-generation BCF design, the core material was changed to poly(butylene terephthalate) (King *et al.*, 2000).

FIG. 5. Creep characteristics of various graft materials (Weinberg, 1998).

Absorbable Synthetic Fibers

Another series of synthetic fibers used in clinical applications are constructed from polymers that are designed to be absorbed over time when placed in the body. They classically have been used as sutures, but have also been used experimentally for neurological, vascular graft, and tissue scaffold applications. Table 3 is a list of bioabsorbable polymers that have been used in the past to fabricate medical devices. When in contact with the body, these polymers degrade either by hydrolysis or by enzymatic degradation into nontoxic by-products. They break down or degrade either through an erosion process that starts on the exterior surface of the fiber and continues until the fiber has been totally absorbed, or by a bulk erosion mechanism in which the process is autocatalytic and starts in the center of the fiber. Caution should be exercised when using these types of materials. In vascular applications, the risk of distal embolization to the microvasculature may occur if small pieces of the polymer break off during the erosion or absorption process.

Modified Natural Fibers

In addition to synthetic polymers, a class of fibers exists that is composed of natural biopolymer based materials. In contrast to synthetic fibers that have been adapted for medical use, natural fibers have evolved naturally and so can be particularly suited for medical applications. Cellulose, which is obtained from processed cotton or wood pulp, is one of the most common fiber-forming biopolymers. Because of the highly absorbent nature of cellulose fibers, they are commonly used in feminine hygiene products, diapers, and other absorbable applications, but typically are not used *in vivo* because of the highly inflammatory reactions associated with these materials. In certain cases, these properties can be used to advantage such as in the aforementioned hemostat Surgicel. In this application, the thrombogenicity and hydration characteristics of the regenerated cellulose are used in stopping internal bleeding from blood vessels and the surface of internal organs. Also of growing interest are fibers created from modified polysaccharides including alginates, xanthan gum, chitosan, dextran, and reticulated cellulose (Shalaby and Shah, 1991; Keys, 1996).

TABLE 3 Absorbable Synthetic Polymers

Type	Chemical and physical aspects	Construction/useful forms	Comments/applications
Poly(glycolide) (PGA)	Thermoplastic crystalline polymer ($T_m = 225^\circ\text{C}$, $T_g = 40\text{--}45^\circ\text{C}$)	Multifilament yarns, for weaving, knitting and braiding, sterilized by ethylene oxide	Absorbable sutures and meshes (for defect repairs and periodontal inserts)
10/90 Poly(L-lactide-co-glycolide) (Polyglactin 910)	Thermoplastic crystalline co-polymer ($T_m = 205^\circ\text{C}$, $T_g = 43^\circ\text{C}$)	Multifilament yarns, for weaving, knitting and braiding, sterilized by ethylene oxide	Absorbable sutures and meshes
Poly(p-dioxanone) (PDS)	Thermoplastic crystalline co-polymer, ($T_m = 110\text{--}115^\circ\text{C}$, $T_g = 10^\circ\text{C}$)	Melt spun to monofilament yarn	Sutures, intramedullary pins and ligating clips
Poly(alkylene oxalates)	A family of absorbable polymers with T_m between 64 and 104°C	Can be spun to monofilament and multifilament yarns	Experimental sutures
Isomorphic poly(hexamethylene-co-trans-1, 4-cyclohexane dimethylene oxalates)	A family of crystalline polymers with T_m between 64 and 225°C	Can be spun to monofilament and multifilament yarns	Experimental sutures

These materials are obtained from algae, crustacean shells, and through bacterial fermentation. A list of several forms of alginates and their proposed uses is presented in Table 4 (Keys, 1996). Another natural material, chitosan, has been used to fabricate surgical sutures and meshes, and it is currently under investigation for use as a substrate or scaffold for tissue-engineered materials (Skjak-Break and Sanford, 1989). Chitosan and alginate fibers are formed when the polymer is coagulated in a wet solution spinning process.

Silk and collagen are two natural fibers that have been widely used in medicine for multiple applications. Silk from the silkworm, *Bombyx mori*, has been used for decades as a suture. Because of the fineness of individual silk fibers, it is necessary to braid the individual fibers or brins together into thicker yarn bundles. Collagen has been used either in a reconstituted form or in its natural state. Reconstituted collagen is obtained from enzymatic chemical treatment of either bovine skin or tendon followed by reconstitution into fibrils. These fibrils can then

be spun into fibers and fabricated into textile structures or can be left in their native fibrillar form for use in hemostatic mats and tissue-engineered substrates. "Catgut," a natural collagen-based suture material obtained from ovine intestine, which is cross-linked and cut into narrow strips, was one of the first bioabsorbable fibers used in surgery.

Hybrid Bicomponent Fibers

Hybrid bicomponent fiber technology is a novel fiber concept that has been under development for a number of years for use in vascular grafts and other cardiovascular applications. One of the configurations of a bicomponent fiber is a sheath of an absorbable polymer around an inner core of a second nonabsorbable or less absorbable polymer. With a multifilament BCF yarn, each of the filaments of the yarn bundle is identical and contains an identical inner core and outer sheath. Prior to the development of the BCF yarn, when a bicomponent fabric was to be produced it was fabricated by weaving, braiding, or knitting together two (or more) homogenous yarns (e.g., a polyester yarn and a PLA yarn). With such constructions, the tissue or blood sees multiple polymers at the same time. In contrast, with BCF technology only one polymer in the sheath makes initial contact with the tissue. If the outer sheath of a BCF fiber is composed of a bioabsorbable material such as PGA, the inner core polymer is only exposed when the sheath is absorbed. The composition and molecular weight of the polymer and the thickness of the sheath regulate its absorption rate. The hypothesis relating to the BCF concept is that the healing process can be modulated by slowly exposing the less biocompatible inner core material. Preliminary data has shown that the absorption rate can be regulated and will affect the healing process (King *et al.*, 1999). By constructing the inner core from a nonabsorbable biostable polymer such as PET, or a slower absorbing polymer such as PLA, the strength of the fiber will be maintained even as the outer sheath dissolved.

TABLE 4 Potential Uses of Alginates (Keys, 1996)

Type	Current use
Ca alginate (non-woven)	Absorbent wound dressings Pledgets Scaffold for cell culture Surgical hemostats
Ca alginate (particulate)	Acid-labile conjugates of alginate and doxorubicin Sequestration of ^{90}Sr from ingested contaminated food and water
Na alginate (ultra pure)	Microencapsulation Bioreactors
Ca/Na alginate (hydrogel)	Wound management

Additionally, drugs can be incorporated into the outer absorbable sheath and delivered at predefined rates depending on the choice and thickness of the outer polymer. By using this BCF technology, both the material strength profile and the biological properties can be engineered into the fiber to meet specific medical requirements.

CONSTRUCTION

After a fiber or yarn is produced, it is then fabricated into a textile structure in order to obtain the desired mechanical and biological properties. Typical biotextile structures used for medical applications include nonwovens, wovens, knits, and braids. Within each of these configurations, many variations exist. Each type of construction has positive and negative attributes, and in most cases, the final choice represents a compromise between desired and actual fabricated properties. For example, woven fabrics typically are stronger and can be fabricated with lower porosities or water/blood permeability as compared to knits, but are stiffer, less flexible, and more difficult to handle and suture. Knits have higher permeability than woven designs and are easier to suture, but may dilate after implantation. Braids have great flexibility, but can be unstable except when subject to longitudinal load, as in the case of a suture. Multilayer braids are more stable, but are also thicker and less flexible than unidimensional braids. Each construction is a compromise.

Nonwovens

By definition, a nonwoven is a textile structure produced directly from fibers without the intermediate step of yarn production. The fibers are either bonded or interlocked together by means of mechanical or thermal action, or by using an adhesive or solvent or a combination these approaches. Figure 6 is a representation of both wet and dry nonwoven forming processes. The fibers may be oriented randomly or preferentially in one or more directions, and by combining multiple layers one can engineer the mechanical properties independently in the machine (lengthwise) and cross directions. The average pore size of a nonwoven web depends on the density of fibers, as well as the average fiber diameter, and falls under a single distribution (Krcma, 1971). For this reason some tissue-engineered substrates under development use nonwovens to form the underlying tissue scaffold (Chu, 2002).

Woven Fabrics

The term “woven” is used to describe a textile configuration where the primary structural yarns are oriented at 90° to each other. The machine direction is called the warp direction and the cross direction is identified as the filling or weft direction. Because of the orthogonal relationship between the warp and filling yarns, woven structures display low elongation and high breaking strength in both directions. There are many types of woven constructions including plain, twill, and satin weaves (Robinson, 1967). Figure 7 is a sketch showing several weave

designs commonly used in vascular graft fabrications. Water permeability is one critical parameter used in the assessment of textile structures for vascular implants. Water permeability is a measure of the water flux through a fabric under controlled conditions and is given in units of $\text{ml cm}^{-2} \text{min}^{-1}$. It is measured by placing fabric into a test fixture having a fixed orifice size and applying a pressure of 120 mm Hg across the fabric. The water passing through the fabric is collected and measured over time and water permeability is calculated (ISO 7198, Section 8.2.2, Water Permeability). Surgeons use this parameter as a guide to determine if “pre-clotting” of a graft material is necessary prior to implantation. “Pre-clotting” is a process where a graft material is clotted with a patient’s blood prior to implantation, rendering the fabric nonpermeable to blood after implantation. Fabric grafts with water permeability values less than $50 \text{ ml cm}^{-2} \text{min}^{-1}$ usually do not require pre-clotting prior to implantation. The water permeability of the woven graft fabrics can be controlled through the weaving and finishing process and can range from a low of $50 \text{ ml cm}^{-2} \text{min}^{-1}$ up to about $350 \text{ ml cm}^{-2} \text{min}^{-1}$. Above this range, a woven fabric starts becoming mechanically unstable.

Table 5 offers a list of a number of commercial woven graft designs with their respective mechanical properties. As can be seen, many variations in design are possible, presenting a difficult selection process for the surgeon. It is interesting to note that the choice of a graft by a surgeon is often based on the graft’s “ease of handling” or “ease of suturing” rather than on its reported long-term performance. Plain weaves, in contrast to knits, can be made very thin ($< 0.004 \text{ in.}$) and have thus become the material of choice for many endovascular graft designs.

FIG. 7. Examples of woven graft designs.

TABLE 5 Woven Graft Properties and Construction (King, 1991)

Prosthesis	Type of weave	Ends per inch	Picks per inch	Bursting strength (N)	Water permeability	Suture retention strength (N)	Dilatation at 120 mm Hg (%)
Twill woven	1/1 Plain with float	42p22f	48	280	330	25	0
Debakey soft woven	1/1 Plain	52	32	366	220	35	0.2

Knits

Knitted constructions are made by interloping yarns in horizontal rows and vertical columns of stitches. They are softer, more flexible and easily conformable, and have better handling characteristics than woven graft designs. Knit fabrics can be built with water permeability values as high as $5,000 \text{ ml cm}^{-2} \text{ min}^{-1}$ and still maintain structural stability. Currently, highly porous grafts materials are usually coated or impregnated with collagen or gelatin so that the surgeon does not have to perform the time consuming pre-clotting process at the time of surgery. The water permeability values for non-coated knitted grafts range from about $1200 \text{ ml cm}^{-2} \text{ min}^{-1}$ up to about $3500 \text{ ml cm}^{-2} \text{ min}^{-1}$. When knits are produced,

the fabric is typically very open and requires special processing to tighten the looped structure and lower its permeability. This compaction process is usually done using a chemical shrinking agent such as methylene chloride or by thermal shrinking. Because of their open structure, knits are typically easier to suture and have better handling characteristics; however, in vascular graft applications, some ultralightweight designs have been known to continuously dilate or expand when implanted in hypertensive patients. It is not uncommon to have lighter weight weft knitted grafts increase up to 20% in diameter shortly after implantation.

As is the case with woven structures, there are several variations in knits; the most common are the weft knit and warp knit constructions (see Fig. 8). Warp knitted structures have

FIG. 8. Types of knit fabrics (Spencer, 1983).

less stretch than weft knits, and therefore are inherently more dimensionally stable, being associated with less dilation *in vivo*. Warp knits do not run and ravel when cut at an angle (King, 1991). Warp knits can be further modified by the addition of an extra yarn in the structure, which adds thickness, bulk, and surface roughness to the fabric. This structure is commonly known as a velour knit. The addition of the velour yarn, while making the fabric feel softer, results in a more intense acute inflammatory reaction and increases the amount of tissue ingrowth into the fabric.

Figures 9A and 9B demonstrate the difference in the level of inflammatory response as seen with plain and velour knit designs, respectively. Figure 9A is a photomicrograph of a Golaski Microkit weft knit with high water permeability. This high porosity weft knit design utilized nontexturized yarns that resulted in a mild inflammatory response as seen at 4 weeks. In contrast, the Microvel fabric, which is a warp knit velour design using texturized yarns, shows an intense acute response at 3 days (Fig. 9B). This more intense acute reaction was designed intentionally so as to make the graft easier to pre-clot and to increase the extent of tissue incorporation into the graft wall.

Braids

Braids have found their way into medical use primarily in the manufacture of suture materials and anterior cruciate ligament (ACL) prostheses. Common braided structures involve the interlacing of an even number of yarns, leading to diamond, regular, and Hercules structures that can be either two- or three-dimensional (see Fig. 10). A myriad of structural forms can be achieved with 3D braiding, such as “I” beams, channels, and solid tubes. A sketch of a flat braiding machine is included in Fig. 11.

PROCESSING AND FINISHING

Once a fabric has been produced from yarn, the subsequent processing steps are known as finishing. As mentioned previously, the starting yarn may contain additives that can result in cytotoxicity and adverse reactions when in contact with tissue. Some of these additives, such as titanium dioxide, which is used as a delusterant to increase the amount of light reflected, are inside the spun fiber and cannot be removed in the finishing operation. Other surface finishes, on the other hand, such as yarn lubricants, can be removed with the proper cleaning and scouring operations. Typically such surface additives are mineral oil based and demand specially designed aqueous-based washing procedures or dry-cleaning techniques with organic solvents to ensure complete removal. In addition to such surface lubricants, the warp yarns may be coated with a sizing agent prior to weaving. This sizing protects the yarns from surface abrasion and filament breakage during weaving. Since each polymer and fabrication process is different, the finishing operation must be material and device specific. Finishing includes such steps as cleaning, heat setting, bleaching, shrinking (compaction), inspection, packaging, and sterilization and will influence the ultimate properties of the biotextile fabric. Figure 12 represents a schematic of a typical finishing operation used in vascular graft manufacturing. The chemicals used in the finishing operation may differ among manufacturers and are usually considered proprietary. If the cleaning process is properly designed, all surface finishes are removed during the finishing process. Testing of the finished product for cytotoxicity and residual extractables is typically used to ensure all the surface additives are removed from the product’s surface prior to packaging and sterilization.

TESTING AND EVALUATION

Once the biotextile is in its final form, it must be tested and evaluated to confirm that it meets published standards and its intended end use. The testing will include component testing on each component including the textile as well as final functional testing of the entire device. When developing and implementing a testing program, various pieces of reference information may apply, including ASTM standards, AAMI/ISO standards, FDA documents, prior regulatory submissions, and the results of failure analyses. In setting up the test plan a fine balance is

FIG. 9. (A) Weft knit inflammatory response at 4 weeks (Golaski Microkit); (B) Warp knit inflammatory response at 3 days (Microvel). (See color plate)

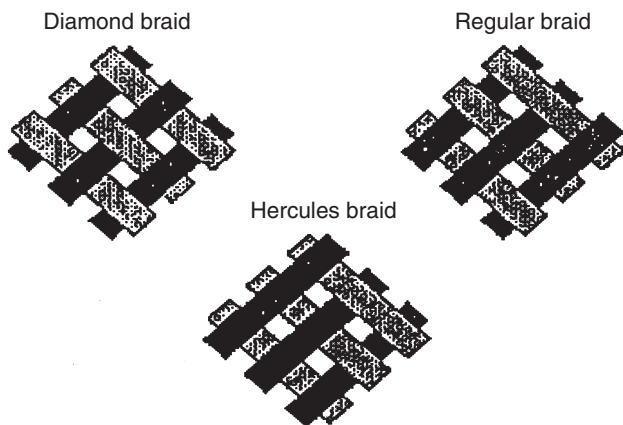

FIG. 10. Braided constructions.

needed so as to minimize the scope of the testing program while still ensuring that the polymer, textile, and final product will be safe and efficacious. Table 6 is a list of the suggested test methods used in the development of a textile-based vascular graft for large vessel replacement (ANSI/AAMI/ISO, 2001).

APPLICATIONS

The application of fibers and biotextiles as components for implantable devices is widespread and covers all aspects of medicine and health care. Textiles are used as basic care items such as drapes, protective apparel, wound dressings, and diapers and in complex devices such as heart valve sewing rings, vascular grafts, hernia repair meshes, and percutaneous access devices.

Flat braider and braid

FIG. 11. Sketch of flat braider.

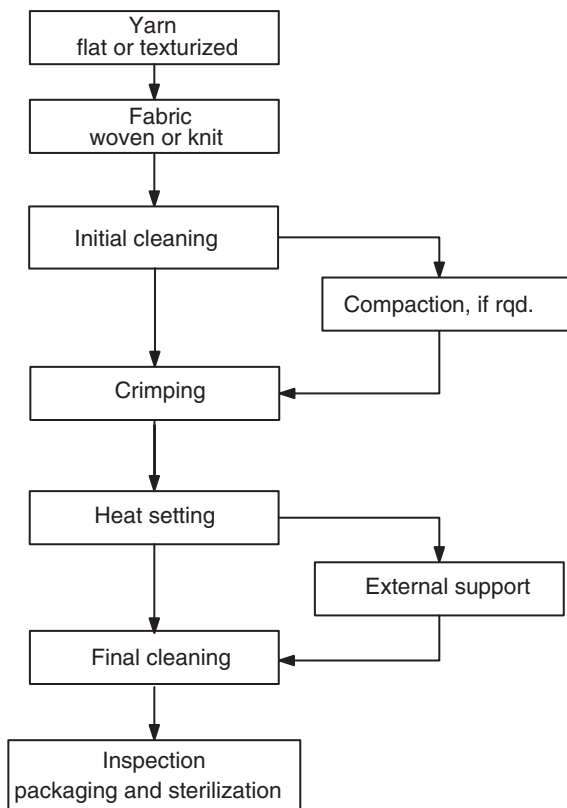

FIG. 12. Typical graft finishing operation.

Drapes and Protective Apparel

The most common nonimplantable medical use of textiles is for protective surgical gowns, operating room drapes, masks, and shoe covers. Nonwovens and wovens are most frequently

used for these applications, with nonwovens being the material of choice for single-use (disposable) products, and wovens for reusable items. Most of these barrier-type fabrics are made from cellulose (cotton, viscose rayon, and wood pulp), polyethylene, and polypropylene fibers. Many fabrics contain finishes that render them water repellent depending on the clinical need. Additionally, such fabrics must generally be fire retardant because of the risk of explosions due to

exposure to flammable gases used for anesthesia. In applications such as facemasks, the fabric must minimize the passage of bacteria through the mask. This can be ensured by engineering the appropriate pore size distribution in the filtration fabric (Schreuder-Gibson, 2002). Antibacterial coatings are also placed on surgical drapes to minimize the risk of wound contamination. Drapes and protective apparel typically require some assembly that can be done either through conventional sewing or by ultrasonic seaming methods. The latter method is preferred for those products used in sterile fields since the holes created by conventional sewing needles can render the fabric permeable to liquids and liquid-borne pathogens. Drapes are usually constructed of a nonwoven fabric laminated to a plastic film to ensure that they are impervious to blood and other fluids. Another common use of textiles is in the fabrication of adhesive tapes. These tapes generally consist of an adhesive layer that is laminated onto a woven, knitted, or nonwoven fabric substrate.

Topical and Percutaneous Applications

Textiles have been used for many years as bandages, wound coverings, and diapers. Gauze, which is basically an open woven structure made from cotton fiber, is manufactured in many forms and sold by many companies worldwide. Elastic bandages are basically woven tapes where an expandable yarn, such as spandex polyurethane, is placed in the warp direction to allow for longitudinal stretch and recovery. Development continues to improve wound dressing products by the addition of antibiotics, barrier fabrics, growth factors, and modification of the basic underlining bandage construction. One example of the latter is the work of Karamuk *et al.* (2001), in which a three-layered laminate was formed from a nonwoven polyester/polypropylene/cotton outer layer, a monofilament polyester middle layer, and a three-dimensional embroidered polyester inner layer with large pores to promote angiogenesis.

Blood access devices are a class of medical devices where tubes, wires, or other components pass through the skin. These include percutaneous drug delivery devices, blood access shunts, air or power lines for heart and left ventricular assist devices, and many types of leads. All of these devices suffer from the same basic problem, a high risk of infection at the skin-device interface due to the migration of bacteria along the surface of the percutaneous lead. If a textile cuff is placed around the tube, at the point of entry through the skin, aggressive tissue ingrowth into the fabric reduces the risk of infection at the percutaneous site. These cuffs are usually made from knits, nonwoven felts, and velour materials. Once a device is infected, it must be removed to prevent further spreading of the infection. Surface additives, such as silver or antibiotics, are sometimes coated on the fabric to reduce infection rates (Butany, 2002; Takai, 2002).

In Vivo Applications

Cardiovascular Devices

Biotextiles developed for cardiovascular use include applications such as heart valve sewing rings, angioplasty rings,

vascular grafts, valved conduits, endovascular stent grafts, and the components of left ventricular assist devices. One of the most important uses of textile fabrics in medicine is in the fabrication of large diameter vascular grafts (10 mm to 40 mm in diameter). As previously noted, polyester [poly(ethylene terephthalate)] is the principal polymer used to fabricate vascular grafts. These grafts can either be woven or knitted and are produced in straight or bifurcated configurations. Within each type of construction, various properties can be incorporated into the product as illustrated in Table 5. Manufacturers recommend that all woven and knit grafts with water permeability rates over $50 \text{ ml cm}^{-2} \text{ min}^{-1}$ be pre-clotted to prevent blood loss through the fabric at the time of implantation. To eliminate the need for this pre-clotting procedure, textile-based vascular grafts are usually manufactured with a coating or sealant of collagen or gelatin.

Today a substantial amount of research activity is being directed toward the development of a small vessel prosthesis with diameters less than 6 mm for coronary artery bypass and tibial/popliteal artery replacement. Currently, no successful commercial products exist to meet this market need. The question still remains as to whether a biotextile will work as a small vessel prosthesis if it is fabricated to have the required compliance and mechanical properties and its surface is modified with surface coatings, growth factors, and other bioactive agents to prevent thrombosis and thrombo-embolic events. Current development activities are directed toward tissue-engineered grafts (Teebken, 2002; Huang, 2000), coated or surface-modified synthetic and textile grafts (Chinn, 1998), and biologically based grafts (Weinberg, 1995).

During the past 10 years, large amounts of financial and personnel resources have gone into the development of endovascular stent grafts (Makaroun, 2002). These grafts have been used for aortic aneurysm repair, occlusive disease, and vascular trauma. Endovascular prostheses or stent grafts are tubular grafts with an internal or external stent or rigid scaffold. The stent grafts range in size from about 20 mm up to 40 mm ID and are collapsed and folded into catheters and inserted through the femoral artery, thus avoiding the need for open surgery. The stents are typically made from nitinol, stainless steel, and Elgiloy wires and are similar to the coronary stents, however, much larger in diameter (e.g., 24 mm versus 4 mm, respectively). There are balloon expandable or self-expanding stents, which are manufactured in straight or bifurcated configurations. The stents are then covered in either ultrathin ePTFE (Cartes-Zumelzu, 2002) or woven polyester (Areydi, 2003). Most of the endovascular graft designs incorporate an ultrathin woven polyester tube. Most biotextile tubes are plain woven structures with water permeabilities ranging from 150 to $300 \text{ ml cm}^{-2} \text{ min}^{-1}$ depending on the manufacturer. They have been woven from 40 or 50 denier untexturized polyester yarn so as to minimize the overall wall thickness of the device.

General Surgery

Three key applications of biotextiles in general surgery are sutures, hemostatic devices, and hernia repair meshes. Commercial sutures are typically monofilament or braided; they can be constructed of natural materials such as silk

TABLE 7 Comparison between Commercial Hemostats (Ethicon, 1998)

	Surgicel Fibrillar Hemostat	Oxycel	Collagen power	Gelfoam
Bacterial activity	Inhibits bacterial growth	No antibacterial activity	No antibacterial activity	No antibacterial activity
Hemostasis time	3.5 to 4.5 minutes	2 to 8 minutes	2 to 4 minutes	Not specified
Bioresorbability	7 to 14 days	3 to 4 weeks	8 to 10 weeks	4 to 6 weeks
Packaging	Foil/Tyvek Sterile	Glass vials	Glass jars	Peel envelope
Preparation	Packaged for use	Packaged for use	Packaged for use	Must be cut/soaked

or collagen (catgut), or synthetic materials such as nylon, polypropylene, and polyester. Sutures can be further classified into absorbable and nonabsorbable types. For obvious reasons, when blood vessels are ligated, only nonabsorbable sutures are used, and these are typically constructed of either braided polyester or polypropylene monofilaments. On the other hand, when ligating soft tissue or closing wounds subcutaneously, absorbable sutures are preferred. Absorbable sutures do not create a chronic inflammatory response and do not require removal. These are typically made from poly(glycolic acid) (PGA) or poly(glycolide-co-lactide) copolymers.

Another common application of biotextiles and fiber technology in general surgery is the use of absorbable hemostatic agents, including those constructed of collagen and oxidized regenerated cellulose. As mentioned previously, these can be fabricated as nonwoven mats or woven and knitted fabrics, or they can be left in fibrillar form. Table 7 highlights some commercially available hemostatic agents and their representative properties. As can be seen in Table 7, collagen-based hemostatic devices are available in layered fibril, foam, and powdered forms. The regenerated cellulose pad is also available as a knitted fabric and is sold under the trade name of Surgicel. This material is commonly used to control suture line bleeding. The nonwoven and powdered forms are generally used to stop diffuse bleeding that results from trauma to the liver and spleen. Experience has shown that the loose fibril form is more difficult to use, so most surgeons prefer the more structured form of the product.

Various forms of open mesh fabrics are used as secondary support material in hernia repair. Traditional constructions are warp knitted from polypropylene monofilaments, and some forms of the mesh are preshaped for easy installation. More recently three-dimensional Raschel knits using polyester multifilament yarns have been found to be more flexible and therefore can be implanted endoscopically. As with other textile structures, various properties can be engineered into the mesh to meet design goals that may include added flexibility, increased strength, reduced thickness, improved handling, and better suture holding strength. Some designs include a protein or microporous PTFE layer on one side only, which reduces the risk of unwanted adhesions *in vivo*.

Orthopedics

Attempts have been made to construct replacement ligaments and tendons using woven and braided fabrications. One design, which has had some limited clinical success, is

a prestretched knitted graft, material used to repair separated shoulder joints. A similar design, using a high-tenacity polyester woven web inside of a prestretched knitted graft, was evaluated for anterior cruciate ligament (ACL) repair in the knee joint with limited success. In general, biotextiles have had limited success in orthopedic ligament and tendon applications as a result of abrasion wear problems, inadequate strength, and poor bone attachment (Guidoin, 2000). An attempt was made to use a braided PTFE structure for ACL repair, but early failures occurred as a result of creep problems associated with the PTFE polymer. Roolker (2000) recently reported on using the e-PTFE ligament prosthesis on 52 patients. However, during the follow-up they experienced increasing knee instability over time indicating prosthesis failure. Copper (2000) and Lu (2001) have reported the development of a three-dimensional bioabsorbable braid using poly(glycolide-co-lactide) fibers for ligament replacement. They were able to modify the scaffold porosity, mechanical properties and matrix design using a three-dimensional braiding technique. A successful ACL ligament replacement would be a significant advance for orthopedic surgery, but at present, no biotextile or other type of prosthesis has shown clinical promise.

Tissue Engineering Scaffolds and The Future

One key area of research gaining significant attention over the past several years is tissue engineered scaffolds. This technology combines an engineered scaffold, or three-dimensional structure, with living cells. These scaffolds can be constructed of various materials and into various shapes depending on the desired application. One such concept is the use of the biodegradable hydrogel-textile substrate (Chu, 2002). Their concept uses a 3D porous biodegradable hydrogel on a nonwoven fabric structure. An alternate concept developed by Karamuk (2000, 2001) uses a 3D embroidered scaffold to form a tissue-engineered substrate. With this concept, polyester yarns were used to form a complex textile structure, which allowed for easy deformation that they believe will enhance cellular attachment and cell growth. Risbud (2002) reported on the development of 3D chitosan-collagen hydrogel coating for fabric meshes to support endothelial cell growth. They are directing their research toward the development of liver bioreactors.

Further in the future, various novel concepts will be undergoing development. Heim (2002) reported on the development of a textile-based tissue engineered heart valve.

Using microfiber woven technology, Heim *et al.* hypothesized that the filaments could be oriented along the stress lines and the fabric based leaflet structure would have good fatigue resistance with minimal bending stiffness. Significant development is required before this concept can be used *in vivo*. **Coatings on textile based vascular grafts continue to be an area of interest.**

Coury (2000) reported on the use of a synthetic hydrogel coating based on poly(ethylene glycol) (PEG) to replace collagen. If successful, the use of a synthetic coating would be preferable to use of a collagen one since it will reduce manufacturing costs and graft-to-graft variability that typically occurs with naturally derived collagen materials. As mentioned earlier, even silk is undergoing modifications to enhance its biocompatibility for cardiovascular applications by sulfation and copolymerization with various monomers (Tamada, 2000). These concepts will provide new and novel implantable products for advancing medical treatments and therapies in the future.

SUMMARY

In summary, it can be stated that the use of biotextiles in medicine will continue to grow as new polymers, coatings, constructions, and finishing processes are introduced to meet the device needs of the future. In particular, advances in genetic engineering, fiber spinning, and surface modification technologies will provide a new generation of biopolymers and fibrous materials with unique chemical, mechanical, biological, and surface properties that will be responsible for achieving the previously unobtainable goal of tissue-engineered organs.

2.5 HYDROGELS

Nicholas A. Peppas

Hydrogels are water-swollen, cross-linked polymeric structures containing either covalent bonds produced by the simple reaction of one or more comonomers, physical cross-links from entanglements, association bonds such as hydrogen bonds or strong van der Waals interactions between chains (Peppas, 1987), or crystallites bringing together two or more macromolecular chains (Hickey and Peppas, 1995). Hydrogels have received significant attention because of their exceptional promise in biomedical applications. The classic book by Andrade (1976) offers some of the best work that was available prior to 1975. The more recent book and other reviews by Peppas (1987, 2001) addresses the preparation, structure, and characterization of hydrogels.

Here, we concentrate on some features of the preparation of hydrogels, as well as characteristics of their structure and chemical and physical properties.

CLASSIFICATION AND BASIC STRUCTURE

Depending on their method of preparation, ionic charge, or physical structure features, hydrogels may be classified in several categories. Based on the method of preparation, they may be (i) homopolymer hydrogels, (ii) copolymer hydrogels, (iii) multipolymer hydrogels, or (iv) interpenetrating polymeric hydrogels. Homopolymer hydrogels are cross-linked networks of one type of hydrophilic monomer unit, whereas copolymer hydrogels are produced by cross-linking of two comonomer units, at least one of which must be hydrophilic to render them swellable. Multipolymer hydrogels are produced from three or more comonomers reacting together (see e.g., Lowman and Peppas, 1997, 1999). Finally, interpenetrating polymeric hydrogels are produced by preparing a first network that

is then swollen in a monomer. The latter reacts to form a second intermeshing network structure. Based on their ionic charges, hydrogels may be classified (Ratner and Hoffman, 1976; Brannon-Peppas and Harland, 1990) as (i) neutral hydrogels, (ii) anionic hydrogels, (iii) cationic hydrogels, or (iv) ampholytic hydrogels. Based on physical structural features of the system, they can be classified as (i) amorphous hydrogels, (ii) semicrystalline hydrogels, or (iii) hydrogen-bonded or complexation structures. In amorphous hydrogels, the macromolecular chains are arranged randomly. Semicrystalline hydrogels are characterized by dense regions of ordered macromolecular chains (crystallites). Finally, hydrogen bonds and complexation structures may be responsible for the three-dimensional structure formed.

Structural evaluation of hydrogels reveals that ideal networks are only rarely observed. Figure 1A shows an ideal macromolecular network (hydrogel) indicating tetrafunctional cross-links (junctions) produced by covalent bonds. However, in real networks it is possible to encounter multifunctional junctions (Fig. 1B) or physical molecular entanglements (Fig. 1C) playing the role of semipermanent junctions. Hydrogels with molecular defects are always possible. Figures 1D and 1E indicate two such effects: unreacted functionalities with partial entanglements (Fig. 1D) and chain loops (Fig. 1E). Neither of these effects contributes to the mechanical or physical properties of a polymer network.

The terms “cross-link,” “junction,” or “tie-point” (an open circle symbol in Fig. 1D) indicate the connection points of several chains. These junctions may be carbon atoms, but they are usually small chemical bridges [e.g., an acetal bridge in the case of cross-linked poly(vinyl alcohol)] with molecular weights much smaller than those of the cross-linked polymer chains. In other situations, a junction may be an association of macromolecular chains caused by van der Waals forces, as in the case of the glycoprotein network structure of natural mucus, or an aggregate formed by hydrogen bonds, as in the case of aged microgels formed in polymer solutions.

Finally, the network structure may include effective junctions that can be either simple physical entanglements of permanent or semipermanent nature, or ordered chains forming crystallites. Thus, the junctions should never be considered as points without volume, which is the usual assumption made when developing structural models for analysis of the cross-linked structure of hydrogels (Flory, 1953). Instead, they have a finite size and contribute to the deformational distribution during biomedical applications.

PREPARATION

Hydrogels are prepared by swelling cross-linked structures in water or biological fluids. Water or aqueous solutions may be present during the initial preparation of the cross-linked structure. Methods of preparation of the initial networks include chemical cross-linking, photopolymerization, or irradiative cross-linking (Peppas *et al.*, 2000).

Chemical cross-linking calls for direct reaction of a linear or branched polymer with at least one difunctional,

FIG. 1. (A) Ideal macromolecular network of a hydrogel. (B) Network with multifunctional junctions. (C) Physical entanglements in a hydrogel. (D) Unreacted functionality in a hydrogel. (E) Chain loops in a hydrogel.

small molecular weight, cross-linking agent. This agent usually links two longer molecular weight chains through its di- or multifunctional groups. A second method involves a copolymerisation-cross-linking reaction between one or more abundant monomers and one multifunctional monomer that is present in relatively small quantities. A third method involves using a combination of monomer and linear polymeric chains that are cross-linked by means of an interlinking agent, as in the production of polyurethanes. Several of these techniques can be performed in the presence of UV light leading to rapid formation of a three-dimensional network. Ionizing radiation cross-linking (Chapiro, 1962) utilizes electron beams, gamma rays, or X-rays to excite a polymer and produce a cross-linked structure via free radical reactions.

SWELLING BEHAVIOR

The physical behavior of hydrogels is dependent on their equilibrium and dynamic swelling behavior in water, since upon preparation they must be brought in contact with water to yield the final, swollen network structure. Figure 2 shows one of two possible processes of swelling. A dry, hydrophilic cross-linked network is placed in water. Then, the macromolecular chains interact with the solvent molecules owing to the relatively good thermodynamic compatibility. Thus, the network expands to the solvated state.

The Flory-Huggins theory can be used to calculate thermodynamic quantities related to that mixing process. Flory (1953) developed the initial theory of the swelling of cross-linked polymer gels using a Gaussian distribution of the polymer chains. His model describing the equilibrium degree of cross-linked polymers postulated that the degree to which a polymer network swelled was governed by the elastic retractive forces of the polymer chains and the thermodynamic compatibility of the polymer and the solvent molecules. In terms of the free energy of the system, the total free energy change upon swelling was written as:

$$\Delta G = \Delta G_{\text{elastic}} + \Delta G_{\text{mix}} \quad (1)$$

Here, $\Delta G_{\text{elastic}}$ is the contribution due to the elastic retractive forces and ΔG_{mix} represents the thermodynamic compatibility of the polymer and the swelling agent (water).

Upon differentiation of Eq. 1 with respect to the water molecules in the system, an expression can be derived for the chemical potential change of water in terms of the elastic and mixing contributions due to swelling.

$$\mu_1 - \mu_{1,0} = \Delta\mu_{\text{elastic}} + \Delta\mu_{\text{mix}} \quad (2)$$

Here, μ_1 is the chemical potential of water within the gel and $\mu_{1,0}$ is the chemical potential of pure water.

At equilibrium, the chemical potentials of water inside and outside of the gel must be equal. Therefore, the elastic and mixing contributions to the chemical potential will balance one another at equilibrium. The chemical potential change upon mixing can be determined from the heat of mixing and the entropy of mixing. Using the Flory-Huggins theory, the

chemical potential of mixing can be expressed as:

$$\Delta\mu_{\text{mix}} = RT \left(\ln(1 - 2\nu_{2,s}) + \nu_{2,s} + \chi_1 \nu_{2,s}^2 \right) \quad (3)$$

where χ_1 is the polymer-water interaction parameter, $\nu_{2,s}$ is the polymer volume fraction of the gel, T is absolute temperature, and R is the gas constant.

This thermodynamic swelling contribution is counterbalanced by the retractive elastic contribution of the cross-linked structure. The latter is usually described by the rubber elasticity theory and its variations (Peppas, 1987). Equilibrium is attained in a particular solvent at a particular temperature when the two forces become equal. The volume degree of swelling, Q (i.e., the ratio of the actual volume of a sample in the swollen state divided by its volume in the dry state), can then be determined from Eq. 4.

$$\nu_{2,s} = \frac{\text{Volume of polymer}}{\text{Volume of swollen gel}} = \frac{V_p}{V_{\text{gel}}} = 1/Q \quad (4)$$

Researchers working with hydrogels for biomedical applications prefer to use other parameters in order to define the equilibrium-swelling behavior. For example, Yasuda *et al.* (1969) introduced the use of the so-called hydration ratio, H , which has been accepted by those researchers who use hydrogels for contact lens applications (Peppas and Yang, 1981). Another definition is that of the weight degree of swelling, q , which is the ratio of the weight of the swollen sample to that of the dry sample.

In general, highly swollen hydrogels include those of cellulose derivatives, poly(vinyl alcohol), poly(*N*-vinyl-2-pyrrolidone) (PNVP), and poly(ethylene glycol), among others. Moderately and poorly swollen hydrogels are those of poly(hydroxyethyl methacrylate) (PHEMA) and many of its derivatives. In general, a basic hydrophilic monomer can be copolymerized with other more or less hydrophilic monomers to achieve desired swelling properties. Such processes have led to a wide range of swellable hydrogels, as Gregonis *et al.* (1976), Peppas (1987, 1997), and others have pointed out. Knowledge of the swelling characteristics of a polymer is of utmost importance in biomedical and pharmaceutical applications since the equilibrium degree of swelling influences (i) the solute diffusion coefficient through these hydrogels, (ii) the surface properties and surface mobility, (iii) the optical properties,

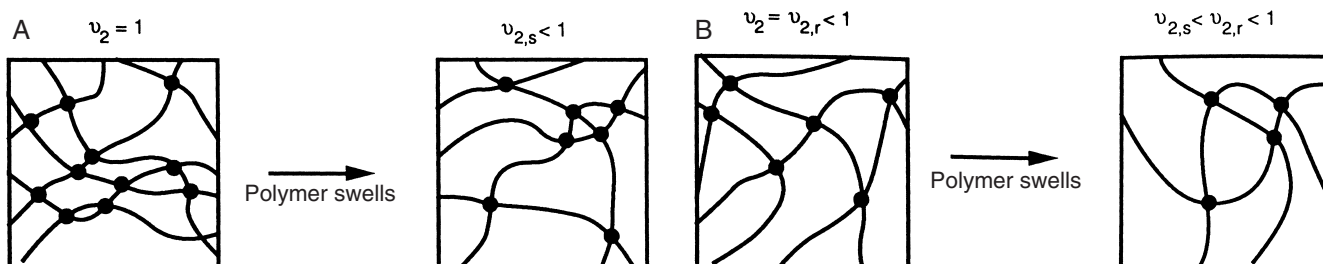

FIG. 2. (A) Swelling of a network prepared by cross-linking in dry state. (B) Swelling of a network prepared by cross-linking in solution.

especially in relation to contact lens applications, and (iv) the mechanical properties.

DETERMINATION OF STRUCTURAL CHARACTERISTICS

The parameter that describes the basic structure of the hydrogel is the molecular weight between cross-links, \bar{M}_c (as shown in Fig. 1A). This parameter defines the average molecular size between two consecutive junctions regardless of the nature of those junctions and can be calculated by Eq. 5.

$$\frac{1}{\bar{M}_c} = \frac{2}{\bar{M}_c} - \frac{(v/V_1) [\ln(1 - v_{2,s}) + v_{2,s} + \chi_1 v_{2,s}^2]}{(v_{2,s}^{1/3} - v_{2,s}/2)} \quad (5)$$

An additional parameter of importance in structural analysis of hydrogels is the cross-linking density, ρ_x , which is defined by Eq. 6.

$$\rho_x = \frac{1}{\bar{v}\bar{M}_c} \quad (6)$$

In these equations, v is the specific volume of the polymer (i.e., the reciprocal of the amorphous density of the polymer), and \bar{M}_n is the initial molecular weight of the un-cross-linked polymer.

PROPERTIES OF IMPORTANT BIOMEDICAL HYDROGELS

The multitude of hydrogels available leaves numerous choices for polymeric formulations. The best approach for developing a hydrogel with the desired characteristics for biomedical application is to correlate the macromolecular structures of the polymers available with the swelling and mechanical characteristics desired (Peppas *et al.*, 2000; Peppas, 2001).

The most widely used hydrogel is water-swollen, cross-linked PHEMA, which was introduced as a biological material by Wichterle and Lim (1960). The hydrogel is inert to normal biological processes, shows resistance to degradation, is permeable to metabolites, is not absorbed by the body, is biocompatible, withstands heat sterilization without damage, and can be prepared in a variety of shapes and forms.

The swelling, mechanical, diffusional, and biomedical characteristics of PHEMA gels have been studied extensively. The properties of these hydrogels are dependent upon their method of preparation, polymer volume fraction, degree of cross-linking, temperature, and swelling agent.

Other hydrogels of biomedical interest include polyacrylamides. Tanaka (1979) has done extensive studies on the abrupt swelling and deswelling of partially hydrolyzed acrylamide gels with changes in swelling agent composition, curing time, degree of cross-linking, degree of hydrolysis, and temperature. These studies have shown that the ionic groups produced in an acrylamide gel upon hydrolysis give the gel

a structure that shows a discrete transition in equilibrium-swollen volume with environmental changes.

Discontinuous swelling in partially hydrolyzed polyacrylamide gels has been studied by Gehrke *et al.* (1986). Besides HEMA and acrylamides, *N*-vinyl-2-pyrrolidone (NVP), methacrylic acid (MAA), methyl methacrylate (MMA), and maleic anhydride (MAH) have all been proven useful as monomers for hydrogels in biomedical applications. For instance, cross-linked PNVP is used in soft contact lenses. Small amounts of MAA as a comonomer have been shown to dramatically increase the swelling of PHEMA polymers. Owing to the hydrophobic nature of MMA, copolymers of MMA and HEMA have a lower degree of swelling than pure PHEMA (Brannon-Peppas and Peppas, 1991). All of these materials have potential use in advanced technology applications, including biomedical separations, and biomedical and pharmaceutical devices.

INTELLIGENT OR SMART HYDROGELS

Hydrogels may exhibit swelling behavior dependent on the external environment. Over the past 30 years there has been a significant interest in the development and analysis of environmentally or physiologically responsive hydrogels (Peppas, 1991). Environmentally responsive materials show drastic changes in their swelling ratio due to changes in their external pH, temperature, ionic strength, nature and composition of the swelling agent, enzymatic or chemical reaction, and electrical or magnetic stimuli (Peppas, 1993). In most responsive networks, a critical point exists at which this transition occurs.

An interesting characteristic of numerous responsive gels is that the mechanism causing the network structural changes can be entirely reversible in nature. The ability of pH- or temperature-responsive gels to exhibit rapid changes in their swelling behavior and pore structure in response to changes in environmental conditions lend these materials favorable characteristics as carriers for bioactive agents, including peptides and proteins. This type of behavior may allow these materials to serve as self-regulated, pulsatile drug delivery systems.

pH-Sensitive Hydrogels

One of the most widely studied types of physiologically responsive hydrogels is pH-responsive hydrogels. These hydrogels are swollen ionic networks containing either acidic or basic pendant groups. In aqueous media of appropriate pH and ionic strength, the pendant groups can ionize developing fixed charges on the gel. All ionic materials exhibit a pH and ionic strength sensitivity. The swelling forces developed in these systems are increased over those of nonionic materials. This increase in swelling force is due to the localization of fixed charges on the pendant groups. As a result, the mesh size of the polymeric networks can change significantly with small pH changes.

Temperature Sensitive Hydrogels

Another class of environmentally sensitive gels exhibits temperature-sensitive swelling behavior due to a change in the polymer/swelling agent compatibility over the temperature range of interest. Temperature-sensitive polymers typically exhibit a lower critical solution temperature (LCST), below which the polymer is soluble. Above this temperature, the polymers are typically hydrophobic and do not swell significantly in water (Kim, 1996). However, below the LCST, the cross-linked gel swells to significantly higher degrees because of the increased compatibility with water.

Complexing Hydrogels

Some hydrogels may exhibit environmental sensitivity due to the formation of polymer complexes. Polymer complexes are insoluble, macromolecular structures formed by the non-covalent association of polymers with affinity for one another. The complexes form as a result of the association of repeating units on different chains (interpolymer complexes) or on separate regions of the same chain (intrapolymer complexes). Polymer complexes are classified by the nature of the association as stereocomplexes, polyelectrolyte complexes, or hydrogen-bonded complexes. The stability of the associations is dependent on such factors as the nature of the swelling agent, temperature, type of dissolution medium, pH and ionic strength, network composition and structure, and length of the interacting polymer chains.

In this type of gel, complex formation results in the formation of physical cross-links in the gel. As the degree of effective cross-linking is increased, the network mesh size and degree of swelling is significantly reduced. As a result, if hydrogels are used as drug carriers, the rate of drug release will decrease dramatically upon the formation of interpolymer complexes.

APPLICATIONS

Biomedical Applications

The physical properties of hydrogels make them attractive for a variety of biomedical and pharmaceutical applications. Their biocompatibility allows them to be considered for medical applications, whereas their hydrophilicity can impart desirable release characteristics to controlled and sustained release formulations.

Hydrogels exhibit properties that make them desirable candidates for biocompatible and blood-compatible biomaterials (Merrill *et al.*, 1987). Nonionic hydrogels for blood contact applications have been prepared from poly(vinyl alcohol), polyacrylamides, PNVP, PHEMA, and poly(ethylene oxide) (Peppas *et al.*, 1999). Heparinized polymer hydrogels also show promise as materials for blood-compatible applications (Sefton, 1987).

One of the earliest biomedical applications of hydrogels was in contact lenses (Tighe, 1976; Peppas and Yang, 1981) because of their relatively good mechanical stability, favorable refractive index, and high oxygen permeability.

Other potential applications of hydrogels include (Peppas, 1987) artificial tendon materials, wound-healing bioadhesives, artificial kidney membranes, articular cartilage, artificial skin, maxillofacial and sexual organ reconstruction materials, and vocal cord replacement materials (Byrne *et al.*, 2002).

Pharmaceutical Applications

Pharmaceutical hydrogel applications have become very popular in recent years. Pharmaceutical hydrogel systems include equilibrium-swollen hydrogels, i.e., matrices that have a drug incorporated in them and are swollen to equilibrium. The category of solvent-activated, matrix-type, controlled-release devices comprises two important types of systems: swellable and swelling-controlled devices. In general, a system prepared by incorporating a drug into a hydrophilic, glassy polymer can be swollen when brought in contact with water or a simulant of biological fluids. This swelling process may or may not be the controlling mechanism for diffusional release, depending on the relative rates of the macromolecular relaxation of the polymer and drug diffusion from the gel.

In swelling-controlled release systems, the bioactive agent is dispersed into the polymer to form nonporous films, disks, or spheres. Upon contact with an aqueous dissolution medium, a distinct front (interface) is observed that corresponds to the water penetration front into the polymer and separates the glassy from the rubbery (gel-like) state of the material. Under these conditions, the macromolecular relaxations of the polymer influence the diffusion mechanism of the drug through the rubbery state. This water uptake can lead to considerable swelling of the polymer with a thickness that depends on time. The swelling process proceeds toward equilibrium at a rate determined by the water activity in the system and the structure of the polymer. If the polymer is cross-linked or if it is of sufficiently high molecular weight (so that chain entanglements can maintain structural integrity), the equilibrium state is a water-swollen gel. The equilibrium water content of such hydrogels can vary from 30% to 90%. If the dry hydrogel contains a water-soluble drug, the drug is essentially immobile in the glassy matrix, but begins to diffuse out as the polymer swells with water. Drug release thus depends on two simultaneous rate processes: water migration into the device and drug diffusion outward through the swollen gel. Since some water uptake must occur before the drug can be released, the initial burst effect frequently observed in matrix devices is moderated, although it may still be present. The continued swelling of the matrix causes the drug to diffuse increasingly easily, ameliorating the slow tailing off of the release curve. The net effect of the swelling process is to prolong and linearize the release curve. Details of hydrogels for medical and pharmaceutical applications have been presented by Korsmeyer and Peppas (1987) for poly(vinyl alcohol) systems, and by Peppas (1981) for PHEMA systems and their copolymers. One of numerous examples of such swelling-controlled systems was reported by Franson and Peppas (1983), who prepared cross-linked copolymer gels of poly(HEMA-co-MAA) of varying compositions. Theophylline release was studied and it was found that near zero-order release could be achieved using copolymers containing 90% PHEMA.

Poly(vinyl alcohol)

Another hydrophilic polymer that has received attention is poly(vinyl alcohol) (PVA). This material holds tremendous promise as a biological drug delivery device because it is nontoxic, is hydrophilic, and exhibits good mucoadhesive properties. Two methods exist for the preparation of PVA gels. In the first method, linear PVA chains are cross-linked using glyoxal, glutaraldehyde, or borate. In the second method, Peppas and Hassan (2000), semicrystalline gels were prepared by exposing aqueous solutions of PVA to repeating freezing and thawing. The freezing and thawing induced crystal formation in the materials and allowed for the formation of a network structure cross-linked with the quasi-permanent crystallites. The latter method is the preferred method for preparation as it allows for the formation of an "ultrapure" network without the use of toxic cross-linking agents. Ficek and Peppas (1993) used PVA gels for the release of bovine serum albumin using novel PVA microparticles.

Poly(ethylene glycol)

Hydrogels of poly(ethylene oxide) (PEO) and poly(ethylene glycol) (PEG) have received significant attention for biomedical applications in the past few years (Graham, 1992). Three major preparation techniques exist for the preparation of cross-linked PEG networks: (i) chemical cross-linking between PEG chains, (ii) radiation cross-linking of PEG chains, and (iii) chemical reaction of mono- and difunctional PEGs. The advantage of using radiation-cross-linked PEO networks is that no toxic cross-linking agents are required. However, it is difficult to control the network structure of these materials. Stringer and Peppas (1996) have prepared PEO hydrogels by radiation cross-linking. In this work, they analyzed the network structure in detail. Additionally, they investigated the diffusional behavior of smaller molecular weight drugs, such as theophylline, in these gels. Kofinas *et al.* (1996) have prepared PEO hydrogels by a similar technique. In this work, they studied the diffusional behavior of various macromolecules in these gels. They noted an interesting, yet previously unreported dependence between the cross-link density and protein diffusion coefficient and the initial molecular weight of the linear PEGs.

Lowman *et al.* (1997) have presented an exciting new method for the preparation of PEG gels with controllable structures. In this work, highly cross-linked and tethered PEG gels were prepared from PEG dimethacrylates and PEG monomethacrylates. The diffusional behavior of diltiazem and theophylline in these networks was studied. The technique presented in this work is promising for the development of a new class of functionalized PEG-containing gels that may be of use in a wide variety of drug delivery applications.

pH-Sensitive Hydrogels

Hydrogels that have the ability to respond to pH changes have been studied extensively over the years. These gels typically contain side ionizable side groups such as carboxylic acids or amine groups. The most commonly studied ionic polymers include poly(acrylamide) (PAAm), poly(acrylic acid) (PAA),

poly(methacrylic acid) (PMAA), poly(diethylaminoethyl methacrylate) (PDEAEMA), and poly(dimethylaminoethyl methacrylate) (PDMAEMA). The swelling and release characteristics of anionic copolymers of PMAA and PHEMA (PHEMA-*co*-MAA) have been investigated. In acidic media, the gels did not swell significantly; however, in neutral or basic media, the gels swelled to a high degree because of ionization of the pendant acid group. Brannon-Peppas and Peppas (1991) have also studied the oscillatory swelling behavior of these gels.

Temperature-Sensitive Hydrogels

Some of the earliest work with temperature-sensitive hydrogels was done by Hirotsu *et al.* (1987). They synthesized cross-linked poly(*N*-isopropyl acrylamide) (PNIPAAm) and determined that the LCST of the PNIPAAm gels was 34.3°C. Below this temperature, significant gel swelling occurred. The transition about this point was reversible. They discovered that the transition temperature was raised by copolymerizing PNIPAAm with small amounts of ionic monomers. Dong and Hoffman (1991) prepared heterogeneous gels containing PNIPAAm that collapsed at significantly faster rates than homopolymers of PNIPAAm. Yoshida *et al.* (1995) and Kaneko *et al.* (1996) developed an ingenious method to prepare comb-type graft hydrogels of PNIPAAm. The main chain of the cross-linked PNIPAAm contained small-molecular-weight grafts of PNIPAAm. Under conditions of gel collapse (above the LCST), hydrophobic regions were developed in the pores of the gel resulting in a rapid collapse. These materials had the ability to collapse from a fully swollen conformation in less than 20 minutes, whereas comparable gels that did not contain graft chains required up to a month to fully collapse. Such systems show major promise for rapid and abrupt or oscillatory release of drugs, peptides, or proteins.

Complexation Hydrogels

Another promising class of hydrogels that exhibit responsive behavior is complexing hydrogels. Bell and Peppas (1995) have discussed a class of graft copolymer gels of PMAA grafted with PEG, poly(MAA-*g*-EG). These gels exhibited pH-dependent swelling behavior due to the presence of acidic pendant groups and the formation of interpolymer complexes between the ether groups on the graft chains and protonated pendant groups. In these covalently cross-linked, complexing poly(MAA-*g*-EG) hydrogels, complexation resulted in the formation of temporary physical cross-links due to hydrogen bonding between the PEG grafts and the PMAA pendant groups. The physical cross-links were reversible in nature and dependent on the pH and ionic strength of the environment. As a result, these complexing hydrogels exhibit drastic changes in their mesh size in response to small changes of pH.

Promising new methods for the delivery of chemotherapeutic agents using hydrogels have been recently reported. Novel biorecognizable sugar-containing copolymers have been investigated for the use in targeted delivery of anti-cancer drugs. Peterson *et al.* (1996) have used poly(*N*-2-hydroxypropyl methacrylamide) carriers for the treatment of ovarian cancer.

Self-Assembled Structures

In the past few years there have been new, creative methods of preparation of novel hydrophilic polymers and hydrogels that may represent the future in drug delivery applications. The focus in these studies has been the development of polymeric structures with precise molecular architectures. Stupp *et al.* (1997) synthesized self-assembled triblock copolymer nanostructures that may have very promising biomedical applications.

Star Polymers

Dendrimers and star polymers (Dvornik and Tomalia, 1996) are exciting new materials because of the large number of functional groups available in a very small volume. Such systems could have tremendous promise in drug targeting applications. Merrill (1993) has offered an exceptional review of PEO star polymers and applications of such systems in the biomedical and pharmaceutical fields. Griffith and Lopina (1995) have prepared gels of controlled structure and large biological functionality by irradiation of PEO star polymers. Such new structures could have particularly promising drug delivery applications when combined with emerging new technologies such as molecular imprinting.

2.6 APPLICATIONS OF “SMART POLYMERS” AS BIOMATERIALS

Allan S. Hoffman

INTRODUCTION

Stimulus-responsive, “intelligent” polymers are polymers that respond with sharp, large property changes to small changes in physical or chemical conditions. They are also known as “smart” or “environmentally sensitive” polymers. These polymers can take many forms; they may be dissolved in aqueous solution, adsorbed or grafted on aqueous–solid interfaces, or cross-linked in the form of hydrogels.

Many different stimuli have been investigated, and they are listed in Table 1. Typically, when the polymer’s critical response is stimulated, the behavior will be as follows (Fig. 1):

- The smart polymer that is dissolved in an aqueous solution will show a sudden onset of turbidity as it phase separates, and if its concentration is high enough, it will convert from a solution to a gel.

TABLE 1 Environmental Stimuli

FIG. 1. Schematic illustration showing the different types of responses of “intelligent” polymer systems to environmental stimuli. Note that all systems are reversible when the stimulus is reversed (Hoffman *et al.*, *Journal of Biomedical Materials Research* © 2000).

- The smart polymer that is chemically grafted to a surface and is stimulated to phase separate will collapse, converting that interface from a hydrophilic to a hydrophobic interface. If the smart polymer is in solution and it is stimulated to phase separate, it may physically adsorb to a hydrophobic surface whose composition has a balance of hydrophobic and polar groups that is similar to the phase-separated smart polymer.
- The smart polymer that is cross-linked in the form of a hydrogel will exhibit a sharp collapse, and release much of its swelling solution.

These phenomena are reversed when the stimulus is reversed. Sometimes the rate of reversion is slower when the polymer has to redissolve or the gel has to reswell in aqueous media. The rate of collapse or reversal of smart polymer systems is sensitive to the dimensions of the smart polymer system, and it will be much more rapid for systems with nanoscale dimensions.

Smart polymers may be physically mixed with or chemically conjugated to biomolecules to yield a large and diverse family of polymer–biomolecule hybrid systems that can respond to biological as well as to physical and chemical stimuli. Biomolecules that may be combined with smart polymer systems include proteins and oligopeptides, sugars and polysaccharides, single and double-stranded oligonucleotides, RNA and DNA, simple lipids and phospholipids, and a wide spectrum of recognition ligands and synthetic drug molecules. In addition, polyethylene glycol (PEG, which is also a smart polymer) may be conjugated to the smart polymer backbone to provide it with “stealth” properties (Fig. 2).

Combining a smart polymer and a biomolecule produces a new, smart “biohybrid” system that can synergistically

combine the individual properties of the two components to yield new and unusual properties. One could say that these biohybrids are “doubly smart.” Among the most important of these systems are the smart polymer–biomolecule conjugates, especially the polymer–drug and polymer–protein conjugates. Such smart bioconjugates, and even a physical mixture of the individual smart polymers and biomolecules, may be physically adsorbed or chemically immobilized on solid surfaces. The biomolecule may also be physically or chemically entrapped in smart hydrogels. All of these hybrid systems have been extensively studied and this chapter reviews these studies. There have been a number of successful applications in both medicine and biotechnology for such smart polymer–biomolecule systems, and as such, they represent an important extension of polymeric biomaterials beyond their well-known uses in implants and medical devices. Several review articles are available on these interesting smart hybrid biomaterials (Hoffman, 1987, 1995, 1997; Hoffman *et al.*, 1999, 2000; Okano *et al.*, 2000).

SMART POLYMERS IN SOLUTION

There are many polymers that exhibit thermally induced precipitation (Table 2), and the polymer that has been studied most extensively is poly(*N*-isopropyl acrylamide), or PNIPAAm. This polymer is soluble in water below 32°C, and it precipitates sharply as temperature is raised above 32°C (Heskins and Guillet, 1968). The precipitation temperature is called the lower critical solution temperature, or LCST. If the solution contains buffer and salts the LCST will be

FIG. 2. Schematic illustration showing the variety of natural or synthetic biomolecules which may be conjugated to a smart polymer. In some cases, only one molecule may be conjugated, such as a recognition protein, which may be linked to the protein at a reactive terminal group of the polymer, or it may be linked at a reactive pendant group along the polymer backbone. In other cases more than one molecule may be conjugated along the polymer backbone, such as a targeting ligand along with many drug molecules (Hoffman *et al.*, *Journal of Biomedical Materials Research* © 2000).

Poly(acryl-L-amino acid amides)
Others
Poly(methacrylic acid)

FIG. 3. Copolymerization of a thermally sensitive polymer, PNIPAAm, with a more hydrophilic comonomer, AAm, raises the LCST of the copolymer, whereas copolymerization with a more hydrophobic comonomer, N-tBAAm, lowers the LCST (Hoffman *et al.*, *Journal of Biomedical Materials Research* © 2000).

reduced several degrees. If NIPAAm monomer is copolymerized with more hydrophilic monomers such as acrylamide, the LCST increases and may even disappear. If NIPAAm monomer is copolymerized with more hydrophobic monomers, such as *n*-butylacrylamide, the LCST decreases (Fig. 3) (Priest *et al.*, 1987). NIPAAm may also be copolymerized with pH-sensitive monomers, leading to random copolymers with temperature- and pH-responsive components (Dong and Hoffman, 1987; Zareie *et al.*, 2000) (see also Chapter 7.14 on drug delivery systems). NIPAAm has been copolymerized with pH-responsive macromonomers, leading to graft copolymers that independently exhibit two separate stimulus-responsive behaviors (Chen and Hoffman, 1995).

A family of thermally gelling, biodegradable triblock copolymers has been developed for injectable drug delivery formulations (Vernon *et al.*, 2000; Lee *et al.*, 2001; Jeong *et al.*, 2002). They form a medium viscosity, injectable solution at room temperature and a solid hydrogel at 37°C. These polymers are based on compositions of hydrophobic, degradable polyesters combined with PEO. The copolymers are triblocks with varying MW segments of PLGA and PEO. Typical compositions are PEO-PLGA-PEO and PLGA-PEO-PLGA.

Tirrell (1987) and more recently, Stayton, Hoffman, and co-workers have studied the behavior of pH-sensitive alpha-alkylacrylic acid polymers in solution (Lackey *et al.*, 1999; Murthy *et al.*, 1999; Stayton *et al.*, 2000). As pH is lowered, these polymers become increasingly protonated and hydrophobic, and eventually phase separate; this transition can be sharp, resembling the phase transition at the LCST. If a polymer such as poly(ethylacrylic acid) or poly(propylacrylic acid) is in the vicinity of a lipid bilayer membrane as pH is lowered, the polymer will interact with the membrane and disrupt it. These polymers have been used in intracellular drug delivery to disrupt endosomal membranes as pH drops in the endosome, enhancing the cytosolic delivery of drugs, and avoiding

exposure to lysosomal enzymes. (See further discussion in Chapter 7.14 on drug delivery systems.)

SMART POLYMER-PROTEIN BIOCONJUGATES IN SOLUTION

Smart polymers may be conjugated randomly to proteins by binding the reactive end of the polymer or reactive pendant groups along the polymer backbone to reactive sites on the protein (Fig. 4). One may utilize chain transfer free radical polymerization to synthesize oligomers with one functional end group, which can then be derivatized to form a reactive group that can be conjugated to the protein. NIPAAm has also been copolymerized with reactive comonomers (e.g., *N*-hydroxysuccinimide acrylate, or NHS acrylate) to yield a random copolymer with reactive pendant groups, which have then been conjugated to the protein. Vinyl monomer groups have been conjugated to proteins to provide sites for copolymerization with free monomers such as NIPAAm. These synthesis methods are described in several publications (Cole *et al.*, 1987; Monji and Hoffman, 1987; Shoemaker *et al.*, 1987; Chen *et al.*, 1990; Chen and Hoffman, 1990, 1994; Yang *et al.*, 1990; Takei *et al.*, 1993a; Monji *et al.*, 1994; Ding *et al.*, 1996) (see also Chapter 2.16 on biologically functional materials).

Normally the lysine amino groups are the most reactive protein sites for random polymer conjugation to proteins, and *N*-hydroxysuccinimide (NHS) attachment chemistry is most often utilized. Other possible sites include -COOH groups of aspartic or glutamic acid, -OH groups of serine or tyrosine, and -SH groups of cysteine residues. The most likely attachment site will be determined by the reactive group on the polymer and the reaction conditions, especially the pH. Because these conjugations are generally carried out in a nonspecific way, the conjugated polymer can interfere sterically with the protein's active site or modify its microenvironment, typically reducing the bioactivity of the protein. On rare occasions the

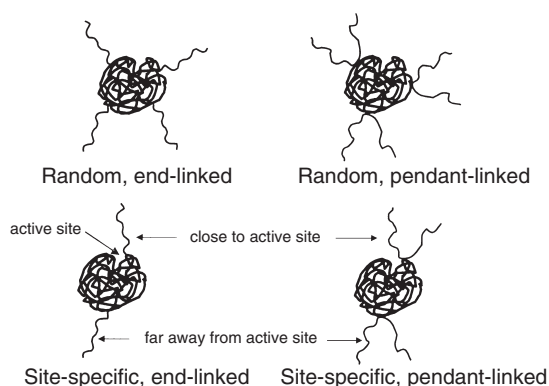

FIG. 4. Various types of random and site-specific smart polymer-protein conjugates. In the latter case, conjugation near the active site of the protein is intended to provide stimulus control of the recognition process of the protein for its ligand, whereas conjugation far away from the active site should avoid any interference of the polymer with the protein's natural activity (Hoffman *et al.*, *Journal of Biomedical Materials Research* © 2000).

conjugation of a polymer increases the activity of the protein. (e.g., Ding *et al.*, 1998).

Biomedical uses of smart polymers in solution have mainly been as conjugates with proteins. Random conjugation of temperature-sensitive (mainly) and pH-sensitive (occasionally) polymers to proteins has been extensively investigated, and applications of these conjugates have been focused on immunoassays, affinity separations, enzyme recovery, and drug delivery (Schneider *et al.*, 1981; Okamura *et al.*, 1984; Nguyen and Luong, 1989; Taniguchi *et al.*, 1989, 1992; Chen and Hoffman, 1990; Monji *et al.*, 1990; Pecs *et al.*, 1991; Park and Hoffman, 1992; Takei *et al.*, 1993b, 1994; Galaev and Mattiasson, 1993; Fong *et al.*, 1999; Anastase-Ravion *et al.*, 2001). In some cases the “smart” polymer is a polyligand, such as polybiotin or poly(glycosyl methacrylate), which is used to phase separate target molecules by complexation to multiple binding sites on target proteins, such as streptavidin and Concanavalin A, respectively (Larsson and Mosbach, 1979; Morris *et al.*, 1993; Nakamae *et al.*, 1994). Wu, Hoffman, and Yager (1992, 1993) have synthesized PNIPAAm–phospholipid conjugates for use in drug delivery formulations as components of thermally sensitive composites and liposomes.

SMART POLYMERS ON SURFACES

One may covalently graft a polymer to a surface by exposing the surface to ionizing radiation in the presence of the monomer (and in the absence of air), or by preirradiating the polymer surface in air, and later contacting the surface with the monomer solution and heating in the absence of air. (See also Chapter 1.4 on surface properties of materials.) These surfaces exhibit stimulus-responsive changes in wettability (Uenoyama and Hoffman, 1988; Takei *et al.*, 1994; Kidoaki *et al.*, 2001). Ratner and co-workers have used a gas plasma discharge to deposit temperature-responsive coatings from a NIPAAm monomer vapor plasma (Pan *et al.*, 2001). Okano and Yamato and co-workers have utilized the radiation grafting technique to form cell culture surfaces having a surface layer of grafted PNIPAAm. (Yamato and Okano, 2001; Shimizu *et al.*, 2003). They have cultured cells to confluent sheets on these surfaces at 37°C, which is above the LCST of the polymer. When the PNIPAAm collapses, the interface becomes hydrophobic and leads to adsorption of cell adhesion proteins, enhancing the cell culture process. Then when the temperature is lowered, the interface becomes hydrophilic as the PNIPAAm chains rehydrate, and the cell sheets release from the surface (along with the cell adhesion proteins). The cell sheet can be recovered and used in tissue engineering, e.g., for artificial cornea and other tissues. Patterned surfaces have also been prepared (Yamato *et al.*, 2001). Smart polymers may also be grafted to surfaces to provide surfaces of gradually varying hydrophilicity and hydrophobicity as a function of the polymer composition and conditions. This phenomenon has been applied by Okano, Kikuchi, and co-workers to prepare chromatographic column packing, leading to eluate-free (“green”) chromatographic separations (Kobayashi *et al.*, 2001; Kikuchi and Okano, 2002). Ishihara *et al.* (1982, 1984b) developed photoresponsive coatings and membranes that reversibly

changed surface wettability or swelling, respectively, due to the photoinduced isomerization of an azobenzene-containing polymer.

SITE-SPECIFIC SMART POLYMER BIOCONJUGATES ON SURFACES

Conjugation of a responsive polymer to a specific site near the ligand-binding pocket of a genetically engineered protein is a powerful new concept. Such site-specific protein–smart polymer conjugates can permit sensitive environmental control of the protein’s recognition process, which controls all living systems. Stayton and Hoffman *et al.* (Stayton *et al.*, 2000) have designed and synthesized smart polymer–protein conjugates where the polymer is conjugated to a specific site on the protein, usually a reactive –SH thiol group from cysteine that has been inserted at the selected site (Fig. 5). This is accomplished by utilizing cassette mutagenesis to insert a site-specific mutation into the DNA sequence of the protein, and then cloning the mutant in cell culture. This method is applicable only to proteins whose complete peptide sequence is known. The preparation of the reactive smart polymer is similar to the method described above, but now the reactive end or pendant groups and the reaction conditions are specifically designed to favor conjugation to –SH groups rather than to –NH₂ groups. Typical SH-reactive polymer end groups include maleimide and vinyl sulfone groups.

The specific site for polymer conjugation can be located far away from the active site (Chilkoti *et al.*, 1994), in order to avoid interference with the biological functioning of the protein, or nearby or even within the active site, in order to control the ligand–protein recognition process and the biological activity of the protein (Fig. 4) (Ding *et al.*, 1999, 2001; Bulmus *et al.*, 1999; Stayton *et al.*, 2000; Shimoboji *et al.*, 2001, 2002a, b, 2003). The latter has been most studied by

FIG. 5. Schematic illustration of the process for preparing an immobilized, site-specific conjugate of a smart polymer with a genetically-engineered, mutant protein (Hoffman *et al.*, *Journal of Biomedical Materials Research* © 2000).

the Stayton/Hoffman group. Temperature-, pH-, and light-sensitive smart polymers have been used to form such novel, “doubly smart” bioconjugates. Since the objective is to control the activity of the protein, and not to phase separate it, these smart polymer-engineered protein bioconjugates have usually been immobilized on the surfaces of microbeads or nanobeads. Stayton, Hoffman, and co-workers have used such beads in microfluidic devices for immunoassays (Malmstadt *et al.*, 2003). Earlier work by Hoffman and co-workers established the importance of matching the smart polymer composition with the surface composition in order to enhance the stimulus-driven adsorption of the smart polymer on the surface (Miura *et al.*, 1994). Others have also recently utilized this phenomenon in microfluidic devices (Huber *et al.*, 2003).

The proteins that have been most studied by the Stayton/Hoffman group to date include streptavidin and the enzyme cellulase. PNIPAAm-streptavidin site-specific bioconjugates have been used to control access of biotin to its binding site on streptavidin, and have enabled separation of biotinylated proteins according to the size of the protein (Ding *et al.*, 2001). Ding, Stayton, and Hoffman *et al.* (1999) also found that raising the temperature to thermally induce the collapse of the polymer “triggered” the release of the bound biotin molecules (Ding *et al.*, 1999). For the site-specific enzyme conjugates, a combined temperature- and light-sensitive polymer was conjugated to specific sites on an endocellulase, which provided on-off control of the enzyme activity with either light or temperature (Shimoboji *et al.*, 2001, 2002a, b, 2003).

Triggered release of bound ligands by the smart polymer-engineered protein bioconjugates could be used to release therapeutics, such as for topical drug delivery to the skin or mucosal surfaces of the body, and also for localized delivery of drugs within the body by stimulated release at pretargeted sites using noninvasive, focused stimuli, or delivery of stimuli from catheters. Triggered release could also be used to release and recover affinity-bound ligands from chromatographic and other supports in eluate-free conditions, including capture and release of specific cell populations to be used in stem cell and bone marrow transplantation. These processes could involve two different stimulus-responsive polymers with sensitivities to the same or different stimuli. For delicate target ligands such as peptides and proteins, recovery could be affected without the need for time-consuming and harsh elution conditions. Triggered release could also be used to remove inhibitors, toxins, or fouling agents from the recognition sites of immobilized or free enzymes and affinity molecules, such as those used in biosensors, diagnostic assays, or affinity separations. This could be used to “regenerate” such recognition proteins for extended process use. Light-controlled binding and release of site-specific protein conjugates may be utilized as a molecular switch for various applications in biotechnology, medicine, and bioelectronics, including hand-held diagnostic devices, biochips, and lab-on-a-chip devices.

Fong, Stayton, and Hoffman (Fong *et al.*, 1999) have developed an interesting construct to control the distance of the PNIPAAm from the active site. For this purpose, they conjugated one sequence of complementary nucleotides to a specific site near the binding pocket of streptavidin, and a second sequence to the end of a PNIPAAm chain. Then, by controlling

the location and length of the complementary sequence, the self-assembly via hybridization of the two single-chain DNA sequences could be used to control the distance of the polymer from the streptavidin binding site.

SMART POLYMER HYDROGELS

When a smart polymer is cross-linked to form a gel, it will collapse and re-swell in water as a stimulus raises or lowers it through its critical condition. PNIPAAm gels have been extensively studied, starting with the pioneering work of Toyochi Tanaka in 1981 (Tanaka, 1981). Since then, the properties of PNIPAAm hydrogels have been widely investigated in the form of beads, slabs, and multilamellar laminates (Park and Hoffman, 1992a, b, 1994; Hu *et al.*, 1995, 1998; Mitsumata *et al.*, 2001; Kaneko *et al.*, 2002; Gao and Hu, 2002). Okano and co-workers have developed smart gels that collapse very rapidly, by grafting PNIPAAm chains to the PNIPAAm backbone in a cross-linked PNIPAAm hydrogel (Yoshida *et al.*, 1995; Masahiko *et al.*, 2003). Smart hydrogel compositions have been developed that are both thermally gelling and biodegradable (Zhong *et al.*, 2002; Yoshida *et al.*, 2003). These sol-gel systems have been used to deliver drugs by *in vivo* injections and are discussed in the section on smart polymers in solution, and also in more detail in Chapter 7.14 on drug delivery systems.

Hoffman and co-workers were among the first to recognize the potential of PNIPAAm hydrogels as biomaterials; they showed that the smart gels could be used (a) to entrap enzymes and cells, and then turn them on and off by inducing cyclic collapse and swelling of the gel, and (b) to deliver or remove biomolecules, such as drugs or toxins, respectively, by stimulus-induced collapse or swelling (Dong and Hoffman, 1986, 1987, 1990; Park and Hoffman, 1988, 1990a, b, c) (Fig. 6). One unique hydrogel was developed by Dong and Hoffman (1991). This pH- and temperature-sensitive hydrogel was based on a random copolymer of NIPAAm and AAC, and it was shown to release a model drug linearly over a 4-hour period as the pH went from gastric to enteric conditions at 37°C. At body temperature the NIPAAm component was trying to maintain the gel in the collapsed state, while as the pH went from acidic to neutral conditions, the AAC component was becoming ionized, forcing the gel to swell and slowly release the drug (see Fig. 6B).

Kim, Bae, and co-workers have investigated smart gels containing entrapped cells that could be used as artificial organs (Vernon *et al.*, 2000). Matsuda and co-workers have incorporated PNIPAAm into physical mixtures with natural polymers such as hyaluronic acid and gelatin, for use as tissue engineering scaffolds (Ohya *et al.*, 2001a, b).

Peppas and co-workers (Robinson and Peppas, 2002) have studied pH-sensitive gels in the form of nanospheres. Nakamae, Hoffman, and co-workers developed novel compositions of smart gels containing phosphate groups that were used to bind cationic proteins as model drugs and then to release them by a combination of thermal stimuli and ion exchange (Nakamae *et al.*, 1992, 1997; Miyata *et al.*, 1994).

FIG. 6. Schematic illustration showing three ways that smart gel formulations may be stimulated to release bioactive agents: (A) thermally induced collapse, which is relevant to skin or mucosal drug delivery; (B) pH-induced swelling, which is relevant to oral drug delivery, where the swelling is induced by the increase in pH in going from the gastric to enteric regions; and (C) sol-to-gel formation, which is relevant to injectable or topical formulations of a triblock copolymer solution that are thermally gelled at body temperature. For *in vivo* uses, the block copolymer is designed to be degradable. The first two apply to cross-linked gels applied topically or orally, and the third is relevant to thermally induced formation of gels from polymer solutions that are delivered topically or by injection. (See also Chapter 7.14 on drug delivery systems.)

SMART GELS THAT RESPOND TO BIOLOGICAL STIMULI

A number of drug delivery devices have been designed to respond to biologic signals in a feedback manner. Most of these gels contain an immobilized enzyme. Heller and Trescony (1979) were among the first to work with smart enzyme gels. In this early example, urease was immobilized in a gel, and urea was metabolized to produce ammonia, which caused a local pH change, leading to a permeability change in the surrounding gel. Ishihara *et al.* (1985) also developed a urea-responsive gel containing immobilized urease. Smart enzyme gels containing glucose oxidase (GOD) were designed to respond to a more relevant signal, that of increasing glucose concentration. In a typical device, when glucose concentration increases, the entrapped GOD converts the glucose in the presence of oxygen to gluconic acid and hydrogen peroxide. The former lowers pH, and the latter is an oxidizing agent. Each of these byproduct signals has been used in various smart hydrogel systems to increase the permeability of the gel barrier to insulin delivery (Horbett *et al.*, 1984; Albin *et al.*, 1985; Ishihara *et al.*, 1983, 1984a; Ishihara and Matsui, 1986; Ito *et al.*, 1989; Iwata and Matsuda, 1988).

In one case, the lowered pH due to the GOD by-product, gluconic acid, accelerated hydrolytic erosion of the polymer matrix that also contained entrapped insulin, releasing the insulin (Heller *et al.*, 1990). Siegel and co-workers have used

the glucose-stimulated swelling and collapse of hydrogels containing entrapped glucose oxidase to drive a hydrogel piston in an oscillating manner, for release of insulin in a glucose-driven, feedback manner (Dhanarajan *et al.*, 2002). Other smart enzyme gels for drug delivery have been developed based on activation of an inactivated enzyme by a biologic signal (Schneider *et al.*, 1973; Roskos *et al.*, 1993).

Smart gels have also been developed that are based on affinity recognition of a biologic signal. Makino *et al.* (1990) developed a smart system that contained glycosylated insulin bound by affinity of its glucose groups to an immobilized Concanavalin A in a gel. When glucose concentration increases, the free glucose competes off the insulin, which is then free to diffuse out of the gel. Nakamae *et al.* (1994) developed a gel based on a similar concept, using a cross-linked poly(glycosylethyl methacrylate) hydrogel containing physically or chemically entrapped Concanavalin A. In this case, the ConA is bound by affinity to the pendant glucose groups on the polymer backbone, acting as a cross-linker because of its four affinity binding sites for glucose; when free glucose concentration increases, the ConA is competed off the polymer backbone. This leads to swelling of the gel, which acts to increase permeation of insulin through the gel. Miyata and co-workers have designed and synthesized smart affinity hydrogels that are stimulated to swell or collapse by the binding of affinity biomolecules (Miyata *et al.*, 1999, 2002).

Chapter 7.14 covers smart bioresponsive gels as drug delivery systems in more detail.

CONCLUSIONS

Smart polymers in solution, on surfaces, and as hydrogels have been utilized in many interesting ways, especially in combination with biomolecules such as proteins and drugs. Important applications include affinity separations, enzyme processes, immunoassays, drug delivery, and toxin removal. These smart polymer–biomolecule systems represent an important extension of polymeric biomaterials beyond their well-known uses in implants and medical devices.

2.7 BIORESORBABLE AND BIOERODIBLE MATERIALS

Joachim Kohn, Sascha Abramson, and Robert Langer

INTRODUCTION

Since a degradable implant does not have to be removed surgically once it is no longer needed, degradable polymers are of value in short-term applications that require only the temporary presence of a device. An additional advantage is that the use of degradable implants can circumvent some of the problems related to the long-term safety of permanently implanted devices. A potential concern relating to the use of degradable implants is the toxicity of the implant's degradation products. Since all of the implant's degradation products are released into the body of the patient, the design of a degradable implant

requires careful attention to testing for potential toxicity of the degradation products. This chapter covers basic definitions relating to the process of degradation and/or erosion, the most important types of *synthetic*, degradable polymers available today, a classification of degradable medical implants, and a number of considerations specific for the design and use of degradable medical polymers (shelf life, sterilization, etc.).

DEFINITIONS RELATING TO THE PROCESS OF EROSION AND/OR DEGRADATION

Currently four different terms (biodegradation, bioerosion, bioabsorption, and bioresorption) are being used to indicate that a given material or device will eventually disappear after having been introduced into a living organism. However, when reviewing the literature, no clear distinctions in the meaning of these four terms are evident. Likewise, the meaning of the prefix “bio” is not well established, leading to the often-interchangeable use of the terms “degradation” and “biodegradation,” or “erosion” and “bioerosion.” Although efforts have been made to establish generally applicable and widely accepted definitions for all aspects of biomaterials research (Williams, 1987), there is still significant confusion even among experienced researchers in the field as to the correct terminology of various degradation processes.

Generally speaking, the term “degradation” refers to a chemical process resulting in the cleavage of covalent bonds. Hydrolysis is the most common chemical process by which polymers degrade, but degradation can also occur via oxidative and enzymatic mechanisms. In contrast, the term “erosion” refers often to physical changes in size, shape, or mass of a device, which could be the consequence of either degradation or simply dissolution. Thus, it is important to realize that erosion can occur in the absence of degradation, and degradation can occur in the absence of erosion. A sugar cube placed in water erodes, but the sugar does not chemically degrade. Likewise, the embrittlement of plastic when exposed to UV light is due to the degradation of the chemical structure of the polymer and takes place before any physical erosion occurs.

In the context of this chapter, we follow the usage suggested by the Consensus Conference of the European Society for Biomaterials (Williams, 1987) and refer to “biodegradation” only when we wish to emphasize that a biological agent (enzyme, cell, or microorganism) is causing the chemical degradation of the implanted device. After extensive discussion in the literature, it is now widely believed that the chemical degradation of the polymeric backbone of poly(lactic acid) is predominantly controlled by simple hydrolysis and occurs independently of any biological agent (Vert *et al.*, 1991). Consequently, the degradation of poly(lactic acid) to lactic acid should not be described as “biodegradation.” In agreement with Heller’s suggestion (Heller, 1987), we define a “bioerodible polymer” as a water-insoluble polymer that is converted under physiological conditions into water-soluble material(s) without regard to the specific mechanism involved in the erosion process. “Bioerosion” includes therefore both physical processes (such as dissolution) and chemical processes (such

as backbone cleavage). Here the prefix “bio” indicates that the erosion occurs under physiological conditions, as opposed to other erosion processes, caused for example by high temperature, strong acids or bases, UV light, or weather conditions. The terms “bioresorption” and “bioabsorption” are used interchangeably and often imply that the polymer or its degradation products are removed by cellular activity (e.g., phagocytosis) in a biological environment. These terms are somewhat superfluous and have not been clearly defined.

OVERVIEW OF CURRENTLY AVAILABLE DEGRADABLE POLYMERS

From the beginnings of the material sciences, the development of highly stable materials has been a major research challenge. Today, many polymers are available that are virtually nondestructible in biological systems, e.g., Teflon, Kevlar, or poly(ether ether ketone) (PEEK). On the other hand, the development of degradable biomaterials is a relatively new area of research. The variety of available, degradable biomaterials is still too limited to cover a wide enough range of diverse material properties. Thus, the design and synthesis of new, degradable biomaterials is currently an important research challenge, in particular within the context of tissue engineering where the development of new biomaterials that can provide predetermined and controlled cellular responses is a critically needed component of most practical applications of tissue engineering (James and Kohn, 1996).

Degradable materials must fulfill more stringent requirements in terms of their biocompatibility than nondegradable materials. In addition to the potential problem of toxic contaminants leaching from the implant (residual monomers, stabilizers, polymerization initiators, emulsifiers, sterilization by-products), one must also consider the potential toxicity of the degradation products and subsequent metabolites. The practical consequence of this consideration is that only a limited number of nontoxic, monomeric starting materials have been successfully applied to the preparation of degradable biomaterials.

Over the past decade dozens of hydrolytically unstable polymers have been suggested as degradable biomaterials; however, in most cases no attempts have been made to develop these new materials for specific medical applications. Thus, detailed toxicological studies *in vivo*, investigations of degradation rate and mechanism, and careful evaluations of the physicomaterial properties have so far been published for only a very small fraction of those polymers. An even smaller number of synthetic, degradable polymers have so far been used in medical implants and devices that gained approval by the Food and Drug Administration (FDA) for use in patients. Note that the FDA does not approve polymers or materials per se, but only specific devices or implants. As of 1999, only five distinct synthetic, degradable polymers have been approved for use in a narrow range of clinical applications. These polymers are poly(lactic acid), poly(glycolic acid), polydioxanone, polycaprolactone, and a poly(PCPP-SA anhydride) (see later discussion). A variety of other synthetic, degradable biomaterials currently in clinical

TABLE 1 Degradable Polymers and Representative Applications under Investigation

Degradable polymer	Current major research applications
Synthetic degradable polyesters	
Poly(glycolic acid), poly(lactic acid), and copolymers	Barrier membranes, drug delivery, guided tissue regeneration (in dental applications), orthopedic applications, stents, staples, sutures, tissue engineering
Polyhydroxybutyrate (PHB), polyhydroxyvalerate (PHV), and copolymers thereof	Long-term drug delivery, orthopedic applications, stents, sutures
Polycaprolactone	Long-term drug delivery, orthopedic applications, staples, stents
Polydioxanone	Fracture fixation in non-load-bearing bones, sutures, wound clip
Other synthetic degradable polymers	
Polyanhydrides	Drug delivery
Polycyanoacrylates	Adhesives, drug delivery
Poly(amino acids) and "pseudo"-Poly(amino acids)	Drug delivery, tissue engineering, orthopedic applications
Poly(ortho ester)	Drug delivery, stents
Polyphosphazenes	Blood contacting devices, drug delivery, skeletal reconstruction
Poly(propylene fumarate)	Orthopedic applications
Some natural resorbable polymers	
Collagen	Artificial skin, coatings to improve cellular adhesion, drug delivery, guided tissue regeneration in dental applications, orthopedic applications, soft tissue augmentation, tissue engineering, scaffold for reconstruction of blood vessels, wound closure
Fibrinogen and fibrin	Tissue sealant
Gelatin	Capsule coating for oral drug delivery, hemorrhage arrester
Cellulose	Adhesion barrier, hemostat
Various polysaccharides such as chitosan, alginate	Drug delivery, encapsulation of cells, sutures, wound dressings
Starch and amylose	Drug delivery

use are blends or copolymers of these base materials such as a wide range of copolymers of lactic and glycolic acid. Note that this listing does not include polymers derived from animal sources such as collagen, gelatin, or hyaluronic acid.

Recent research has led to a number of well-established investigational polymers that may find practical applications as degradable implants within the next decade. It is beyond the scope of this chapter to fully introduce all of the polymers and their applications under investigation, thus only representative examples of these polymers are described here. This chapter will concern itself mostly with *synthetic* degradable polymers, as *natural* polymers (e.g., polymers derived from animal or plant sources) are described elsewhere in this book. Table 1 provides an overview of some representative degradable polymers. For completeness, some of the natural polymers have also been included here. Structural formulas of commonly investigated synthetic degradable polymers are provided in Fig. 1. It is an interesting observation that a large proportion of the currently investigated, *synthetic*, degradable polymers are polyesters. It remains to be seen whether some of the alternative backbone structures such as polyanhydrides, polyphosphazenes, polyphosphonates, polyamides, or polycarbonates will be able to challenge the predominant position of the polyesters in the future.

Polydioxanone (PDS) is a poly(ether ester) made by a ring-opening polymerization of *p*-dioxanone monomer. PDS has gained increasing interest in the medical field and pharmaceutical field due to its degradation to low-toxicity

monomers *in vivo*. PDS has a lower modulus than PLA or PGA. It became the first degradable polymer to be used to make a monofilament suture. PDS has also been introduced to the market as a suture clip as well as a bone pin marketed under the name OrthoSorb in the USA and Ethipin in Europe.

Poly(hydroxybutyrate) (PHB), poly(hydroxyvalerate) (PHV), and their copolymers represent examples of biore-sorbable polyesters that are derived from microorganisms. Although this class of polymers are examples of *natural* materials (as opposed to *synthetic* materials), they are included here because they have similar properties and similar areas of application as the widely investigated poly(lactic acid). PHB and its copolymers with up to 30% of 3-hydroxyvaleric acid are now commercially available under the trade name "Biopol" (Miller and Williams, 1987). PHB and PHV are intracellular storage polymers providing a reserve of carbon and energy to microorganisms similar to the role of starch in plant metabolism. The polymers can be degraded by soil bacteria (Senior *et al.*, 1972) but are relatively stable under physiological conditions (pH 7, 37°C). Within a relatively narrow window, the rate of degradation can be modified slightly by varying the copolymer composition; however, all members of this family of polymers require several years for complete resorption *in vivo*. *In vivo*, PHB degrades to D-3-hydroxybutyric acid, which is a normal constituent of human blood (Miller and Williams, 1987). The low toxicity of PHB may at least in part be due to this fact.

PHB homopolymer is very crystalline and brittle, whereas the copolymers of PHB with hydroxyvaleric acid are

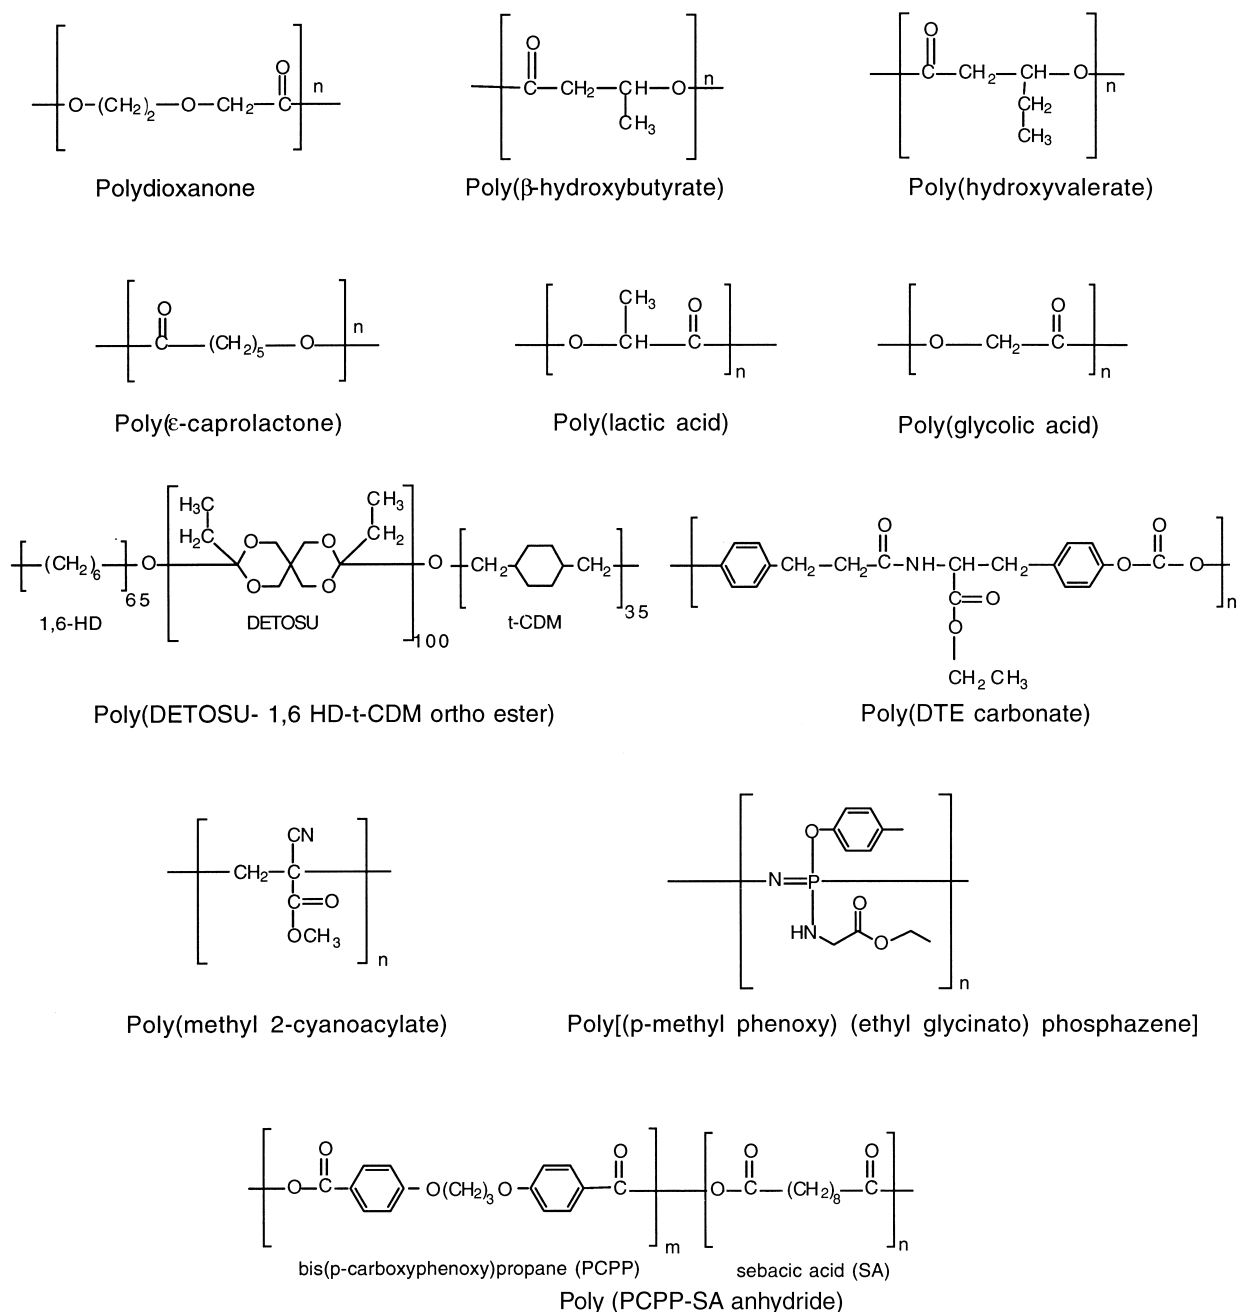

FIG. 1. Chemical structures of widely investigated degradable polymers.

less crystalline, more flexible, and more readily processible (Barham *et al.*, 1984). The polymers have been considered in several biomedical applications such as controlled drug release, sutures, artificial skin, and vascular grafts, as well as industrial applications such as medical disposables. PHB is especially attractive for orthopedic applications because of its slow degradation time. The polymer typically retained 80% of its original stiffness over 500 days on *in vivo* degradation (Knowles, 1993).

Polycaprolactone (PCL) became available commercially following efforts at Union Carbide to identify synthetic polymers that could be degraded by microorganisms (Huang, 1985). It is a semicrystalline polymer. The high solubility of polycaprolactone, its low melting point (59–64°C), and its exceptional ability to form blends has stimulated research on its application as a biomaterial. Polycaprolactone degrades at a slower pace than PLA and can therefore be used in drug delivery devices that remain active for over 1 year. The release

characteristics of polycaprolactone have been investigated in detail by Pitt and his co-workers (Pitt *et al.*, 1979). The Capronor system, a 1-year implantable contraceptive device (Pitt, 1990), has become commercially available in Europe and the United States. The toxicology of polycaprolactone has been extensively studied as part of the evaluation of Capronor. Based on a large number of tests, ϵ -caprolactone and polycaprolactone are currently regarded as nontoxic and tissue-compatible materials. Polycaprolactone is currently being researched as part of wound dressings, and in Europe, it is already in clinical use as a degradable staple (for wound closure).

Polyanhydrides were explored as possible substitutes for polyesters in textile applications but failed ultimately because of their pronounced hydrolytic instability. It was this property that prompted Langer and his co-workers to explore polyanhydrides as degradable implant materials (Tamada and Langer, 1993). Aliphatic polyanhydrides degrade within days, whereas some aromatic polyanhydrides degrade over several years. Thus aliphatic-aromatic copolymers are usually employed which show intermediate rates of degradation depending on the monomer composition.

Polyanhydrides are among the most reactive and hydrolytically unstable polymers currently used as biomaterials. The high chemical reactivity is both an advantage and a limitation of polyanhydrides. Because of their high rate of degradation, many polyanhydrides degrade by surface erosion without the need to incorporate various catalysts or excipients into the device formulation. On the other hand, polyanhydrides will react with drugs containing free amino groups or other nucleophilic functional groups, especially during high-temperature processing (Leong *et al.*, 1986). The potential reactivity of the polymer matrix toward nucleophiles limits the type of drugs that can be successfully incorporated into a polyanhydride matrix by melt processing techniques. Along the same line of reasoning, it has been questioned whether amine-containing biomolecules present in the interstitial fluid around an implant could react with anhydride bonds present at the implant surface.

A comprehensive evaluation of the toxicity of the polyanhydrides showed that, in general, the polyanhydrides possess excellent *in vivo* biocompatibility (Attawia *et al.*, 1995). The most immediate applications for polyanhydrides are in the field of drug delivery. Drug-loaded devices made of polyanhydrides can be prepared by compression molding or microencapsulation (Chasin *et al.*, 1990). A wide variety of drugs and proteins including insulin, bovine growth factors, angiogenesis inhibitors (e.g., heparin and cortisone), enzymes (e.g., alkaline phosphatase and β -galactosidase), and anesthetics have been incorporated into polyanhydride matrices, and their *in vitro* and *in vivo* release characteristics have been evaluated (Park *et al.*, 1998; Chasin *et al.*, 1990). Additionally, polyanhydrides have been investigated for use as nonviral vectors of delivering DNA in gene therapy (Shea and Mooney, 2001). The first polyanhydride-based drug delivery system to enter clinical use is for the delivery of chemotherapeutic agents. An example of this application is the delivery of BCNU (bis-chloroethylnitrosourea) to the brain for the treatment of glioblastoma multiforme, a universally fatal brain cancer (Madrid *et al.*, 1991). For this application,

BCNU-loaded implants made of the polyanhydride derived from bis-*p*-carboxyphenoxypropane and sebacic acid received FDA regulatory approval in the fall of 1996 and are currently being marketed under the name Gliadel.

Poly(ortho esters) are a family of synthetic, degradable polymers that have been under development for a number of years (Heller *et al.*, 1990). Devices made of poly(ortho esters) can erode by "surface erosion" if appropriate excipients are incorporated into the polymeric matrix. Since surface eroding, slab-like devices tend to release drugs embedded within the polymer at a constant rate, poly(ortho esters) appear to be particularly useful for controlled-release drug delivery applications. For example, poly(ortho esters) have been used for the controlled delivery of cyclobenzaprine and steroids and a significant number of publications describe the use of poly(ortho esters) for various drug delivery applications (Heller, 1993). Poly(ortho esters) have also been investigated for the treatment of postsurgical pain, osteoarthritis, and ophthalmic diseases (Heller *et al.*, 2002). Since the ortho ester linkage is far more stable in base than in acid, Heller and his co-workers controlled the rate of polymer degradation by incorporating acidic or basic excipients into the polymer matrix. One concern about the "surface erodability" of poly(ortho esters) is that the incorporation of highly water-soluble drugs into the polymeric matrix can result in swelling of the polymer matrix. The increased amount of water imbibed into the matrix can then cause the polymeric device to exhibit "bulk erosion" instead of "surface erosion" (see below for a more detailed explanation of these erosion mechanisms) (Okada and Toguchi, 1995).

By now, there are three major types of poly(ortho esters). First, Choi and Heller prepared the polymers by the transesterification of 2,2'-dimethoxyfuran with a diol. The next generation of poly(ortho esters) was based on an acid-catalyzed addition reaction of diols with diketeneacetals (Heller *et al.*, 1980). The properties of the polymers can be controlled to a large extent by the choice of the diols used in the synthesis. Recently, a third generation of poly(ortho esters) have been prepared. These materials are very soft and can even be viscous liquids at room temperature. Third-generation poly(ortho esters) can be used in the formulation of drug delivery systems that can be injected rather than implanted into the body.

Poly(amino acids) and "Pseudo"-Poly(amino acids) Since proteins are composed of amino acids, it is an obvious idea to explore the possible use of poly(amino acids) in biomedical applications (Anderson *et al.*, 1985). Poly(amino acids) were regarded as promising candidates since the amino acid side chains offer sites for the attachment of drugs, cross-linking agents, or pendent groups that can be used to modify the physicochemical properties of the polymer. In addition, poly(amino acids) usually show a low level of systemic toxicity, due to their degradation to naturally occurring amino acids.

Early investigations of poly(amino acids) focused on their use as suture materials (Miyamae *et al.*, 1968), as artificial skin substitutes (Spira *et al.*, 1969), and as drug delivery systems (McCormick-Thomson and Duncan, 1989). Various drugs have been attached to the side chains of

poly(amino acids), usually via a spacer unit that distances the drug from the backbone. Poly(amino acid)-drug combinations investigated include poly(L-lysine) with methotrexate and pepstatin (Campbell *et al.*, 1980), and poly(glutamic acid) with adriamycin, a widely used chemotherapeutic agent (van Heeswijk *et al.*, 1985).

Despite their apparent potential as biomaterials, poly(amino acids) have actually found few practical applications. Most poly(amino acids) are highly insoluble and nonprocessable materials. Since poly(amino acids) have a pronounced tendency to swell in aqueous media, it can be difficult to predict drug release rates. Furthermore, the antigenicity of polymers containing three or more amino acids limits their use in biomedical applications (Anderson *et al.*, 1985). Because of these difficulties, only a few poly(amino acids), usually derivatives of poly(glutamic acid) carrying various pendent chains at the γ -carboxylic acid group, have been investigated as implant materials (Lescure *et al.*, 1989). So far, no implantable devices made of a poly(amino acid) have been approved for clinical use in the United States.

In an attempt to circumvent the problems associated with conventional poly(amino acids), backbone-modified "pseudo"-poly(amino acids) were introduced in 1984 (Kohn and Langer, 1984, 1987). The first "pseudo"-poly(amino acids) investigated were a polyester from N-protected *trans*-4-hydroxy-L-proline, and a polyiminocarbonate derived from tyrosine dipeptide. The tyrosine-derived "pseudo"-poly(amino acids) are easily processed by solvent or heat methods and exhibit a high degree of biocompatibility. Recent studies indicate that the backbone modification of poly(amino acids) may be a generally applicable approach for the improvement of the physicochemical properties of conventional poly(amino acids). For example, tyrosine-derived polycarbonates (Nathan and Kohn, 1996) are high-strength materials that may be useful in the formulation of degradable orthopedic implants. One of the tyrosine-derived pseudo-poly(amino acids), poly(DTE carbonate) exhibits a high degree of bone conductivity (e.g., bone tissue will grow directly along the polymeric implant) (Choueka *et al.*, 1996; James and Kohn, 1997).

The reason for the improved physicochemical properties of "pseudo"-poly(amino acids) relative to conventional poly(amino acids) can be traced to the reduction in the number of interchain hydrogen bonds: In conventional poly(amino acids), individual amino acids are polymerized via repeated amide bonds leading to strong interchain hydrogen bonding. In natural peptides, hydrogen bonding is one of the interactions leading to the spontaneous formation of secondary structures such as α -helices or β -pleated sheets. Strong hydrogen bonding also results in high processing temperatures and low solubility in organic solvents which tends to lead to intractable polymers with limited applications. In "pseudo"-poly(amino acids), half on the amide bonds are replaced by other linkages (such as carbonate, ester, or iminocarbonate bonds) that have a much lower tendency to form interchain hydrogen bonds, leading to better processibility and, generally, a loss of crystallinity.

Polycyanoacrylates are used as bioadhesives. Methyl cyanoacrylates are more commonly used as general-purpose glues and are commercially available as "Crazy Glue."

Methyl cyanoacrylate was used during the Vietnam war as an emergency tissue adhesive, but is no longer used today. Butyl cyanoacrylate is approved in Canada and Europe as a dental adhesive. Cyanoacrylates undergo spontaneous polymerization at room temperature in the presence of water, and their toxicity and erosion rate after polymerization differ with the length of their alkyl chains (Gombotz and Pettit, 1995). All polycyanoacrylates have several limiting properties: First, the monomers (cyanoacrylates) are very reactive compounds that often have significant toxicity. Second, upon degradation polycyanoacrylates release formaldehyde resulting in intense inflammation in the surrounding tissue. In spite of these inherent limitations, polycyanoacrylates have been investigated as potential drug delivery matrices and have been suggested for use in ocular drug delivery (Deshpande *et al.*, 1998).

Polyphosphazenes are very unusual polymers, whose backbone consists of nitrogen-phosphorus bonds. These polymers are at the interface between inorganic and organic polymers and have unusual material properties. Polyphosphazenes have found industrial applications, mainly because of their high thermal stability. They have also been used in investigations for the formulation of controlled drug delivery systems (Allcock, 1990). Polyphosphazenes are interesting biomaterials, in many respects. They have been claimed to be biocompatible and their chemical structure provides a readily accessible "pendant chain" to which various drugs, peptides, or other biological compounds can be attached and later released via hydrolysis. Polyphosphazenes have been examined for use in skeletal tissue regeneration (Laurencin *et al.*, 1993). Another novel use of polyphosphazenes is in the area of vaccine design where these materials were used as immunological adjuvants (Andrianov *et al.*, 1998).

Poly(glycolic acid) and poly(lactic acid) and their copolymers are currently the most widely investigated, and most commonly used synthetic, bioerodible polymers. In view of their importance in the field of biomaterials, their properties and applications will be described in more detail.

Poly(glycolic acid) (PGA) is the simplest linear, aliphatic polyester (Fig. 1). Since PGA is highly crystalline, it has a high melting point and low solubility in organic solvents. PGA was used in the development of the first totally synthetic, absorbable suture. PGA sutures have been commercially available under the trade name "Dexon" since 1970. A practical limitation of Dexon sutures is that they tend to lose their mechanical strength rapidly, typically over a period of 2 to 4 weeks after implantation. PGA has also been used in the design of internal bone fixation devices (bone pins). These pins have become commercially available under the trade name "Biofix."

In order to adapt the materials properties of PGA to a wider range of possible applications, copolymers of PGA with the more hydrophobic poly(lactic acid) (PLA) were intensively investigated (Gilding and Reed, 1979, 1981). The hydrophobicity of PLA limits the water uptake of thin films to about 2% and reduces the rate of backbone hydrolysis as compared to PGA. Copolymers of glycolic acid and lactic acid have been developed as alternative sutures (trade names "Vicryl" and "Polyglactin 910").

It is noteworthy that there is no linear relationship between the ratio of glycolic acid to lactic acid and the physicochemical properties of the corresponding copolymers. Whereas PGA is highly crystalline, crystallinity is rapidly lost in copolymers of glycolic acid and lactic acid. These morphological changes lead to an increase in the rates of hydration and hydrolysis. Thus, 50:50 copolymers degrade more rapidly than either PGA or PLA.

Since lactic acid is a chiral molecule, it exists in two stereoisomeric forms that give rise to four morphologically distinct polymers: the two stereoregular polymers, D-PLA and L-PLA, and the racemic form D,L-PLA. A fourth morphological form, meso-PLA, can be obtained from D,L-lactide but is rarely used in practice.

The polymers derived from the optically active D and L monomers are semicrystalline materials, while the optically inactive D,L-PLA is always amorphous. Generally, L-PLA is more frequently employed than D-PLA, since the hydrolysis of L-PLA yields L(+)-lactic acid, which is the naturally occurring stereoisomer of lactic acid.

The differences in the crystallinity of D,L-PLA and L-PLA have important practical ramifications: Since D,L-PLA is an amorphous polymer, it is usually considered for applications such as drug delivery, where it is important to have a homogeneous dispersion of the active species within the carrier matrix. On the other hand, the semicrystalline L-PLA is preferred in applications where high mechanical strength and toughness are required, such as sutures and orthopedic devices.

PLA and PGA and their copolymers have been investigated for more applications than any other degradable polymer. The high interest in these materials is based, not on their superior materials properties, but mostly on the fact that these polymers have already been used successfully in a number of approved medical implants and are considered safe, nontoxic, and biocompatible by regulatory agencies in virtually all developed countries. Therefore, implantable devices prepared from PLA, PGA, or their copolymers can be brought to market in less time and for a lower cost than similar devices prepared from novel polymers whose biocompatibility is still unproven.

Currently available and approved products include sutures, GTR membranes for dentistry, bone pins, and implantable drug delivery systems. The polymers are also being widely investigated in the design of vascular and urological stents and skin substitutes, and as scaffolds for tissue engineering and tissue reconstruction. In many of these applications, PLA, PGA, and their copolymers have performed with moderate to high degrees of success. However, there are still unresolved issues: First, in tissue culture experiments, most cells do not attach to PLA or PGA surfaces and do not grow as vigorously as on the surface of other materials, indicating that these polymers are actually poor substrates for cell growth *in vitro*. The significance of this finding for the use of PLA and PGA as tissue engineering scaffolds *in vivo* is currently a topic of debate. Second, the degradation products of PLA and PGA are relatively strong acids (lactic acid and glycolic acid). When these degradation products accumulate at the implant site, a delayed inflammatory response is often observed months to years after implantation (Bergsma *et al.*, 1995; Athanasiou *et al.*, 1998; Törmälä *et al.*, 1998).

APPLICATIONS OF SYNTHETIC, DEGRADABLE POLYMERS AS BIOMATERIALS

Classification of Degradable Medical Implants

Some typical short-term applications of biodegradable polymers are listed in Table 2. From a practical perspective, it is convenient to distinguish between five main types of degradable implants: the temporary support device, the temporary barrier, the drug delivery device, the tissue engineering scaffold, and the multifunctional implant.

A *temporary support device* is used in those circumstances in which the natural tissue bed has been weakened by disease, injury, or surgery and requires some artificial support. A healing wound, a broken bone, or a damaged blood vessel are examples of such situations. Sutures, bone fixation devices (e.g., bone nails, screws, or plates), and vascular grafts would be examples of the corresponding support devices. In all of these instances, the degradable implant would provide temporary, mechanical support until the natural tissue heals and regains its strength. In order for a temporary support device to work properly, a gradual stress transfer should occur: As the natural tissue heals, the degradable implant should gradually weaken. The need to adjust the degradation rate of the temporary support device to the healing of the surrounding tissue represents one of the major challenges in the design of such devices.

Currently, sutures represent the most successful example of a temporary support device. The first synthetic, degradable sutures were made of poly(glycolic acid) (PGA) and became available under the trade name "Dexon" in 1970. This represented the first routine use of a degradable polymer in a major clinical application (Frazza and Schmitt, 1971). Later copolymers of PGA and poly(lactic acid) (PLA) were developed. The widely used "Vicryl" suture, for example, is a 90:10 copolymer of PGA/PLA, introduced into the market in 1974.

TABLE 2 Some "Short-Term" Medical Applications of Degradable Polymeric Biomaterials

Application	Comments
Sutures	The earliest, successful application of synthetic degradable polymers in human medicine.
Drug delivery devices	One of the most widely investigated medical applications for degradable polymers.
Orthopedic fixation devices	Requires polymers of exceptionally high mechanical strength and stiffness.
Adhesion prevention	Requires polymers that can form soft membranes or films.
Temporary vascular grafts and stents made of degradable polymers	Only investigational devices are presently available. Blood compatibility is a major concern.
Tissue engineering or guided tissue regeneration scaffold	Attempts to recreate or improve native tissue function using degradable scaffolds.

Sutures made of polydioxanone (PDS) became available in the United States in 1981. In spite of extensive research efforts in many laboratories, no other degradable polymers are currently used to any significant extent in the formulation of degradable sutures.

A *temporary barrier* has its major medical use in adhesion prevention. Adhesions are formed between two tissue sections by clotting of blood in the extravascular tissue space followed by inflammation and fibrosis. If this natural healing process occurs between surfaces that were not meant to bond together, the resulting adhesion can cause pain, functional impairment, and problems during subsequent surgery. Surgical adhesions are a significant cause of morbidity and represent one of the most significant complications of a wide range of surgical procedures such as cardiac, spinal, and tendon surgery. A temporary barrier could take the form of a thin polymeric film or a meshlike device that would be placed between adhesion-prone tissues at the time of surgery. To be useful, such as temporary barrier would have to prevent the formation of scar tissue connecting adjacent tissue sections, followed by the slow resorption of the barrier material (Hill *et al.*, 1993). This sort of barrier has also been investigated for the sealing of breaches of the lung tissue that cause air leakage.

Another important example of a temporary barrier is in the field of skin reconstruction. Several products are available that are generally referred to as “artificial skin” (Beele, 2002). The first such product consists of an artificial, degradable collagen/glycosaminoglycan matrix that is placed on top of the skin lesion to stimulate the regrowth of a functional dermis. Another product consists of a degradable collagen matrix with preseeded human fibroblasts. Again, the goal is to stimulate the regrowth of a functional dermis. These products are used in the treatment of burns and other deep skin lesions and represent an important application for temporary barrier type devices.

An *implantable drug delivery device* is by necessity a temporary device, as the device will eventually run out of drug or the need for the delivery of a specific drug is eliminated once the disease is treated. The development of implantable drug delivery systems is probably the most widely investigated application of degradable polymers (Langer, 1990). One can expect that the future acceptance of implantable drug delivery devices by physicians and patients alike will depend on the availability of degradable systems that do not have to be explanted surgically.

Since poly(lactic acid) and poly(glycolic acid) have an extensive safety profile based on their use as sutures, these polymers have been very widely investigated in the formulation of implantable controlled release devices. Several implantable, controlled release formulations based on copolymers of lactic and glycolic acid have already become available. However, a very wide range of other degradable polymers have been investigated as well. Particularly noteworthy is the use of a type of polyanhydride in the formulation of an intracranial, implantable device for the administration of BCNU (a chemotherapeutic agent) to patients suffering from glioblastoma multiforme, a usually lethal form of brain cancer (Chasin *et al.*, 1990).

The term *tissue engineering scaffold* will be used in this chapter to describe a degradable implant that is designed to act

as an artificial extracellular matrix by providing space for cells to grow into and to reorganize into functional tissue (James and Kohn, 1996).

It has become increasingly obvious that manmade implantable prostheses do not function as well as the native tissue or maintain the functionality of native tissue over long periods of time. Therefore, tissue engineering has emerged as an interdisciplinary field that utilizes degradable polymers, among other substrates and biologics, to develop treatments that will allow the body to heal itself without the need for permanently implanted, artificial prosthetic devices. In the ideal case, a tissue engineering scaffold is implanted to restore lost tissue function, maintain tissue function, or enhance existing tissue function (Langer and Vacanti, 1993). These scaffolds can take the form of a feltlike material obtained from knitted or woven fibers or from fiber meshes. Alternatively, various processing techniques can be used to obtain foams or sponges. For all tissue engineering scaffolds, pore interconnectivity is a key property, as cells need to be able to migrate and grow throughout the entire scaffold. Thus, industrial foaming techniques, used for example in the fabrication of furniture cushions, are not applicable to the fabrication of tissue engineering scaffolds, as these industrial foams are designed contain “closed pores,” whereas tissue engineering scaffolds require an “open pore” structure. Tissue engineering scaffolds may be preseeded with cells *in vitro* prior to implantation. Alternatively, tissue engineering scaffolds may consist of a cell-free structure that is invaded and “colonized” by cells only after its implantation. In either case, the tissue engineering scaffold must allow the formation of functional tissue *in vivo*, followed by the safe resorption of the scaffold material.

There has been some debate in the literature as to the exact definition of the related term “guided tissue regeneration” (GTR). Guided tissue regeneration is a term traditionally used in dentistry. This term sometimes implies that the scaffold encourages the growth of specific types of tissue. For example, in the treatment of periodontal disease, periodontists use the term “guided tissue regeneration” when using implants that favor new bone growth in the periodontal pocket over soft-tissue ingrowth (scar formation).

One of the major challenges in the design of tissue engineering scaffolds is the need to adjust the rate of scaffold degradation to the rate of tissue healing. Depending upon the application the scaffold, the polymer may need to function on the order of days to months. Scaffolds intended for the reconstruction of bone illustrate this point: In most applications, the scaffold must maintain some mechanical strength to support the bone structure while new bone is formed. Premature degradation of the scaffold material can be as detrimental to the healing process as a scaffold that remains intact for excessive periods of time. The future use of tissue engineering scaffolds has the potential to revolutionize the way aging-, trauma-, and disease-related loss of tissue function can be treated.

Multifunctional devices, as the name implies, combine several of the functions just mentioned within one single device. Over the past few years, there has been a trend toward increasingly sophisticated applications for degradable biomaterials. Usually, these applications envision the combination of several functions within the same device and require the

design of custom-made materials with a narrow range of predetermined materials properties. For example, the availability of biodegradable bone nails and bone screws made of ultrahigh-strength poly(lactic acid) opens the possibility of combining the “mechanical support” function of the device with a “site-specific drug delivery” function: a biodegradable bone nail that holds the fractured bone in place can simultaneously stimulate the growth of new bone tissue at the fracture site by slowly releasing bone growth factors (e.g., bone morphogenic protein or transforming growth factor β) throughout its degradation process.

Likewise, biodegradable stents for implantation into coronary arteries are currently being investigated (Agrawal *et al.*, 1992). The stents are designed to mechanically prevent the collapse and restenosis (reblocking) of arteries that have been opened by balloon angioplasty. Ultimately, the stents could deliver an antiinflammatory or antithrombogenic agent directly to the site of vascular injury. Again, it would potentially be possible to combine a mechanical support function with site specific drug delivery.

Various functional combinations involve the tissue engineering scaffold. Perhaps the most important multifunctional device for future applications is a tissue engineering scaffold that also serves as a drug delivery system for cytokines, growth hormones, or other agents that directly affect cells and tissue within the vicinity of the implanted scaffold. An excellent example for this concept is a bone regeneration scaffold that is placed within a bone defect to allow the regeneration of bone while releasing bone morphogenic protein (BMP) at the implant site. The release of BMP has been reported to stimulate bone growth and therefore has the potential to accelerate the healing rate. This is particularly important in older patients whose natural ability to regenerate tissues may have declined.

The Process of Bioerosion

One of the most important prerequisites for the successful use of a degradable polymer for any medical application is a thorough understanding of the way the device will degrade/erode and ultimately resorb from the implant site. Within the context of this chapter, we are limiting our discussion to the case of a solid, polymeric implant. The transformation of such an implant into water-soluble material(s) is best described by the term “bioerosion.” The bioerosion process of a solid, polymeric implant is associated with macroscopic changes in the appearance of the device, changes in its physicochemical properties and in physical processes such as swelling, deformation, or structural disintegration, weight loss, and the eventual depletion of drug or loss of function.

All of these phenomena represent distinct and often independent aspects of the complex bioerosion behavior of a specific polymeric device. It is important to note that the bioerosion of a solid device is not necessarily due to the chemical cleavage of the polymer backbone or the chemical cleavage of cross-links or side chains. Rather, simple solubilization of the intact polymer, for instance, due to changes in pH, may also lead to the erosion of a solid device.

Two distinct modes of bioerosion have been described in the literature. In “bulk erosion,” the rate of water penetration

into the solid device exceeds the rate at which the polymer is transformed into water-soluble material(s). Consequently, the uptake of water is followed by an erosion process that occurs throughout the entire volume of the solid device. Because of the rapid penetration of water into the matrix of hydrophilic polymers, most of the currently available polymers will give rise to bulk eroding devices. In a typical “bulk erosion” process, cracks and crevices will form throughout the device that may rapidly crumble into pieces. A good illustration for a typical bulk erosion process is the disintegration of an aspirin tablet that has been placed into water. Depending on the specific application, the often uncontrollable tendency of bulk eroding devices to crumble into little pieces can be a disadvantage.

Alternatively, in “surface erosion,” the bioerosion process is limited to the surface of the device. Therefore, the device will become thinner with time, while maintaining its structural integrity throughout much of the erosion process. In order to observe surface erosion, the polymer must be hydrophobic to impede the rapid imbibition of water into the interior of the device. In addition, the rate at which the polymer is transformed into water-soluble material(s) has to be fast relative to the rate of water penetration into the device. Under these conditions, scanning electron microscopic evaluation of surface eroding devices has sometimes shown a sharp border between the eroding surface layer and the intact polymer in the core of the device (Mathiowitz *et al.*, 1990).

Surface eroding devices have so far been obtained only from a small number of hydrophobic polymers containing hydrolytically highly reactive linkages in the backbone. A possible exception to this general rule is enzymatic surface erosion. The inability of enzymes to penetrate into the interior of a solid, polymeric device may result in an enzyme-mediated surface erosion mechanism. Currently, polyanhydrides and poly(ortho esters) are the best known examples of polymers that can be fabricated into surface eroding devices.

Mechanisms of Chemical Degradation

Although bioerosion can be caused by the solubilization of an intact polymer, chemical degradation of the polymer is usually the underlying cause for the bioerosion of a solid, polymeric device. Several distinct types of chemical degradation mechanisms have been identified (Fig. 2) (Rosen *et al.*, 1988). Chemical reactions can lead to cleavage of crosslinks between water-soluble polymer chains (mechanism I), to the cleavage of polymer side chains resulting in the formation of polar or charged groups (mechanism II), or to the cleavage of the polymer backbone (mechanism III). Obviously, combinations of these mechanisms are possible: for instance, a cross-linked polymer may first be partially solubilized by the cleavage of crosslinks (mechanism I), followed by the cleavage of the backbone itself (mechanism III). It should be noted that water is key to all of these degradation schemes. Even enzymatic degradation occurs in aqueous environment.

Since the chemical cleavage reactions described above can be mediated by water or by biological agents such as enzymes and microorganisms, it is possible to distinguish between hydrolytic degradation and biodegradation, respectively. It has often been

FIG. 2. Mechanisms of chemical degradation. Mechanism I involves the cleavage of degradable cross-links between water-soluble polymer chains. Mechanism II involves the cleavage or chemical transformation of polymer side chains, resulting in the formation of charged or polar groups. The presence of charged or polar groups leads then to the solubilization of the intact polymer chain. Mechanism III involves the cleavage of unstable linkages in the polymer backbone, followed by solubilization of the low-molecular-weight fragments.

stated that the availability of water is virtually constant in all soft tissues and varies little from patient to patient. On the other hand, the levels of enzymatic activity may vary widely not only from patient to patient but also between different tissue sites in the same patient. Thus polymers that undergo hydrolytic cleavage tend to have more predictable *in vivo* erosion rates than polymers whose degradation is mediated predominantly by enzymes. The latter polymers tend to be generally less useful as degradable medical implants.

Factors That Influence the Rate of Bioerosion

Although the solubilization of intact polymer as well as several distinct mechanisms of chemical degradation have been recognized as possible causes for the observed bioerosion of a solid, polymeric implant, virtually all currently available

implant materials erode because of the hydrolytic cleavage of the polymer backbone (mechanism III in Fig. 2). We therefore limit the following discussion to solid devices that bioerode because of the hydrolytic cleavage of the polymer backbone.

In this case, the main factors that determine the overall rate of the erosion process are the chemical stability of the hydrolytically susceptible groups in the polymer backbone, the hydrophilic/hydrophobic character of the repeat units, the morphology of the polymer, the initial molecular weight and molecular weight distribution of the polymer, the device fabrication process used to prepare the device, the presence of catalysts, additives, or plasticizers, and the geometry (specifically the surface area to volume ratio) of the implanted device.

The susceptibility of the polymer backbone toward hydrolytic cleavage is probably the most fundamental parameter. Generally speaking, anhydrides tend to hydrolyze

faster than ester bonds that in turn hydrolyze faster than amide bonds. Thus, polyanhydrides will tend to degrade faster than polyesters that in turn will have a higher tendency to bioerode than polyamides. Based on the known susceptibility of the polymer backbone structure toward hydrolysis, it is possible to make predictions about the bioerosion of a given polymer.

However, the actual erosion rate of a solid polymer cannot be predicted on the basis of the polymer backbone structure alone. The observed erosion rate is strongly dependent on the ability of water molecules to penetrate into the polymeric matrix. The hydrophilic versus hydrophobic character of the polymer, which is a function of the structure of the monomeric starting materials, can therefore have an overwhelming influence on the observed bioerosion rate. For instance, the erosion rate of polyanhydrides can be slowed by about three orders of magnitude when the less hydrophobic sebacic acid is replaced by the more hydrophobic bis(carboxy phenoxy)propane as the monomeric starting material. Likewise, devices made of poly(glycolic acid) erode faster than identical devices made of the more hydrophobic poly(lactic acid), although the ester bonds have about the same chemical reactivity toward water in both polymers.

The observed bioerosion rate is further influenced by the morphology of the polymer. Polymers can be classified as either semicrystalline or amorphous. At body temperature (37°C) amorphous polymers with T_g above 37°C will be in a glassy state, and polymers with a T_g below 37°C will be in a rubbery state. In this discussion it is therefore necessary to consider three distinct morphological states: semicrystalline, amorphous-glassy, and amorphous-rubbery.

In the crystalline state, the polymer chains are densely packed and organized into crystalline domains that resist the penetration of water. Consequently, backbone hydrolysis tends to occur in the amorphous regions of a semicrystalline polymer and at the surface of the crystalline regions. This phenomenon is of particular importance to the erosion of devices made of poly(L-lactic acid) and poly(glycolic acid) which tend to have high degrees of crystallinity around 50%.

Another good illustration of the influence of the polymer morphology on the rate of bioerosion is provided by a comparison of poly(L-lactic acid) and poly(D, L-lactic acid): Although these two polymers have chemically identical backbone structures and an identical degree of hydrophobicity, devices made of poly(L-lactic acid) tend to degrade much more slowly than identical devices made of poly(D, L-lactic acid). The slower rate of bioerosion of poly poly(L-lactic acid) is due to the fact that this stereoregular polymer is semicrystalline, while the racemic poly(D, L-lactic acid) is an amorphous polymer.

Likewise, a polymer in its glassy state is less permeable to water than the same polymer when it is in its rubbery state. This observation could be of importance in cases where an amorphous polymer has a glass transition temperature that is not far above body temperature (37°C). In this situation, water sorption into the polymer could lower its T_g below 37°C, resulting in abrupt changes in the bioerosion rate.

The manufacturing process may also have a significant effect on the erosion profile. For example, Mathiowitz and co-workers (Mathiowitz *et al.*, 1990) showed that polyanhydride microspheres produced by melt encapsulation were

very dense and eroded slowly, whereas when the same polymers were formed into microspheres by solvent evaporation, the microspheres were very porous (and therefore more water permeable) and eroded more rapidly.

The preceding examples illustrate an important technological principle in the design of bioeroding devices: The bioerosion rate of a given polymer is not an unchangeable property, but depends to a very large degree on readily controllable factors such as the presence of plasticizers or additives, the manufacturing process, the initial molecular weight of the polymer, and the geometry of the device.

Storage Stability, Sterilization, and Packaging

It is important to minimize premature polymer degradation during fabrication and storage. Traces of moisture can seriously degrade even relatively stable polymers such as poly(bisphenol A carbonate) during injection molding or extrusion. Degradable polymers are particularly sensitive to hydrolytic degradation during high-temperature processing. The industrial production of degradable implants therefore often requires the construction of "controlled atmosphere" facilities where the moisture content of the polymer and the ambient humidity can be strictly controlled.

After fabrication, γ -irradiation or exposure to ethylene oxide may be used for the sterilization of degradable implants. Both methods have disadvantages and as a general rule, the choice is between the lesser of two evils. γ -Irradiation at a dose of 2 to 3 Mrad can result in significant backbone degradation. Since the aliphatic polyesters PLA, PGA, and PDS are particularly sensitive to radiation damage, these materials are usually sterilized by exposure to ethylene oxide and not by γ -irradiation. Unfortunately, the use of the highly dangerous ethylene oxide gas represents a serious safety hazard as well as potentially leaving residual traces in the polymeric device. Polymers sterilized with ethylene oxide must be degassed for extended periods of time.

Additionally, for applications in tissue engineering, biodegradable scaffolds may be preseeded with viable cells or may be impregnated with growth factors or other biologics. There is currently no method that could be used to sterilize scaffolds that contain viable cells without damaging the cells. Therefore, such products must be manufactured under sterile conditions and must be used within a very short time after manufacture. Currently, a small number of products containing preseeded, living cells are in clinical use. These products are extremely expensive, are shipped in special containers, and have little or no shelf life.

Likewise, it has been shown that sterilization of scaffolds containing osteoinductive or chondroinductive agents leads to significant losses in bioactivity, depending on the sterilization method used (Athanasίου *et al.*, 1998). The challenge of producing tissue engineering scaffolds that are preseeded with viable cells or that contain sensitive biological agents has not yet been fully solved.

After sterilization, degradable implants are usually packaged in air-tight aluminum-backed plastic-foil pouches. In some cases, refrigeration may also be required to prevent backbone degradation during storage.

2.8 NATURAL MATERIALS

Ioannis V. Yannas

Natural polymers offer the advantage of being very similar, often identical, to macromolecular substances which the biological environment is prepared to recognize and to deal with metabolically (Table 1). The problems of toxicity and stimulation of a chronic inflammatory reaction, as well as lack of recognition by cells, which are frequently provoked by many synthetic polymers, may thereby be suppressed. Furthermore, the similarity to naturally occurring substances introduces the interesting capability of designing biomaterials that function biologically at the molecular, rather than the macroscopic, level. On the other hand, natural polymers are frequently quite immunogenic. Furthermore, because they are structurally much more complex than most synthetic polymers, their technological manipulation is quite a bit more elaborate. On balance, however, these opposing factors have conspired to lead to a substantial number of biomaterials applications in which naturally occurring polymers, or their chemically modified versions, have provided unprecedented solutions.

An intriguing characteristic of natural polymers is their ability to be degraded by naturally occurring enzymes, a virtual guarantee that the implant will be eventually metabolized by physiological mechanisms. This property may, at first glance,

appear as a disadvantage since it detracts from the durability of the implant. However, it has been used to advantage in biomaterials applications in which it is desired to deliver a specific function for a temporary period of time, following which the implant is expected to degrade completely and to be disposed of by largely normal metabolic processes. Since, furthermore, it is possible to control the degradation rate of the implanted polymer by chemical cross-linking or other chemical modifications, the designer is offered the opportunity to control the lifetime of the implant.

A potential problem to be dealt with when proteins are used as biomaterials is their frequently significant immunogenicity, which, of course, derives precisely from their similarity to naturally occurring substances. The immunological reaction of the host to the implant is directed against selected sites (antigenic determinants) in the protein molecule. This reaction can be mediated by molecules in solution in body fluids (immunoglobulins). A single such molecule (antibody) binds to single or multiple determinants on an antigen. The immunological reaction can also be mediated by molecules that are held tightly to the surface of immune cells (lymphocytes). The implant is eventually degraded. The reaction can be virtually eliminated provided that the antigenic determinants have been previously modified chemically. The immunogenicity of polysaccharides is typically far lower than that of proteins. The collagens are generally weak immunogens relative to the majority of proteins.

Another potential problem in the use of natural polymers as biomaterials derives from the fact that these polymers typically decompose or undergo pyrolytic modification at temperatures below the melting point, thereby precluding the convenience of high-temperature thermoplastics processing methods, such as melt extrusion, during the manufacturing of the implant. However, processes for extruding these temperature-sensitive polymers at room temperature have been developed. Another serious disadvantage is the natural variability in structure of macromolecular substances which are derived from animal sources. Each of these polymers appears as a chemically distinct entity not only from one species to another (species specificity) but also from one tissue to the next (tissue specificity). This testimonial to the elegance of the naturally evolved design of the mammalian body becomes a problem for the manufacturer of implants, which are typically required to adhere to rigid specifications from one batch to the next. Consequently, relatively stringent methods of control of the raw material must be used.

Most of the natural polymers in use as biomaterials today are constituents of the extracellular matrix (ECM) of connective tissues such as tendons, ligaments, skin, blood vessels, and bone. These tissues are deformable, fiber-reinforced composite materials of organ shape as well as of the organism itself. In the relatively crude description of these tissues as if they were manmade composites, collagen and elastin fibers mechanically reinforce a “matrix” that primarily consists of protein polysaccharides (proteoglycans) highly swollen in water. Extensive chemical bonding connects these macromolecules to each other, rendering these tissues insoluble and, therefore, impossible to characterize with dilute solution methods unless the tissue is chemically and physically degraded. In the latter case, the solubilized components are subsequently extracted and

TABLE 1 General Properties of Certain Natural Polymers

	Polymer	Incidence	Physiological function
A. Proteins	Silk	Synthesized by arthropods	Protective cocoon
	Keratin	Hair	Thermal insulation
	Collagen	Connective tissues (tendon, skin, etc.)	Mechanical support
	Gelatin	Partly amorphous collagen	(Industrial product)
	Fibrinogen	Blood	Blood clotting
	Elastin	Neck ligament	Mechanical support
	Actin	Muscle	Contraction, motility
B. Polysaccharides	Myosin	Muscle	Contraction, motility
	Cellulose (cotton)	Plants	Mechanical support
	Amylose	Plants	Energy reservoir
	Dextran	Synthesized by bacteria	Matrix for growth of organism
	Chitin	Insects, crustaceans	Provides shape and form
C. Polynucleotides	Glycosaminoglycans	Connective tissues	Contributes to mechanical support
	Deoxyribonucleic acids (DNA)	Cell nucleus	Direct protein biosynthesis
	Ribonucleic acids (RNA)	Cell nucleus	Direct protein biosynthesis

characterized by biochemical and physicochemical methods. Of the various components of extracellular materials that have been used to fashion biomaterials, collagen is the one most frequently used. Other important components, to be discussed later, include the proteoglycans and elastin.

Almost inevitably, the physicochemical processes used to extract the individual polymer from tissues, as well as subsequent deliberate modifications, alter the native structure, sometimes significantly. The description in this section emphasizes the features of the naturally occurring, or native, macromolecular structures. Certain modified forms of these polymers are also described.

STRUCTURE OF NATIVE COLLAGEN

Structural order in collagen, as in other proteins, occurs at several discrete levels of the structural hierarchy. The collagen in the tissues of a vertebrate occurs in at least 10 different forms, each of these being predominant in a specific tissue. Structurally, these collagens share the characteristic triple helix, and variations among them are restricted to the length of the nonhelical fraction, as well as the length of the helix itself and the number and nature of carbohydrates attached on the triple helix. The collagen in skin, tendon, and bone is mostly type I collagen. Type II collagen is predominant in cartilage, while type III collagen is a major constituent of the blood vessel wall as well as being a minor contaminant of type I collagen in skin. In contrast to these collagens, all of which form fibrils with the distinct collagen periodicity, type IV collagen, a constituent of the basement membrane that separates epithelial tissues from mesodermal tissues, is largely nonhelical and does not form fibrils. We follow here the nomenclature that was proposed by W. Kauzmann (1959) to describe in a general way the structural order in proteins, and we specialize it to the case of type I collagen (Fig. 1).

The primary structure denotes the complete sequence of amino acids along each of three polypeptide chains as well as the location of interchain cross-links in relation to this sequence. Approximately one-third of the residues are glycine and another quarter or so are proline or hydroxyproline. The structure of the bifunctional interchain cross-link is the relatively complex condensation product of a reaction involving lysine and hydroxylysine residues; this reaction continues as the organism matures, thereby rendering the collagens of older animals more difficult to extract from tissues.

The secondary structure is the local configuration of a polypeptide chain that results from satisfaction of stereochemical angles and hydrogen-bonding potential of peptide residues. In collagen, the abundance of glycine residues (Gly) plays a key configurational role in the triplet Gly-X-Y, where X and Y are frequently proline or hydroxyproline, respectively, the two amino acids that control the chain configuration locally by the very rigidity of their ring structures. On the other hand, the absence of a side chain in glycine permits close approach of polypeptide chains in the collagen triple helix.

Tertiary structure refers to the global configuration of the polypeptide chains; it represents the pattern according to which the secondary structure is packed within the complete macromolecule and it constitutes the structural unit that can exist as a physicochemically stable entity in solution, namely, the triple helical collagen molecule.

In type I collagen, two of the three polypeptide chains have identical amino acid composition, consisting of 1056 residues and are termed $\alpha 1(I)$ chains, while the third has a different composition, it consists of 1038 residues and is termed $\alpha 2(I)$. The three polypeptide chains fold to produce a left-handed helix, whereas the three-chain supercoil is actually right-handed with an estimated pitch of about 100 nm (30–40 residues). The helical structure extends over 1014 of the residues in each of the three chains, leaving the remaining residues at the ends (telopeptides) in a nonhelical configuration. The residue

spacing is 0.286 nm and the length of the helical portion of the molecule is, therefore, 1014×0.286 or 290 nm long.

The fourth-order or quaternary structure denotes the repeating supermolecular unit structure, comprising several molecules packed in a specific lattice, which constitutes the basic element of the solid state (microfibril). Collagen molecules are packed in a quasi-hexagonal lattice at an inter-chain distance of about 1.3 nm, which shrinks considerably when the microfibril is dehydrated. Adjacent molecules in the microfibril are approximately parallel to the fibril axis; they all point in the same direction along the fibril and are staggered regularly, giving rise to the well-known D-period of collagen, about 64 nm, which is visible in the electron microscope. Higher levels of order, eventually leading to gross anatomical features that can be readily seen with the naked eye, have been proposed, but there is no general agreement on their definition.

BIOLOGICAL EFFECTS OF PHYSICAL MODIFICATIONS OF THE NATIVE STRUCTURE OF COLLAGEN

Crystallinity in collagen can be detected at two discrete levels of structural order: the tertiary (triple helix) (Fig. 1C) and the quaternary (lattice of triple helices) (Fig. 1D). Each of these levels of order corresponds, interestingly enough, to a separate melting transformation. A solution of collagen triple helices is thus converted to the randomly coiled gelatin by heating above the helix-coil transition temperature, which is approximately 37°C for bovine collagen, or by exceeding a critical concentration of certain highly polarizable anions, e.g., bromide or thiocyanate, in the solution of collagen molecules. Infrared spectroscopic procedures, based on helical marker bands in the mid- and far infrared, have been developed to assay the gelatin content of collagen in the solid or semisolid states in which collagen is commonly used as an implant. Since implanted gelatin is much more rapidly degradable than collagen, a characteristic that can seriously affect implant performance, these assays are essential tools for quality control of collagen-based biomaterials. Frequently, such biomaterials have been processed under manufacturing conditions that may threaten the integrity of the triple helix.

Collagen fibers also exhibit a characteristic banding pattern with a period of about 65 nm (quaternary structure). This pattern is lost reversibly when the pH of a suspension of collagen fibers in acetic acid is lowered below 4.25 ± 0.30 . Transmission electron microscopy or small-angle X-ray diffraction can be used to determine the fraction of fibrils that possess banding as the pH of the system is altered. During this transformation, which appears to be a first-order thermodynamic transition, the triple helical structure remains unchanged. Changes in pH can, therefore, be used to selectively abolish the quaternary structure while maintaining the tertiary structure intact.

This experimental strategy has made it possible to show that the well-known phenomenon of blood platelet aggregation by collagen fibers (the reason for use of collagen sponges as hemostatic devices) is a specific property of the quaternary rather than of the tertiary structure. Thus collagen that is thromboresistant *in vitro* has been prepared by selectively “melting out” the packing order of helices while preserving the triple helices themselves. Figure 2 illustrates the banding pattern of such collagen fibers. Notice that short segments of banded fibrils persist even after very long treatment at low pH, occasionally interrupting long segments of nonbanded fibrils (Fig. 2, inset).

The porosity of a collagenous implant normally makes an indispensable contribution to its performance. A porous structure provides an implant with two critical functions. First, pore channels are ports of entry for cells migrating from adjacent tissues into the bulk of the implant for tissue serum (exudate) that enters via capillary suction or of blood from a hemorrhaging blood vessel nearby. Second, pores endow a material with a frequently enormous specific surface that is made available either for specific interactions with invading cells (e.g., myofibroblasts bind extensively on the surface of porous collagen-glycosaminoglycan copolymer structures that induce regeneration of skin in burned patients) or for interaction with coagulation factors in blood flowing into the device (e.g., hemostatic sponges).

Pores can be incorporated by first freezing a dilute suspension of collagen fibers and then inducing sublimation of the ice crystals by exposing the suspension to low-temperature vacuum. The resulting pore structure is a negative replica of the network of ice crystals (primarily dendrites). It follows that

FIG. 1. Collagen, like other proteins, is distinguished by several levels of structural order. (A) Primary structure—the complete sequence of amino acids along each polypeptide chain. An example is the triple chain sequence of type I calf skin collagen at the N-end of the molecule. Roughly 5% of a complete molecule is shown above. No attempt has been made to indicate the coiling of the chains. Amino acid residues participating in the triple helix are numbered, and the residue-to-residue spacing (0.286 nm) is shown as a constant within the triple helical domain, but not outside it. Bold capitals indicate charged residues which occur in groups (underlined) (Reprinted from J. A. Chapman and D. J. S. Hulmes (1984). In *Ultrastructure of the Connective Tissue Matrix*, A. Ruggeri and P. M. Motta, eds. Martinus Nijhoff, Boston, Chap. 1, Fig. 1, p. 2, with permission.) (B) Secondary structure—the local configuration of a polypeptide chain. The triplet sequence Gly-Pro-Hyp illustrates elements of collagen triple-helix stabilization. The numbers identify peptide backbone atoms. The conformation is determined by trans peptide bonds (3-4, 6-7, and 9-1); fixed rotation angle of bond in proline ring (4-5); limited rotation of proline past the C=O group (bond 5-6); interchain hydrogen bonds (dots) involving the NH hydrogen at position 1 and the C=O at position 6 in adjacent chains; and the hydroxy group of hydroxyproline, possibly through water-bridged hydrogen bonds. (Reprinted from K. A. Piez and A. H. Reddi, editors (1984). *Extracellular Matrix Biochemistry*. Elsevier, New York, Chap. 1, Fig 1.6. p. 7, with permission.) (C) Tertiary structure—the global configuration of polypeptide chains, representing the pattern according to which the secondary structures are packed together within the unit substructure. A schematic view of the type I collagen molecule, a triple helix 300 nm long. (Reprinted from K. A. Piez and A. H. Reddi, editors (1984). *Extracellular Matrix Biochemistry*. Elsevier, New York, Chap. 1, Fig. 1.22, p. 29, with permission.) (D) Quaternary structure—the unit supermolecular structure. The most widely accepted unit is one involving five collagen molecules (microfibril). Several microfibrils aggregate end to end and also laterally to form a collagen fiber that exhibits a regular banding pattern in the electron microscope with a period of about 65 nm. (Reprinted from E. Nimni, editor (1988). *Collagen*, Vol. I, Biochemistry, CRC Press, Boca Raton, FL Chap. 1, Fig. 10, p. 14, with permission.)

FIG. 2. Following exposure to $\text{pH } 4.25 \pm 0.30$ the banding pattern of type I bovine hide collagen practically disappears. Short lengths of banded collagen (B) do, however, persist next to very long lengths of nonbanded collagen (NB), which has tertiary but not quaternary structure. This preparation does not induce platelet aggregation provided that the fibers are prevented from recrystallizing to form banded structures when the pH is adjusted to neutral in order to perform the platelet assay. Stained with 0.5 wt.% phosphotungstic acid. Banded collagen period, about 65 nm. Original magnification: 15,000 \times . Inset original mag.: 75,000 \times . (Reprinted from M. J. Forbes, M. S. dissertation, Massachusetts Institute of Technology, 1980, courtesy of MIT.)

FIG. 3. Illustration of the variety of porous structures that can be obtained with collagen–GAG copolymers by adjusting the kinetics of crystallization of ice to the appropriate magnitude and direction. Pores form when the ice dendrites are eventually sublimated. Scanning electron microscopy. (Courtesy of MIT.)

control of the conditions for ice nucleation and growth can lead to a large variety of pore structures (Fig. 3).

In practice, the average pore diameter decreases with decreasing temperature of freezing while the orientation of pore channel axes depends on the magnitude of the major heat flux vector during freezing. In experimental implants the mean pore diameter has ranged between about 1 and 800 μm ; pore volume fractions have ranged up to 0.995; the specific surface has been varied between about 0.01 and 100 m^2/g dry matrix; and the orientation of axes of pore channels has ranged from strongly uniaxial to almost random. The ability of collagen–glycosaminoglycan copolymers to induce regeneration of tissues such as skin, the conjunctiva and peripheral nerves depends critically, among other factors, on the adjustment of the pore structure to desired levels, e.g., a pore size range of about 20–125 μm for skin regeneration and less than 10 μm for sciatic nerve regeneration appear to be mandatory. Determination of pore structure is based on principles of stereology, the discipline which allows the quantitative statistical

properties of three-dimensional structures of implants to be related to those of two-dimensional projections, e.g., sections used for histological analysis.

CHEMICAL MODIFICATION OF COLLAGEN AND ITS BIOLOGICAL CONSEQUENCES

The primary structure of collagen is made up of long sequences of some 20 different amino acids. Since each amino acid has its own chemical identity, there are 20 types of pendant side groups, each with its own chemical reactivity, attached to the polypeptide chain backbone. As examples, there are carboxylic side groups (from glutamic acid and aspartic acid residues), primary amino groups (lysine, hydroxylysine, and arginine residues), and hydroxylic groups (tyrosine and hydroxylysine). The collagen molecule is therefore subject to modification by a large variety of chemical reagents. Such versatility comes with a price: Even though the choice of

reagents is large, it is important to ascertain that use of a given reagent has actually led to modification of a substantial fraction of the residues of an amino acid in the molecule. This is equivalent to proof that a reaction has proceeded to a desired "yield." Furthermore, proof that a given reagent has attacked only a specific type of amino acid, rather than all amino acid residue types carrying the same functional group, also requires chemical analysis.

Historically, the chemical modification of collagen has been practiced in the leather industry (since about 50% of the protein content of cowhide is collagen) and in the photographic gelatin industry. Today, the increasing use of collagen in biomaterials applications has provided renewed incentive for novel chemical modification, primarily in two areas. First, implanted collagen is subject to degradative attack by collagenases, and chemical cross-linking is a well-known means of decelerating the degradation rate. Second, collagen extracted from an animal source elicits production of antibodies (immunogenicity) and chemical modification of antigenic sites may potentially be a useful way to control the immunogenic response. Although it is widely accepted that implanted collagen elicits synthesis of antibodies at a far smaller concentration than is true of most other implanted proteins, treatment with specific reagents, including enzymatic treatment, or cross-linking, is occasionally used to reduce significantly the immunogenicity of collagen.

Collagen-based implants are normally degraded by mammalian collagenases, naturally occurring enzymes that attack the triple helical molecule at a specific location. Two characteristic products result, namely, the N-terminal fragment, which amounts to about two-thirds of the molecule, and the C-terminal fragment. Both of these fragments become spontaneously transformed (denatured) to gelatin at physiological temperatures via the helix-coil transition and the gelatinized fragments are then cleaved to oligopeptides by naturally occurring enzymes that degrade several other tissue proteins (nonspecific proteases).

Collagenases are naturally present in healing wounds and are credited with a major role in the degradation of collagen fibers at the site of trauma. At about the same time that degradation of collagen and of other ECM components proceeds in the wound bed, these components are being synthesized *de novo* by cells at the same anatomical site. Eventually, new architectural arrangements of collagen fibers, such as scar tissue, are synthesized. Although it is not a replica of the intact tissue, scar tissue forms a stable endpoint to the healing process and acts as a tissue barrier that allows the healed organ to continue functioning at a nearly physiological level. One of the frequent challenges in the design of collagen implants is to modify collagen chemically in a way that the rate of its degradation at the implantation site is either accelerated or slowed down to a desired level.

An effective method for reducing the rate of degradation of collagen by naturally occurring enzymes is by chemical cross-linking. A very simple self-cross-linking procedure, dehydrative cross-linking, is based on the fact that removal of water below ca. 1 wt.% insolubilizes collagen as well as gelatin by inducing formation of interchain peptide bonds. The nature of cross-links formed can be inferred from results of studies using

chemically modified gelatins. Gelatin that had been modified either by esterification of the carboxylic groups of aspartyl and glutamyl residues, or by acetylation of the ϵ -amino groups of lysyl residues, remained soluble in aqueous solvents after exposure of the solid protein to high temperature, while unmodified gelatins lost their solubility. Insolubilization of collagen and gelatin following severe dehydration has been, accordingly, interpreted as the result of drastic removal of the aqueous product of a condensation reaction that led to formation of interchain amide links. The proposed mechanism is consistent with results, obtained by titration, showing that the number of free carboxylic groups and free amino groups in collagen are both significantly decreased following high-temperature treatment.

Removal of water to the extent necessary to achieve a density of cross-links in excess of 10^{-5} mol cross-links/g dry protein, which corresponds to an average molecular weight between crosslinks, M_c , of about 70 kDa, can be achieved within hours by exposure to temperatures in excess of 105°C under atmospheric pressure. The possibility that cross-linking achieved under these conditions is caused by a pyrolytic reaction has been ruled out. Furthermore, chromatographic data have shown that the amino acid composition of collagen remains intact after exposure to 105°C for several days. In fact, it has been observed that gelatin can be cross-linked by exposure to temperatures as low as 25°C provided that a sufficiently high vacuum is present to achieve the drastic moisture removal that drives the cross-linking reaction.

Exposure of highly hydrated collagen to temperatures in excess of ca. 37°C is known to cause reversible melting of the triple helical structure, as described earlier. The melting point of the triple helix increases with the collagen-diluent ratio from 37°C , the helix-coil transition of the infinitely dilute solution, to about 120°C for collagen swollen with as little as 20 wt.% diluent and up to 210°C , the approximate melting point of anhydrous collagen. Accordingly, it is possible to cross-link collagen using the drastic dehydration procedure described above without loss of the triple helical structure. It is simply sufficient to adjust the moisture content of collagen to a low enough level prior to exposure to the high temperature levels required for rapid dehydration.

Dialdehydes have been long known in the leather industry as effective tanning agents and in histological laboratories as useful fixatives. Both of these applications are based on the reaction between the dialdehyde and the ϵ -amino group of lysyl residues in the protein, which induces formation of interchain cross-links. Glutaraldehyde cross-linking is a relatively widely used procedure in the preparation of implantable biomaterials. Free glutaraldehyde is a toxic substance for cells; it cross-links vital cell proteins. However, clinical studies and extensive clinical use of implants have shown that the toxicity of glutaraldehyde becomes effectively negligible after the unreacted glutaraldehyde has been carefully rinsed out following reaction with an implant, e.g., one based on collagen. The nature of the cross-link formed has been the subject of controversy, primarily due to the complex, apparently polymeric, character of this reagent. Considerable evidence supports a proposed anabylsine structure, which is derived from two lysine side chains and two molecules of glutaraldehyde.

Evidence for other mechanisms has been presented. By comparison with other aldehydes, glutaraldehyde has shown itself to be a particularly effective cross-linking agent, as judged, for example, by its ability to increase the crosslink density to very high levels. Values of the average molecule weight between cross-links (M_c) provide the experimenter with a series of collagens in which the enzymatic degradation rate can be studied over a wide range, thereby affording implants that effectively disappear from tissue between a few days and several months following implantation. The mechanism of the reaction between glutaraldehyde and collagen at neutral pH is understood in part; however, the reaction in acidic media has not been studied extensively. Evidence that covalent cross-linking is involved comes from measurements of the equilibrium tensile modulus of films that have been treated to induce cross-linking and have subsequently been gelatinized by treatment in 1 M NaCl at 70°C. Under such conditions, only gelatin films that have been converted into a three-dimensional network by cross-linking support an equilibrium tensile force; by contrast, un-cross-linked specimens dissolve readily in the hot medium.

Several other methods for cross-linking collagen have been studied, including hexamethylene diisocyanate, acyl azide, and a carbodiimide, 1-ethyl-3-(3-dimethylaminopropyl) carbodiimide (EDAC).

The immunogenicity of the collagen used in implants is not insignificant and has been studied assiduously using laboratory preparations. However, the clinical significance of such immunogenicity has been shown to be very low and is often considered to be negligible. The validity of this simple approach to using collagen as a biomaterial was long ago recognized by manufacturers of collagen-based sutures. The apparent reason for the low antigenicity of type I collagen mostly stems from the small species difference among type I collagens (e.g., cow versus human). Such similarity is, in turn, probably understandable in terms of the inability of the triple helical configuration to incorporate the substantial amino acid substitutions that characterize species differences with other proteins. The relative constancy of the structure of the triple helix among the various species is, in fact, the reason why collagen is sometimes referred to as a "successful" protein in terms of its evolution or, rather, the relative lack of it.

In order to reduce the immunogenicity of collagen it is useful to consider the location of its antigenic determinants, i.e., the specific chemical groups that are recognized as foreign by the immunological system of the host animal. The configurational (or conformational) determinants of collagen depend on the presence of the intact triple helix and, consequently, are abolished when collagen is denatured into gelatin; the latter event (see earlier discussion) occurs spontaneously after the triple helix is cleaved by a collagenase. Gelatinization exposes effectively the sequential determinants of collagen over the short period during which gelatin retains its macromolecular character, before it is cleared away following attack by one of several nonspecific proteases. Control of the stability of the triple helix during processing of collagen, therefore, partially prevents the display of the sequential determinants.

Sequential determinants also exist in the nonhelical end (telopeptide region) of the collagen molecule, and this region has been associated with most of the immunogenicity of

TABLE 2 Certain Applications of Collagen-Based Biomaterials

Applications	Physical state
Sutures	Extruded tape (Schmitt, 1985)
Hemostatic agents	Powder, sponge, fleece (Stenzel <i>et al.</i> , 1974; Chvapil, 1979)
Blood vessels	Extruded collagen tube, processed human or animal blood vessel (Nimni, 1988)
Heart valves	Processed porcine heart valve (Nimni, 1988)
Tendon, ligaments	Processed tendon (Piez, 1985)
Burn treatment (dermal regeneration)	Porous collagen-glycosaminoglycan (GAG) copolymers (Yannas <i>et al.</i> , 1981, 1982, 1989; Burke <i>et al.</i> , 1981; Heimbach <i>et al.</i> , 1988)
Peripheral nerve regeneration	Porous collagen-GAG copolymers (Chang and Yannas, 1992)
Meniscus regeneration	Porous collagen-GAG copolymers (Stone <i>et al.</i> , 1989, 1997)
Skin regeneration (plastic surgery)	Porous collagen-GAG copolymers
Intradermal augmentation	Injectable suspension of collagen particles (Piez, 1985)
Gynecological applications	Sponges (Chvapil, 1979)
Drug-delivery systems	Various forms (Stenzel <i>et al.</i> , 1974; Chvapil, 1979)

collagen-based implants. Several enzymatic treatments have been devised to cleave the telopeptide region without destroying the triple helix. Treatment of collagen with glutaraldehyde not only reduces its degradation rate by collagenase but also appears to reduce its antigenicity. The mechanism of this effect is not well understood.

Certain applications of collagen-based biomaterials are shown in Table 2

PROTEOGLYCANS AND GLYCOSAMINOGLYCANS (GAG)

Glycosaminoglycans (GAGs) occur naturally as polysaccharide branches of a protein chain, or protein core, to which they are covalently attached via a specific oligosaccharide linkage. The entire branched macromolecule, which has been described as having a "bottle brush" configuration, is known as a proteoglycan and typically has a molecular weight of about 10^3 kDa.

The structure of GAGs can be generically described as that of an alternating copolymer, the repeat unit consisting of a hexosamine (glucosamine or galactosamine) and of another sugar (galactose, glucuronic acid, or iduronic acid). Individual GAG chains are known to contain occasional substitutions

FIG. 4. Repeat units of glycosaminoglycans. (Reprinted from J. Uitto and A. J. Pereira, editors (1987). *Connective Tissue Disease, Molecular Pathology of the Extracellular Matrix*, Vol. 12 in the series *The Biochemistry of Disease*. Marcel Dekker, New York, Chapter 4, Figs. 1 and 2, p. 85, with permission.)

of one uronic acid for another; however, the nature of the hexosamine component remains invariant along the chain. There are other deviations from the model of a flawless alternating copolymer, such as variations in sulfate content along the chain. It is, nevertheless, useful for the purpose of getting acquainted with the GAGs to show their typical (rather, typified) repeat unit structure, as in Fig. 4. The molecular weight of many GAGs is in the range 5–60 kDa with the exception of hyaluronic acid, the only GAG which is not sulfated; it exhibits molecular weights in the range 50–500 kDa. Sugar units along GAG chains are linked by α or β glycosidic bonds that are 1,3 or 1,4 (Fig. 4). There are several naturally occurring enzymes which degrade specific GAGs, such as hyaluronidase and chondroitinase. These enzymes are primarily responsible

for the physiological turnover rate of GAGs, which is in the range 2–14 days.

The nature of the oligosaccharide linkage appears to be identical for the GAGs, except for keratan sulfate, and is a galactosyl-galactosyl-xylose, with the last glycosidically linked to the hydroxyl group of serine in the protein core.

The very high molecular weight of hyaluronic acid is the basis of most uses of this GAG as a biomaterial: Almost all make use of the exceptionally high viscosity and the facility to form gels that characterize this polysaccharide. Hyaluronic acid gels have found considerable use in ophthalmology because they facilitate cataract surgery as well as retinal reattachment. Other reported uses of GAGs are in the treatment of degenerative joint dysfunction in horses and in

the treatment of certain orthopedic dysfunctions in humans. On the other hand, sulfated GAGs are anionically charged and can induce precipitation of collagen at acidic pH levels, a process that yields collagen-GAG coprecipitates that can be subsequently freeze-dried and covalently cross-linked to yield biomaterials that have been shown capable of inducing regeneration of skin (dermis), peripheral nerves, and the conjunctiva (Table 2).

ELASTIN

Elastin is one of the least soluble protein in the body, consisting as it does of a three-dimensional cross-linked network. It can be extracted from tissues by dissolving and degrading all adjacent substances. It appears to be highly amorphous and thus has eluded elucidation of its structure by crystallographic methods. Fortunately, it exhibits ideal rubber elasticity and it thus becomes possible to study certain features of the macromolecular network. For example, mechanical measurements have shown that the average number of amino acid units between cross-links is 71–84. Insoluble elastin preparations can be degraded by the enzyme elastase. The soluble preparations prepared thereby have not yet been applied extensively as biomaterials.

GRAFT COPOLYMERS OF COLLAGEN AND GLYCOSAMINOGLYCANS

The preceding discussion in this chapter has focused on the individual macromolecular components of ECMs. Naturally occurring ECMs are insoluble networks comprising several macromolecular components. Several types of ECMs are known to play critical roles during organ development. During the past several years certain analogs of ECMs have been synthesized and have been studied as implants. This section summarizes the evidence for the unusual biological activity of a small number of ECM analogs.

In the 1970s it was discovered that a highly porous graft copolymer of type I collagen and chondroitin 6-sulfate was capable of modifying dramatically the kinetics and mechanism of healing of full-thickness skin wounds in rodents. In the adult mammal, full-thickness skin wounds represent anatomical sites that are demonstrably devoid of both epidermis and dermis, the two main tissues that comprise skin, respectively. Such wounds normally close by contraction of wound edges and by synthesis of scar tissue. Previously, collagen and various glycosaminoglycans, each prepared in various forms such as powder and films, had been used to cover such deep wounds without observation of a significant modification in the outcome of the wound healing process.

Surprisingly, grafting of these wounds with the porous CG copolymer on guinea pig wounds blocked the onset of wound contraction by several days and led to synthesis of new connective tissue within about 3 weeks in the space occupied by the copolymer. The copolymer underwent substantial degradation during the 3-week period, at the end of which it had degraded completely at the wound site. Studies of the connective tissue synthesized in place of the degraded

copolymer eventually showed that the new tissue was distinctly different from scar and was very similar, though not identical, to physiological dermis. In particular, new hair follicles and new sweat glands had not been synthesized. This marked the first instance where scar synthesis was blocked in a full-thickness skin wound of an adult mammal and, in its place, a nearly physiological dermis had been synthesized. That this result was not confined to guinea pigs was confirmed by grafting the same copolymer on full-thickness skin wounds in other adult mammals, including swine and, most importantly, human victims of massive burns as well as humans who underwent reconstructive surgery of the skin.

Although a large number of CG copolymers were synthesized and studied as grafts, it was observed that only one possessed the requisite activity to dramatically modify the wound healing process in skin. In view of the nature of its unique regenerative activity this biologically active macromolecular network has been referred to as dermis regeneration template (DRT). The structure of DRT required specification at two scales: At the nanoscale, the average molecular weight of the cross-linked network that was required to induce regeneration of the dermis was $12,500 \pm 5000$; at the microscale, the average pore diameter was between 20 and 120 μm . Relatively small deviations from these structural features led to loss of activity.

The regeneration of dermis was followed by regeneration of a quite different organ, the peripheral nerve. This was accomplished using a distinctly different ECM analog, termed nerve regeneration template (NRT). Although the chemical composition of the two templates was nearly identical, there were significant differences in other structural features. NRT degrades considerably more slowly than DRT (half-life of about 6 weeks for NRT compared to about 2 weeks for DRT) and is also characterized by a much smaller average pore diameter (about 5 μm compared to 20–120 μm for DRT). DRT was also shown capable of inducing regeneration of the conjunctiva, a specialized structure underneath the eyelid that provides for tearing and other functions that preserve normal vision. The mechanism of induced organ regeneration by templates appears to consist primarily of blocking of contraction of the injured site followed by synthesis of new physiological tissue at about the same rate that the tissue originally present is degraded (synchronous isomorphous replacement). These combined findings suggest that other ECM analogs, still to be discovered, could induce regeneration of organs such as a kidney or the pancreas.

2.9 METALS

John B. Brunski

INTRODUCTION

Implant materials in general, and metallic implant materials in particular, have a significant economic and clinical impact on the biomaterials field. The worldwide market for all types of biomaterials was estimated at over \$5 billion in the late 1980s, but grew to about \$20 billion in 2000 and is likely to exceed \$23 billion by 2005. With the recent emergence of the field known as tissue engineering, including its strong biomaterials segment, the rate of market growth has been estimated at about 12 to 20% per year.

For the United States, the biomaterials market has been estimated at about \$9 billion as of the year 2000, with a growth rate of about 20% per year. The division of this market into various submarkets is illustrated by older data: in 1991 the total orthopedic implant and instrument market was about \$2 billion and was made up of joint prostheses made primarily of metallic materials (\$1.4 billion), together with a wide variety of trauma products (\$0.340 billion), instrumentation devices (\$0.266 billion), bone cement accessories (\$0.066 billion), and bone replacement materials (\$0.029 billion). Estimates for other parts of the biomaterials market include \$0.425 billion for oral and maxillofacial implants and \$0.014 billion for periodontal treatments, and materials for alveolar ridge augmentation or maintenance.

Estimates of the size of the total global biomaterials market are substantiated by the statistics on clinical procedures. For example, of the approximately 3.6 million orthopedic operations per year in the United States, four of the 10 most frequent involve metallic implants: open reduction of a fracture and internal fixation (1 on the list); placement or removal of an internal fixation device without reduction of a fracture (6); arthroplasty of the knee or ankle (7), and total hip replacement or arthroplasty of the hip (8). Moreover, 1988 statistics show that although reduction of fractures was first on the list of inpatient procedures (631,000 procedures), second on the list was excision or destruction of an intervertebral disk (250,000 procedures). Since the latter often involves a bone graft of some kind (from the same patient or from a bone bank) and internal fixation with plates and screws, this represents yet another clinical procedure involving significant use of biomaterials. Overall, including all clinical specialties in 1988, statistics showed that about 11 million Americans (about 4.6% of the civilian population) had at least one implant (Moss *et al.*, 1990).

In view of this wide utilization of implants, many of which are metallic, the objective of this chapter is to describe the composition, structure, and properties of current metallic implant alloys. Major themes are the metallurgical principles underlying structure–property relationships, and the role that biomaterials play in the larger problem of design, production, and proper utilization of medical devices.

STEPS IN THE FABRICATION OF IMPLANTS

Understanding the structure and properties of metallic implant materials requires an appreciation of the metallurgical significance of the material's processing history. Since each metallic device will ordinarily differ in exactly how it is manufactured, generic processing steps are outlined in Fig. 1A.

Metal-Containing Ore to Raw Metal Product

With the exception of the noble metals (which do not represent a major fraction of implant metals), metals exist in the Earth's crust in mineral form wherein the metal is chemically combined with other elements, as in the case of metal oxides. These mineral deposits (ore) must be located and mined, and then separated and enriched to provide ore suitable for further processing into pure metal and/or various alloys.

For example, with titanium, certain mines in the southeastern United States yield sands containing primarily common

quartz but also mineral deposits of zircon, titanium, iron, and rare earth elements. The sandy mixture can be concentrated by using water flow and gravity to separate out the metal-containing sands into titanium-containing compounds such as rutile (TiO_2) and ilmenite (FeTiO_3). To obtain rutile, which is particularly good for making metallic titanium, further processing typically involves electrostatic separations. Then, to extract titanium metal from the rutile, one method involves treating the ore with chlorine to make titanium tetrachloride liquid, which in turn is treated with magnesium or sodium to produce chlorides of the latter metals and bulk titanium "sponge" according to the Kroll process. At this stage, the titanium sponge is not of controlled purity. So, depending on the purity grade desired in the final titanium product, it is necessary to refine it further by using vacuum furnaces, remelting, and additional steps. All of this can be critical in producing titanium with the appropriate properties. For example, the four most common grades of commercially pure (CP) titanium differ in oxygen content by only tenths of a percent, but these small differences in oxygen content can make major differences

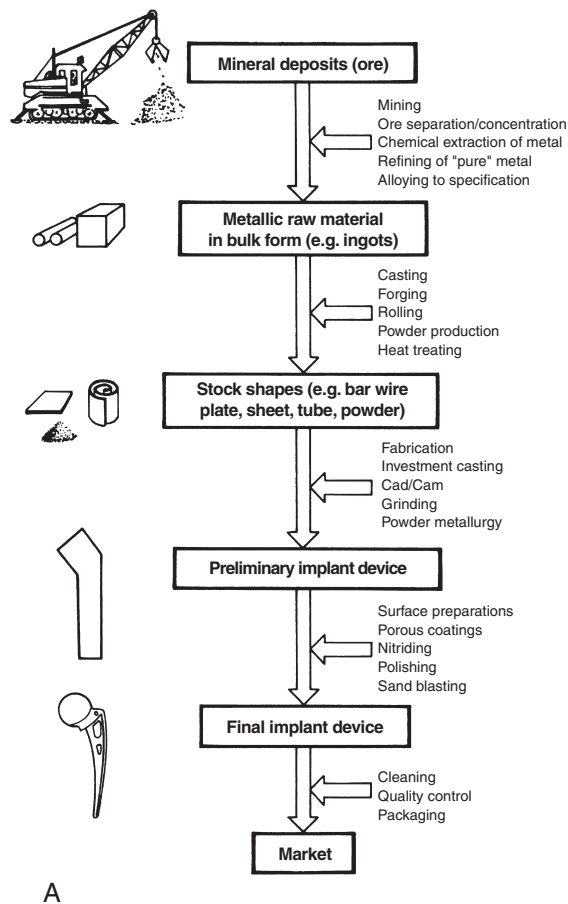

FIG. 1. (A) Generic processing history of a typical metallic implant device, in this case a hip implant. (B) Image of one step during the investment casting ("lost wax") process of manufacturing hip stems; a rack of hip stems can be seen attached to a system of sprues through which molten metal can flow. At this point, ceramic investment material composes the mold into which the molten metal will flow and solidify during casting, thereby replicating the intended shape of a hip stem.

in mechanical properties such as yield and tensile and fatigue strength of titanium, as discussed later in this chapter. In any case, from the preceding extraction steps, the resulting raw metal product eventually emerges in some type of bulk form, such as ingots, which can be supplied to raw materials vendors or metal manufacturers.

In the case of multicomponent metallic implant alloys, the raw metal product will usually have to be processed further both chemically and physically. Processing steps include remelting, the addition of alloying elements, and controlled solidification to produce an alloy that meets certain chemical and metallurgical specifications. For example, to make ASTM (American Society for Testing and Materials) F138 316L stainless steel, iron is alloyed with specific amounts of carbon, silicon, nickel, and chromium. To make ASTM F75 or F90 alloy, cobalt is alloyed with specific amounts of chromium, molybdenum, carbon, nickel, and other elements. Table 1 lists the chemical compositions of some metallic alloys for surgical implants.

Raw Metal Product to Stock Metal Shapes

A metal supplier further processes the bulk raw metal product (metal or alloy) into “stock” bulk shapes, such as bars, wire, sheet, rods, plates, tubes, or powders. These stock shapes may then be sold to specialty companies (e.g., implant manufacturers) who need stock metal that is closer to the final form of the implant. For example, a maker of screw-shaped dental implants might want to buy rods of the appropriate metal to simplify the machining of the screws from the rod stock.

The metal supplier might transform the metal product into stock shapes by a variety of processes, including remelting

and continuous casting, hot rolling, forging, and cold drawing through dies. Depending on the metal, there may also be heat-treating steps (carefully controlled heating and cooling cycles) designed to facilitate further working or shaping of the stock; relieve the effects of prior plastic deformation (e.g., as in annealing); or produce a specific microstructure and properties in the stock material. Because of the high chemical reactivity of some metals at elevated temperatures, high-temperature processes may require vacuum conditions or inert atmospheres to prevent unwanted uptake of oxygen by the metal, all of which adds to cost. For instance, in the production of fine powders of ASTM F75 Co–Cr–Mo alloy, molten metal is often ejected through a small nozzle to produce a fine spray of atomized droplets that solidify while cooling in an inert argon atmosphere.

For metallic implant materials in general, stock shapes are often chemically and metallurgically tested at this early stage to ensure that the chemical composition and microstructure of the metal meet industry standards for surgical implants (ASTM Standards), as discussed later in this chapter. In other words, an implant manufacturer will want assurance that they are buying an appropriate grade of stock metal.

Stock Metal Shapes to Preliminary and Final Metal Devices

Typically, an implant manufacturer will buy stock material and then fabricate preliminary and final forms of the device from the stock material. Specific steps depend on a number of factors, including the final geometry of the implant, the forming and machining properties of the metal, and the costs of alternative fabrication methods.

TABLE 1 Chemical Compositions of Stainless Steels Used for Implants

Material	ASTM designation	Common/trade names	Composition (wt.%)	Notes
Stainless steel	F55 (bar, wire)	AISI 316 LVM	60–65 Fe	F55, F56 specify 0.03 max for P,S. F138, F139 specify 0.025 max for P and 0.010 max for S. LVM = low vacuum melt.
	F56 (sheet, strip)	316L	17.00–20.00 Cr	
	F138 (bar, wire)	316L	12.00–14.00 Ni

Fabrication methods include investment casting (the “lost wax” process), conventional and computer-based machining (CAD/CAM), forging, powder metallurgical processes (e.g., hot isostatic pressing, or HIP), and a range of grinding and polishing steps. A variety of fabrication methods are required because not all implant alloys can be feasibly or economically made in the same way. For instance, cobalt-based alloys are extremely difficult to machine by conventional methods into the complicated shapes of some implants. Therefore, many cobalt-based alloys are frequently shaped into implant forms by investment casting (e.g., Fig. 1B) or powder metallurgy. On the other hand, titanium is relatively difficult to cast, and therefore is frequently machined even though titanium in general is not considered to be an easily machinable metal.

Another aspect of fabrication, which comes under the heading of surface treatment, involves the application of macro- or microporous coatings on implants, or the deliberate production of certain degrees of surface roughness. Such surface modifications have become popular in recent years as a means to improve fixation of implants in bone. The surface coating or roughening can take various forms and require different fabrication technologies. In some cases, this step of the processing history can contribute to metallurgical properties of the final implant device. For example, in the case of alloy beads or “fiber metal” coatings, the manufacturer applies the coating only over specific regions of the implant surface (e.g., on the proximal portion of a femoral stem), and the means by which such a coating is attached to the bulk substrate may involve a process such as high-temperature sintering. Generally, sintering involves heating the coating and substrate to about one-half or more of the alloy’s melting temperature, which is meant to enable diffusive mechanisms to form necks that join the beads in the coating to one another and to the implant’s surface (Fig. 2). Such temperatures can also modify the underlying metallic substrate.

An alternative surface treatment to sintering is plasma or flame spraying a metal onto an implant’s surface. Hot, high-velocity gas plasma is charged with a metallic powder and directed at appropriate regions of an implant surface. The powder particles fully or partially melt and then fall onto the substrate surface, where they solidify rapidly to form a rough coating (Fig. 3).

Other surface treatments are also available, including ion implantation (to produce better surface properties), nitriding, and coating with a thin diamond film. In nitriding, a high-energy beam of nitrogen ions is directed at the implant under vacuum. Nitrogen atoms penetrate the surface and come to rest at sites in the substrate. Depending on the alloy, this process can produce enhanced properties. These treatments are commonly used to increase surface hardness and wear properties.

Finally, the manufacturer of a metallic implant device will normally perform a set of finishing steps. These vary with the metal and manufacturer, but typically include chemical cleaning and passivation (i.e., rendering the metal inactive) in appropriate acid, or electrolytically controlled treatments to remove machining chips or impurities that may have become embedded in the implant’s surface. As a rule, these steps are conducted according to good manufacturing practice (GMP) and ASTM specifications for cleaning and finishing implants.

FIG. 2. Low-power view of the interface between a porous coating and solid substrate in the ASTM F75 Co–Cr–Mo alloy system. Note the structure and geometry of the necks joining the beads to one another and to the substrate. It is worth emphasizing that these steps can be extremely important to the overall biological performance of the implant because they can affect the surface properties of the medical device, which is the surface that comes in direct contact with the blood and other tissues at the implant site.

MICROSTRUCTURES AND PROPERTIES OF IMPLANT METALS

In order to understand the properties of each alloy system in terms of microstructure and processing history, it is essential to know (1) the chemical and crystallographic identities of the phases present in the microstructure; (2) the relative amounts, distribution, and orientation of these phases; and (3) the effects of the phases on properties. This section of the chapter emphasizes mechanical properties of metals used in implant devices even though other properties, such as surface properties and wear properties, must also be considered and may actually be more critical to control in certain medical device applications. (Surface properties of materials are reviewed in more depth in Chapter 1.4 of this book.) The following discussion of implant alloys is divided into the stainless steels, cobalt-based alloys, and titanium-based alloys, since these are the most commonly used metals in medical devices.

Stainless Steels

Composition

Although several types of stainless steels are available for implant use (Table 1), in practice the most common is 316L (ASTM F138, F139), grade 2. This steel has less than 0.030% (wt.%) carbon in order to reduce the possibility of *in vivo* corrosion. The “L” in the designation 316L denotes low carbon content. The 316L alloy is predominantly iron (60–65%) with significant alloying additions of chromium (17–20%) and nickel (12–14%), plus minor amounts of nitrogen, manganese, molybdenum, phosphorus, silicon, and sulfur.

With 316L, the main rationale for the alloying additions involves the metal’s surface and bulk microstructure. The key function of chromium is to permit the development of corrosion-resistant steel by forming a strongly adherent surface oxide (Cr_2O_3). However, the downside to adding Cr is that it tends to stabilize the ferritic (BCC, body-centered cubic) phase of iron and steel, which is weaker than the austenitic (FCC, face-centered cubic) phase. Moreover, molybdenum and silicon are also ferrite stabilizers. So to counter this tendency to form weaker ferrite, nickel is added to stabilize the stronger austenitic phase.

The main reason for the low carbon content in 316L is to improve corrosion resistance. If the carbon content of the steel significantly exceeds 0.03%, there is increased danger of formation of carbides such as Cr_{23}C_6 . Such carbides have the bad habit of tending to precipitate at grain boundaries when the carbon concentration and thermal history are favorable to the kinetics of carbide growth. The negative effect of carbide precipitation is that it depletes the adjacent grain boundary regions of chromium, which in turn has the effect of diminishing

formation of the protective, chromium-based oxide Cr_2O_3 . Steels in which such grain-boundary carbides have formed are called “sensitized” and are prone to fail through corrosion-assisted fractures that originate at the sensitized (weakened) grain boundaries.

Microstructure and Mechanical Properties

Under ASTM specifications, the desirable form of 316L is single-phase austenite (FCC); there should be no free ferritic (BCC) or carbide phases in the microstructure. Also, the steel should be free of inclusions or impurity phases such as sulfide stringers, which can arise primarily from unclean steel-making practices and predispose the steel to pitting-type corrosion at the metal–inclusion interfaces.

The recommended grain size for 316L is ASTM #6 or finer. The ASTM grain size number n is defined by the formula:

$$N = 2^{n-1} \quad (1)$$

where N is the number of grains counted in 1 square inch at 100-times magnification (0.0645 mm^2 actual area). As an example, when $n = 6$, the grain size is about 100 microns or less. Furthermore, the grain size should be relatively uniform throughout (Fig. 4A). The emphasis on a fine grain size is explained by a Hall–Petch-type relationship (Hall, 1951; Petch, 1953) between mechanical yield stress and grain diameter:

$$t_y = t_i + kd^{-m} \quad (2)$$

Here t_y and t_i are the yield and friction stress, respectively; d is the grain diameter; k is a constant associated with propagation of deformation across grain boundaries; and m is approximately 0.5. From this equation it follows that higher yield stresses may be achieved by a metal with a smaller grain diameter d , all other things being equal. A key determinant of grain size is manufacturing history, including details on solidification conditions, cold-working, annealing cycles, and recrystallization.

Another notable microstructural feature of 316L as used in typical implants is plastic deformation within grains (Fig. 4B). The metal is often used in a 30% cold-worked state because cold-worked metal has a markedly increased yield, ultimate tensile, and fatigue strength relative to the annealed state (Table 2). The trade-off is decreased ductility, but ordinarily this is not a major concern in implant products.

In specific orthopedic devices such as bone screws made of 316L, texture may also be a notable feature in the microstructure. Texture means a preferred orientation of deformed grains. Stainless steel bone screws show elongated grains in metallographic sections taken parallel to the long axis of the screws (Fig. 5). Texture arises as a result of the cold drawing or similar cold-working operations inherent in the manufacture of bar rod stock from which screws are usually machined. In metallographic sections taken perpendicular to the screw’s long axis, the grains appear more equiaxed. A summary of representative mechanical properties of 316L stainless is provided in Table 2, but this should only be taken as a general guide, given that final production steps specific to a given implant may often affect properties of the final device.

Cobalt-Based Alloys

Composition

Cobalt-based alloys include Haynes-Stellite 21 and 25 (ASTM F75 and F90, respectively), forged Co–Cr–Mo alloy (ASTM F799), and multiphase (MP) alloy MP35N (ASTM F562). The F75 and F799 alloys are virtually identical in composition (Table 3), each being about 58–70% Co and 26–30% Cr. The key difference is their processing history, as discussed later. The other two alloys, F90 and F562, have slightly less Co and Cr, but more Ni in the case of F562, and more tungsten in the case of F90.

Microstructures and Properties

ASTM F75 The main attribute of this alloy is corrosion resistance in chloride environments, which is related to its bulk

composition and surface oxide (nominally Cr_2O_3). This alloy has a long history in both the aerospace and biomedical implant industries.

When F75 is cast into shape by investment casting (“lost wax” process), the alloy is melted at 1350–1450°C and then poured or pressurized into ceramic molds of the desired shape (e.g., femoral stems for artificial hips, oral implants, dental partial bridgework). The sometimes intricately shaped molds are made by fabricating a wax pattern to near-final dimensions of the implant and then coating (or investing) the pattern with a special ceramic, which then holds its shape after the wax is burned out prior to casting—hence the “lost wax” name of the process. Molten metal is poured into the ceramic mold through sprues, or pathways. Then, once the metal has solidified into the shape of the mold, the ceramic mold is cracked away and processing of the metal continues toward the final device.

FIG. 6. Microstructure of as-cast Co–Cr–Mo ASTM F75 alloy, showing a large grain size plus grain boundary and matrix carbides. (Photo courtesy of Zimmer USA, Warsaw, IN.)

Depending on the exact casting details, this process can produce at least three microstructural features that can strongly influence implant properties, often negatively.

First, as-cast F75 alloy (Figs. 6 and 7A) typically consists of a Co-rich matrix (alpha phase) plus interdendritic and grain-boundary carbides (primarily $M_{23}C_6$, where M represents Co, Cr, or Mo).

There can also be interdendritic Co and Mo-rich sigma intermetallic, and Co-based gamma phases. Overall, the relative amounts of the alpha and carbide phases should be approximately 85% and 15%, respectively. However, because of nonequilibrium cooling, a “cored” microstructure can develop. In this situation, the interdendritic regions become solute (Cr, Mo, C) rich and contain carbides, while the dendrites become depleted in Cr and richer in Co. This is an unfavorable electrochemical situation, with the Cr-depleted regions being anodic with respect to the rest of the microstructure. (This is also an unfavorable situation if a porous coating will subsequently be applied by sintering to this bulk metal.) Subsequent solution-anneal heat treatments at 1225°C for 1 hour can help alleviate this situation.

Second, the solidification during the casting process results not only in dendrite formation, but also in a relatively large grain size. This is generally undesirable because it decreases the yield strength via a Hall–Petch relationship between yield strength and grain diameter (see Eq. 2 in the section on stainless steel). The dendritic growth patterns and large grain diameter (~4 mm) can be easily seen in Fig. 7A, which shows a hip stem manufactured by investment casting.

Third, casting defects may arise. Figure 7B shows an inclusion in the middle of a femoral hip stem. The inclusion was a particle of the ceramic mold (investment stem) material, which presumably broke off and became entrapped within the interior of the mold while the metal was solidifying. This contributed to a fatigue fracture of the implant device *in vivo*, most likely because of stress concentrations and crack initiation sites associated with the ceramic inclusion. For similar reasons, it is also desirable to avoid macro- and microporosity arising from metal shrinkage upon solidification of castings. Figures 7C and 7D exemplify a markedly dendritic microstructure, large grain size, and evidence of microporosity at the fracture surface of a ASTM F75 dental device fabricated by investment casting.

To avoid problems such as the above with cast F75, and to improve the alloy’s microstructure and mechanical properties, powder metallurgical techniques have been used. For example, in hot isostatic pressing (HIP), a fine powder of F75 alloy is compacted and sintered together under appropriate pressure and temperature conditions (about 100 MPa at 1100°C for 1 hour) and then forged to final shape. The typical microstructure (Fig. 8) shows a much smaller grain size (~8 μm) than the as-cast material. Again, according to a Hall–Petch relationship, this microstructure gives the alloy higher yield strength and better ultimate and fatigue properties than the as-cast alloy (Table 2). Generally speaking, the improved properties of the HIP versus cast F75 result from both the finer grain size and a finer distribution of carbides, which has a hardening effect as well.

FIG. 7. (A) Macrophoto of a metallographically polished and etched cross section of a cast Co–Cr–Mo ASTM F75 femoral hip stem, showing dendritic structure and large grain size. (B) Macrophoto of the fracture surface of the same Co–Cr–Mo ASTM F75 hip stem as in (A). Arrow indicates large inclusion within the central region of the cross section. Fracture of this hip stem occurred *in vivo*. (C), (D) Scanning electron micrographs of the fracture surface from a cast F75 subperiosteal dental implant. Note the large grain size, dendritic microstructure, and interdendritic microporosity (arrows).

FIG. 8. Microstructure of the Co–Cr–Mo ASTM F75 alloy made via hot isostatic pressing (HIP), showing the much smaller grain size relative to that in Fig. 6. (Photo courtesy of Zimmer USA, Warsaw, IN.)

In porous-coated prosthetic devices based on F75 alloy, the microstructure will depend on the prior manufacturing history of the beads and substrate metal as well as on the sintering process used to join the beads together and to the underlying bulk substrate. With Co–Cr–Mo alloys, for instance, sintering can be difficult, requiring temperatures near the melting point (1225°C). Unfortunately, these high temperatures can decrease the fatigue strength of the substrate alloy. For example, cast-solution-treated F75 has a fatigue strength of about 200–250 MPa, but it can decrease to about 150 MPa after porous coating treatments. The reason for this decrease probably relates to further phase changes in the nonequilibrium cored microstructure in the original cast F75 alloy. However, it has been found that a modified sintering treatment can return the fatigue strength back up to about 200 MPa (Table 2).

Beyond these metallurgical issues, a related concern with porous-coated devices is the potential for decreased fatigue performance due to stress concentrations inherent in the geometrical features where particles are joined to the substrate (e.g., Fig. 2).

ASTM F799 The F799 alloy is basically a modified F75 alloy that has been mechanically processed by hot forging (at about 800°C) after casting. It is sometimes known as thermo-mechanical Co–Cr–Mo alloy and has a composition slightly different from that of ASTM F75. The microstructure reveals a more worked grain structure than as-cast F75 and a hexagonal close-packed (HCP) phase that forms via a shear-induced transformation of FCC matrix to HCP platelets. This microstructure is not unlike that which occurs in MP35N (see ASTM F562).

The fatigue, yield, and ultimate tensile strengths of this alloy are approximately twice those of as-cast F75 (Table 2).

ASTM F90 Also known as Haynes Stellite 25 (HS-25), F90 alloy is based on Co–Cr–W–Ni. Tungsten and nickel are added to improve machinability and fabrication. In the annealed state, its mechanical properties are about the same as those of F75 alloy, but when cold worked to 44%, the properties more than double (Table 2).

ASTM F562 Known as MP35N, F562 alloy is primarily Co (29–38.8%) and Ni (33–37%), with significant amounts of Cr and Mo. The “MP” in the name refers to the multiple phases in its microstructure. The alloy can be processed by thermal treatments and cold working to produce a controlled microstructure and a high-strength alloy, as follows.

To start with, under equilibrium conditions pure solid cobalt has an FCC Bravais lattice above 419°C and a HCP structure below 419°C. However, the solid-state transformation from FCC to HCP is sluggish and occurs by a martensitic-type shear reaction in which the HCP phase forms with its basal planes (0001) parallel to the close-packed (111) planes in FCC. The ease of this transformation is affected by the stability of the FCC phase, which in turn is affected by both plastic deformation and alloying additions. Now, when cobalt is alloyed to make MP35N, the processing includes 50% cold work, which increases the driving force for the transformation of the FCC to the HCP phase. The HCP phase emerges as fine platelets within FCC grains. Because the FCC grains are small (0.01–0.1 μm, Fig. 9) and the HCP platelets further

FIG. 9. Microstructure of Co-based MP35N, ASTM F562, Biophase. (Photo courtesy of Smith & Nephew Richards, Inc., Memphis, TN.)

impede dislocation motion, the resulting structure is significantly strengthened (Table 2). It can be strengthened even further (as in the case of Richards Biophase) by an aging treatment at 430–650°C. This produces Co_3Mo precipitates on the HCP platelets. Hence, the alloy is truly multiphase and derives strength from the combination of a cold-worked matrix phase, solid solution strengthening, and precipitation hardening. The resulting mechanical properties make the family of MP35N alloys among the strongest available for implant applications.

Titanium-Based Alloys

Composition

Commercially pure (CP) titanium (ASTM F67) and extra-low interstitial (ELI) Ti–6Al–4V alloy (ASTM F136) are the two most common titanium-based implant biomaterials. The F67 CP Ti is 98.9–99.6% Ti (Table 4). The oxygen content of

CP Ti (and other interstitial elements such as C and N) affects its yield and its tensile and fatigue strengths significantly, as discussed shortly.

With Ti–6Al–4V ELI alloy, the individual Ti–Al and Ti–V phase diagrams suggest the effects of the alloying additions in the ternary alloy. That is, since Al is an alpha (HCP) phase stabilizer while V is a beta (BCC) phase stabilizer, it turns out that the Ti–6Al–4V alloy used for implants is an alpha-beta alloy. The alloy's properties depend on prior treatments.

Microstructure and Properties

ASTM F67 For relatively pure titanium implants, as exemplified by many current dental implants, typical microstructures are single-phase alpha (HCP), showing evidence of mild (30%) cold work and grain diameters in the range of 10–150 μm (Fig. 10), depending on manufacturing. The nominal mechanical properties are listed in Table 2. Interstitial elements (O, C, N) in both pure titanium and the Ti–6Al–4V alloy strengthen the metal through interstitial solid solution strengthening mechanisms, with nitrogen having approximately twice the hardening effect (per atom) of either carbon or oxygen.

As noted, it is clear that the oxygen content of CP Ti (and the interstitial content generally) will affect its yield and its tensile and fatigue strengths significantly. For example, data available in the ASTM standard show that at 0.18% oxygen (grade 1), the yield strength is about 170 MPa, whereas at 0.40% (grade 4) the yield strength is about 485 MPa. Likewise, the ASTM standard shows that the tensile strength increases with oxygen content.

The literature establishes that the fatigue limit of unalloyed CP Ti is typically increased by interstitial content, in particular the oxygen content. For example, Fig. 11A shows data from Beevers and Robinson (1969), who tested vacuum-annealed CP Ti having a grain size in the range 200–300 μm in tension-compression at a mean stress of zero, at 100 cycles/sec. The 10^7 cycle endurance limit, or fatigue limit, for Ti 115 (0.085 wt.% O, grade 1), Ti 130 (0.125 wt.% O, grade 1), and Ti 160 (0.27 wt.% O, grade 3) was 88.3, 142, and

FIG. 10. Microstructure of moderately cold-worked commercial purity titanium, ASTM F67, used in an oral implant.

216 MPa, respectively. Figure 11B shows similar results from Turner and Roberts' (1968) fatigue study on CP Ti (tension-compression, 160 cycles/sec, mean stress = zero) having a grain size in the range 26–32 μm . Here the fatigue limit for “H. P. Ti” (0.072 wt.% O, grade 1), Ti 120 (0.087 wt.% O, grade 1), and Ti 160 (0.32 wt.% O, grade 3) was 142, 172, and 295 MPa, respectively—again increasing with increasing oxygen content. Also, for grade 4 Ti in the cold-worked state, Steinemann *et al.* (1993) reported a 10^7 endurance limit of 430 MPa.

Figure 11C, from Conrad *et al.* (1973), summarizes data from several fatigue studies on CP Ti at 300K. Note that the ratio of fatigue limit to yield stress is relatively constant at about 0.65, independent of interstitial content and grain size. Conrad *et al.* suggest that this provides evidence that “the high cycle fatigue strength is controlled by the same dislocation mechanisms as the flow [yield] stress” (p. 996). The work of Turner and Roberts also reported that the ratio f (fatigue limit/ultimate tensile strength)—which is also called the “fatigue ratio” in materials design textbooks (e.g., Charles and Crane, 1989, p. 106)—was 0.43 for the high-purity Ti (0.072 wt.% O), 0.50 for Ti 120 (0.087 wt.% O), and 0.53 for Ti 160 (0.32 wt.% O). It seems clear that interstitial content affects the yield and tensile and fatigue strengths in CP Ti.

Also, cold work appears to increase the fatigue properties of CP Ti. For example, Disegi (1990) quoted bending fatigue data from for annealed versus cold-worked CP Ti in the form of unnotched 1.0 mm-thick sheet (Table 5); there was a moderate increase in UTS and “plane bending fatigue strength” when comparing annealed versus cold-rolled Ti samples. In these data, the ratio of fatigue strength to ultimate tensile strength (“endurance ratio” or “fatigue ratio”, see paragraph

above) varied between 0.45 and 0.66. Whereas the *ASM Metals Handbook* (Wagner, 1996) noted that the fatigue limit for high-purity Ti was only about 10% larger for cold-worked versus annealed material, Desegi's data shows that the fatigue strength increased by about 28%, on average.

In recent years there has been increasing interest in the chemical and physical nature of the oxide on the surface of titanium and its 6Al–4V alloy and its biological significance. The nominal composition of the oxide is TiO_2 for both metals, although there is some disagreement about exact oxide chemistry in pure versus alloyed Ti. Although there is no dispute that the oxide provides corrosion resistance, there is some controversy about exactly how it influences the biological performance of titanium at molecular and tissue levels, as suggested in literature on osseointegrated oral and maxillofacial implants by Brånemark and co-workers in Sweden (e.g., Kasemo and Lausmaa, 1988).

ASTM F136 This alloy is an alpha–beta alloy, the microstructure of which depends upon heat treating and mechanical working. If the alloy is heated into the beta phase field (e.g., above 1000°C, the region where only BCC beta is thermodynamically stable) and then cooled slowly to room temperature, a two-phase Widmanstätten structure is produced (Fig. 12). The HCP alpha phase (which is rich in Al and depleted in V) precipitates out as plates or needles having a specific crystallographic orientation within grains of the beta (BCC) matrix. Alternatively, if cooling from the beta phase field is very fast (as in oil quenching), a “basketweave” microstructure will develop, owing to martensitic or bainitic (nondiffusional shear) solid-state transformations. Most commonly, the F136 alloy

FIG. 11. TABLE 5 Plane Bending Fatigue Data for Unnotched 1.0-mm-Thick Unalloyed Titanium Sheet, Tested at 58 cycles/sec in Air (from Disegi, 1990)

Ultimate tensile strength (MPa)	Sample condition	Plane bending fatigue strength (MPa)
371	Annealed	246
402	Annealed	235
432	Annealed	284
468	Annealed	284
510	Cold rolled	265
667	Cold rolled	314
667	Cold rolled	343
745	Cold rolled	334
766	Cold rolled	343
772	Cold rolled	383
820	Cold rolled	383

is heated and worked at temperatures near but not exceeding the beta transus, and then annealed to give a microstructure of fine-grained alpha with beta as isolated particles at grain boundaries (mill annealed, Fig. 13).

Interestingly, all three of the just-noted microstructures in Ti-6Al-4V alloy lead to about the same yield and ultimate tensile strengths, but the mill-annealed condition is superior in high-cycle fatigue (Table 2), which is a significant consideration.

Like the Co-based alloys, the above microstructural aspects for the Ti systems need to be considered when evaluating the structure-property relationships of porous-coated or plasma-sprayed implants. Again, as in the case of the cobalt-based alloys, there is the technical problem of successfully attaching the coating onto the metallic substrate while maintaining adequate properties of both coating and substrate. Optimizing the fatigue properties of Ti-6Al-4V porous-coated implants becomes an interdisciplinary design problem involving not only metallurgy but also surface properties and fracture mechanics.

CONCLUDING REMARKS

It should be evident that metallurgical principles guide understanding of structure-property relationships and inform judgments about implant design, just as they would in the design process for any well-engineered product. Although this chapter's emphasis has been on mechanical properties (for the sake of specificity), other properties, in particular surface texture, are receiving increasing attention in relation to biological performance of implants. Timely examples of this are (a) efforts

FIG. 12. Widmanstätten structure in cast Ti-Al-4V, ASTM F136. Note prior beta grains (three large grains are shown in the photo) and platelet alpha structure within grains. (Photo courtesy of Zimmer USA, Warsaw, IN.)

FIG. 13. Microstructure of wrought and mill-annealed Ti-6Al-4V, showing small grains of alpha (light) and beta (dark). (Photo courtesy of Zimmer USA, Warsaw, IN.)

to attach relevant biomolecules to metallic implant surfaces to promote certain desired interfacial activities; and (b) efforts to texture implant surfaces to optimize molecular and cellular reactions.

Another point to remember is that the intrinsic material properties of metallic implants—such as elastic modulus, yield strength, or fatigue strength—are not the sole determinant of implant performance and success. Certainly it is true that inadequate attention to material properties can doom a device to failure. However, it is also true that even with the best material, a device can fail because of faulty structural properties, inappropriate use of the implant, surgical error, or inadequate mechanical design of the implant in the first place. As an illustration of this point, Fig. 14 shows a plastically deformed 316L stainless steel Harrington spinal distraction rod that failed *in vivo* by metallurgical fatigue. An investigation of this case concluded that failure occurred not because 316L cold-worked stainless steel had poor fatigue properties per se, but rather due to a combination of factors: (a) the surgeon bent the rod to make it fit a bit better in the patient, but this increased the bending moment and bending stresses on the rod at the first ratchet junction, which was a known problem area; (b) the stress concentrations at the ratchet end of the rod were severe enough to significantly increase stresses at the first ratchet junction, which was indeed the eventual site of the fatigue fracture; and (c) spinal fusion did not occur in the patient, which contributed to relatively persistent loading of the rod over several months postimplantation. Here the point is that all three of these factors could have been anticipated and addressed during the initial design of the rod, during which both structural and material properties would be considered in various stress

analyses related to possible failure modes. It must always be recalled that implant design is a multifaceted problem in which materials selection is only a part of the problem.

2.10 CERAMICS, GLASSES, AND GLASS-CERAMICS

Larry L. Hench and Serena Best

Ceramics, glasses, and glass-ceramics include a broad range of inorganic/nonmetallic compositions. In the medical industry, these materials have been essential for eyeglasses, diagnostic instruments, chemical ware, thermometers, tissue culture flasks, and fiber optics for endoscopy. Insoluble porous glasses have been used as carriers for enzymes, antibodies,

and antigens, offering the advantages of resistance to microbial attack, pH changes, solvent conditions, temperature, and packing under high pressure required for rapid flow (Hench and Ethridge, 1982).

Ceramics are also widely used in dentistry as restorative materials such as in gold–porcelain crowns, glass-filled ionomer cements, and dentures. These dental ceramics are discussed by Phillips (1991).

This chapter focuses on ceramics, glasses, and glass-ceramics used as implants. Although dozens of compositions have been explored in the past, relatively few have achieved clinical success. This chapter examines differences in processing and structure, describes the chemical and microstructural basis for their differences in physical properties, and relates properties and tissue response to particular clinical applications. For a historical review of these biomaterials, see Hulbert *et al.* (1987).

TYPES OF BIOCERAMICS—TISSUE ATTACHMENT

It is essential to recognize that no one material is suitable for all biomaterial applications. As a class of biomaterials, ceramics, glasses, and glass-ceramics are generally used to repair or replace skeletal hard connective tissues. Their success depends upon achieving a stable attachment to connective tissue.

The mechanism of tissue attachment is directly related to the type of tissue response at the implant–tissue interface. No material implanted in living tissue is inert because all materials elicit a response from living tissues. There are four types of tissue response (Table 1) and four different means of attaching prostheses to the skeletal system (Table 2).

A comparison of the relative chemical activity of the different types of bioceramics, glasses, and glass-ceramics is shown in Fig. 1. The relative reactivity shown in Fig. 1A correlates very closely with the rate of formation of an interfacial bond of ceramic, glass, or glass-ceramic implants with bone (Fig. 1B). Figure 1B is discussed in more detail in the section on bioactive glasses and glass-ceramics in this chapter.

The relative level of reactivity of an implant influences the thickness of the interfacial zone or layer between the material and tissue. Analyses of implant material failures during the past 20 years generally show failure originating at the biomaterial–tissue interface. When biomaterials are nearly inert (type 1 in Table 2 and Fig. 1) and the interface is not chemically or biologically bonded, there is relative movement and progressive development of a fibrous capsule in soft and hard tissues.

TABLE 1 Types of Implant–Tissue Response

If the material is toxic, the surrounding tissue dies.
If the material is nontoxic and biologically inactive (nearly inert), a fibrous tissue of variable thickness forms.
If the material is nontoxic and biologically active (bioactive), an interfacial bond forms.
If the material is nontoxic and dissolves, the surrounding tissue replaces it.

TABLE 2 Types of Bioceramic–Tissue Attachment and Their Classification

Type of attachment	Example
1. Dense, nonporous, nearly inert ceramics attach by bone growth into surface irregularities by cementing the device into the tissues or by press-fitting into a defect (termed “morphological fixation”).	Al ₂ O ₃ (Single crystal and polycrystalline)
2. For porous inert implants, bone ingrowth occurs that mechanically attaches the bone to the material (termed “biological fixation”).	Al ₂ O ₃ (Polycrystalline) Hydroxyapatite-coated porous metals
3. Dense, nonporous surface-reactive ceramics, glasses, and glass-ceramics attach directly by chemical bonding with the bone (termed “bioactive fixation”).	Bioactive glasses Bioactive glass-ceramics Hydroxyapatite
4. Dense, nonporous (or porous) resorbable ceramics are designed to be slowly replaced by bone.	Calcium sulfate (Plaster of Paris) Tricalcium phosphate Calcium-phosphate salts

FIG. 1. Bioactivity spectra for various bioceramic implants: (A) relative rate of bioreactivity, (B) time dependence of formation of bone bonding at an implant interface.

The presence of movement at the biomaterial–tissue interface eventually leads to deterioration in function of the implant or the tissue at the interface, or both. The thickness of the non-adherent capsule varies, depending upon both material (Fig. 2) and extent of relative motion.

The fibrous tissue at the interface of dense Al₂O₃ (alumina) implants is very thin. Consequently, as discussed later, if alumina devices are implanted with a very tight mechanical fit and are loaded primarily in compression, they are very successful. In contrast, if a type 1 nearly inert implant is loaded so that interfacial movement can occur, the fibrous capsule can become several hundred micrometers thick, and the implant can loosen very quickly.

FIG. 2. Comparison of interfacial thickness (μm) of reaction layer of bioactive implants of fibrous tissue of inactive bioceramics in bone.

The mechanism behind the use of nearly inert microporous materials (type 2 in Table 2 and Fig. 1) is the ingrowth of tissue into pores on the surface or throughout the implant. The increased interfacial area between the implant and the tissues results in an increased resistance to movement of the device in the tissue. The interface is established by the living tissue in the pores. Consequently, this method of attachment is often termed “biological fixation.” It is capable of withstanding more complex stress states than type 1 implants with “morphological fixation.” The limitation with type 2 porous implants, however, is that for the tissue to remain viable and healthy, it is necessary for the pores to be greater than 50 to 150 μm (Fig. 2). The large interfacial area required for the porosity is due to the need to provide a blood supply to the ingrown connective tissue (vascular tissue does not appear in pore sizes less than 100 μm). Also, if micromovement occurs at the interface of a porous implant and tissue is damaged, the blood supply may be cut off, the tissues will die, inflammation will ensue, and the interfacial stability will be destroyed. When the material is a porous metal, the large increase in surface area can provide a focus for corrosion of the implant and loss of metal ions into the tissues. This can be mediated by using a bioactive ceramic material such as hydroxyapatite (HA) as a coating on the metal. The fraction of large porosity in any material also degrades the strength of the material proportional to the volume fraction of porosity. Consequently, this approach to solving interfacial stability works best when materials are used as coatings or as unloaded space fillers in tissues.

Resorbable biomaterials (type 4 in Table 2 and Fig. 1) are designed to degrade gradually over a period of time and be replaced by the natural host tissue. This leads to a very thin or non-existent interfacial thickness (Fig. 2). This is the optimal biomaterial solution, if the requirements of strength and short-term performance can be met, since natural tissues can repair and replace themselves throughout life. Thus, resorbable biomaterials are based on biological principles of repair that have evolved over millions of years. Complications in the development of resorbable bioceramics are (1) maintenance of strength and the stability of the interface during the degradation period and replacement by the natural host tissue, and

(2) matching resorption rates to the repair rates of body tissues (Fig. 1A) (e.g., some materials dissolve too rapidly and some too slowly). Because large quantities of material may be replaced, it is also essential that a resorbable biomaterial consist only of metabolically acceptable substances. This criterion imposes considerable limitations on the compositional design of resorbable biomaterials. Successful examples of resorbable polymers include poly(lactic acid) and poly(glycolic acid) used for sutures, which are metabolized to CO_2 and H_2O and therefore are able to function for an appropriate time and then dissolve and disappear (see Chapters 2, 6, and 7 for other examples). Porous or particulate calcium phosphate ceramic materials such as tricalcium phosphate (TCP) have proved successful for resorbable hard tissue replacements when low loads are applied to the material.

Another approach to solving problems of interfacial attachment is the use of bioactive materials (type 3 in Table 2 and Fig. 1). Bioactive materials are intermediate between resorbable and bioinert. A bioactive material is one that elicits a specific biological response at the interface of the material, resulting in the formation of a bond between the tissues and the material. This concept has now been expanded to include a large number of bioactive materials with a wide range of rates of bonding and thicknesses of interfacial bonding layers (Figs. 1 and 2). They include bioactive glasses such as Bioglass; bioactive glass-ceramics such as Ceravital, A-W glass-ceramic, or machineable glass-ceramics; dense HA such as Durapatite or Calcite; and bioactive composites such as HA-polyethylene, HA-Bioglass, Palavital, and stainless steel fiber-reinforced Bioglass. All of these materials form an interfacial bond with adjacent tissue. However, the time dependence of bonding, the strength of bond, the mechanism of bonding, and the thickness of the bonding zone differ for the various materials.

It is important to recognize that relatively small changes in the composition of a biomaterial can dramatically affect whether it is bioinert, resorbable, or bioactive. These compositional effects on surface reactions are discussed in the section on bioactive glasses and glass-ceramics.

CHARACTERISTICS AND PROCESSING OF BIOCERAMICS

The types of implants listed in Table 2 are made using different processing methods. The characteristics and properties of the materials, summarized in Table 3, differ greatly, depending upon the processing method used.

The primary methods of processing ceramics, glasses, and glass-ceramics are summarized in Fig. 3. These methods yield five categories of microstructures:

1. Glass
2. Cast or plasma-sprayed polycrystalline ceramic
3. Liquid-phase sintered (vitrified) ceramic
4. Solid-state sintered ceramic
5. Polycrystalline glass-ceramic

Differences in the microstructures of the five categories are primarily a result of the different thermal processing steps

required to produce them. Alumina and calcium phosphate bioceramics are made by fabricating the product from fine-grained particulate solids. For example, a desired shape may be obtained by mixing the particulates with water and an organic binder, then pressing them in a mold. This is termed "forming." The formed piece is called green ware. Subsequently, the temperature is raised to evaporate the water (i.e., drying) and the binder is burned out, resulting in bisque ware. At a very much higher temperature, the part is densified during firing. After cooling to ambient temperature, one or more finishing steps may be applied, such as polishing. Porous ceramics are produced by adding a second phase that decomposes prior to densification, leaving behind holes or pores (Schors and Holmes, 1993), or transforming natural porous organisms,

such as coral, to porous HA by hydrothermal processing (Roy and Linnehan, 1974).

The interrelation between microstructure and thermal processing of various bioceramics is shown in Fig. 3, which is a binary phase diagram consisting of a network-forming oxide such as SiO_2 (silica), and some arbitrary network modifier oxide (MO) such as CaO. When a powdered mixture of MO and SiO_2 is heated to the melting temperature T_m , the entire mass will become liquid (L). The liquid will become homogeneous when held at this temperature for a sufficient length of time. When the liquid is cast (paths 1B, 2, 5), forming the shape of the object during the casting, either a glass or a polycrystalline microstructure will result. Plasma spray coating follows path 1A. However, a network-forming oxide is not necessary to produce plasma-sprayed coatings such as hydroxyapatites, which are polycrystalline (Lacefield, 1993).

If the starting composition contains a sufficient quantity of network former (SiO_2), and the casting rate is sufficiently slow, a glass will result (path 1B). The viscosity of the melt increases greatly as it is cooled, until at approximately T_1 , the glass transition point, the material is transformed into a solid.

If either of these conditions is not met, a polycrystalline microstructure will result. The crystals begin growing at T_L and complete growth at T_2 . The final material consists of the equilibrium crystalline phases predicted by the phase diagram. This type of cast object is not often used commercially because the large shrinkage cavity and large grains produced during cooling make the material weak and subject to environmental attack.

If the MO and SiO_2 powders are first formed into the shape of the desired object and fired at a temperature T_3 , a liquid-phase sintered structure will result (path 3). Before firing, the composition will contain approximately 10–40% porosity, depending upon the forming process used. A liquid will be formed first at grain boundaries at the eutectic temperature, T_2 . The liquid will penetrate between the grains, filling the pores, and will draw the grains together by capillary attraction. These effects decrease the volume of the powdered compact.

FIG. 3. Relation of thermal processing schedules of various bioceramics to equilibrium phase diagram.

Since the mass remains unchanged and is only rearranged, an increased density results. Should the compact be heated for a sufficient length of time, the liquid content can be predicted from the phase diagram. However, in most ceramic processes, liquid formation does not usually proceed to equilibrium owing to the slowness of the reaction and the expense of long-term heat treatments.

The microstructure resulting from liquid-phase sintering, or vitrification as it is commonly called, will consist of small grains from the original powder compact surrounded by a liquid phase. As the compact is cooled from T_3 to T_2 , the liquid phase will crystallize into a fine-grained matrix surrounding the original grains. If the liquid contains a sufficient concentration of network formers, it can be quenched into a glassy matrix surrounding the original grains.

A powder compact can be densified without the presence of a liquid phase by a process called solid-state sintering. This is the process usually used for manufacturing alumina and dense HA bioceramics. Under the driving force of surface energy gradients, atoms diffuse to areas of contact between particles. The material may be transported by either grain boundary diffusion, volume diffusion, creep, or any combination of these, depending upon the temperature or material involved. Because long-range migration of atoms is necessary, sintering temperatures are usually in excess of one-half of the melting point of the material: $T > T_L/2$ (path 4).

The atoms move so as to fill up the pores and open channels between the grains of the powder. As the pores and open channels are closed during the heat treatment, the crystals become tightly bonded together, and the density, strength, and fatigue resistance of the object improve greatly. The microstructure of a material that is prepared by sintering consists of crystals bonded together by ionic-covalent bonds with a very small amount of remaining porosity.

The relative rate of densification during solid-state sintering is slower than that of liquid-phase sintering because material transport is slower in a solid than in a liquid. However, it is possible to solid-state sinter individual component materials such as pure oxides since liquid development is not necessary. Consequently, when high purity and uniform fine-grained microstructures are required (e.g., for bioceramics) solid-state sintering is essential.

The fifth class of microstructures is called glass-ceramics because the object starts as a glass and ends up as a polycrystalline ceramic. This is accomplished by first quenching a melt to form the glass object. The glass is transformed into a glass-ceramic in two steps. First, the glass is heat treated at a temperature range of 500–700°C (path 5a) to produce a large concentration of nuclei from which crystals can grow. When sufficient nuclei are present to ensure that a fine-grained structure will be obtained, the temperature of the object is raised to a range of 600–900°C, which promotes crystal growth (path 5b). Crystals grow from the nuclei until they impinge and up to 100% crystallization is achieved. The resulting microstructure is nonporous and contains fine-grained, randomly oriented crystals that may or may not correspond to the equilibrium crystal phases predicted by the phase diagram. There may also be a residual glassy matrix, depending on the duration of the ceraming heat treatment. When phase separation occurs

(composition B in Fig. 3), a nonporous, phase-separated, glass-in-glass microstructure can be produced. Crystallization of phase-separated glasses results in very complex microstructures. Glass-ceramics can also be made by pressing powders and a grain boundary glassy phase (Kokubo, 1993). For additional details on the processing of ceramics, see Reed (1988) or Onoda and Hench (1978), and for processing of glass-ceramics, see McMillan (1979).

NEARLY INERT CRYSTALLINE CERAMICS

High-density, high-purity (>99.5%) alumina is used in load-bearing hip prostheses and dental implants because of its excellent corrosion resistance, good biocompatibility, high wear resistance, and high strength (Christel *et al.*, 1988; Hulbert, 1993; Hulbert *et al.*, 1987; Miller *et al.*, 1996). Although some dental implants are single-crystal sapphires (McKinney and Lemons, 1985), most Al_2O_3 devices are very fine-grained polycrystalline $\alpha\text{-Al}_2\text{O}_3$ produced by pressing and sintering at $T = 1600\text{--}1700^\circ\text{C}$. A very small amount of MgO (<0.5%) is used to aid sintering and limit grain growth during sintering.

Strength, fatigue resistance, and fracture toughness of polycrystalline $\alpha\text{-Al}_2\text{O}_3$ are a function of grain size and percentage of sintering aid (i.e., purity). Al_2O_3 with an average grain size of < 4 μm and > 99.7% purity exhibits good flexural strength and excellent compressive strength. These and other physical properties are summarized in Table 4, along with the International Standards Organization (ISO) requirements for alumina implants. Extensive testing has shown that alumina implants that meet or exceed ISO standards have excellent resistance to dynamic and impact fatigue and also resist subcritical crack growth (Drre and Dawihl, 1980). An increase in

TABLE 4 Physical Characteristics of Al_2O_3 Bioceramics

	High alumina ceramics	ISO Standard 6474

^aSurface roughness value.

average grain size to $>17\ \mu\text{m}$ can decrease mechanical properties by about 20%. High concentrations of sintering aids must be avoided because they remain in the grain boundaries and degrade fatigue resistance.

Methods exist for lifetime predictions and statistical design of proof tests for load-bearing ceramics. Applications of these techniques show that load limits for specific prostheses can be set for an Al_2O_3 device based upon the flexural strength of the material and its use environment (Ritter *et al.*, 1979). Load-bearing lifetimes of 30 years at 12,000-N loads have been predicted (Christel *et al.*, 1988). Results from aging and fatigue studies show that it is essential that Al_2O_3 implants be produced at the highest possible standards of quality assurance, especially if they are to be used as orthopedic prostheses in younger patients.

Alumina has been used in orthopedic surgery for nearly 20 years (Miller *et al.*, 1996). Its use has been motivated largely by two factors: its excellent type 1 biocompatibility and very thin capsule formation (Fig. 2), which permits cementless fixation of prostheses; and its exceptionally low coefficients of friction and wear rates.

The superb tribologic properties (friction and wear) of alumina occur only when the grains are very small ($<4\ \mu\text{m}$) and have a very narrow size distribution. These conditions lead to very low surface roughness values ($R_a < 4.0.02\ \mu\text{m}$, Table 4). If large grains are present, they can pull out and lead to very rapid wear of bearing surfaces owing to local dry friction.

Alumina on load-bearing, wearing surfaces, such as in hip prostheses, must have a very high degree of sphericity, which is produced by grinding and polishing the two mating surfaces together. For example, the alumina ball and socket in a hip prosthesis are polished together and used as a pair. The long-term coefficient of friction of an alumina–alumina joint decreases with time and approaches the values of a normal joint. This leads to wear on alumina-articulating surfaces being nearly 10 times lower than metal–polyethylene surfaces (Fig. 4).

Low wear rates have led to widespread use in Europe of alumina noncemented cups press-fitted into the acetabulum of the hip. The cups are stabilized by the growth of bone into grooves or around pegs. The mating femoral ball surface is also made of alumina, which is bonded to a metallic stem. Long-term results in general are good, especially for younger patients. However, Christel *et al.* (1988) caution that stress shielding, owing to

FIG. 4. Time dependence of coefficient of friction and wear of alumina–alumina versus metal–polyethylene hip joint (*in vitro* testing).

the high elastic modulus of alumina, may be responsible for cancellous bone atrophy and loosening of the acetabular cup in old patients with senile osteoporosis or rheumatoid arthritis. Consequently, it is essential that the age of the patient, nature of the disease of the joint, and biomechanics of the repair be considered carefully before any prosthesis is used, including alumina ceramics.

Zirconia (ZrO_2) is also used as the articulating ball in total hip prostheses. The potential advantages of zirconia in load-bearing prostheses are its lower modulus of elasticity and higher strength (Hench and Wilson, 1993). There are insufficient data to determine whether these properties will result in higher clinical success rates over long times (>15 years).

Other clinical applications of alumina prostheses reviewed by Hulbert *et al.* (1987) include knee prostheses; bone screws; alveolar ridge and maxillofacial reconstruction; ossicular bone substitutes; keratoprotheses (corneal replacements); segmental bone replacements; and blade, screw, and post dental implants.

POROUS CERAMICS

The potential advantage offered by a porous ceramic implant (type 2, Table 2, Figs. 1 and 2) is its inertness combined with the mechanical stability of the highly convoluted interface that develops when bone grows into the pores of the ceramic. The mechanical requirements of prostheses, however, severely restrict the use of low-strength porous ceramics to nonload-bearing applications. Studies reviewed by Hench and Ethridge (1982), Hulbert *et al.* (1987), and Schors and Holmes (1993) have shown that when load-bearing is not a primary requirement, porous ceramics can provide a functional implant. When pore sizes exceed $100\ \mu\text{m}$, bone will grow within the interconnecting pore channels near the surface and maintain its vascularity and long-term viability. In this manner, the implant serves as a structural bridge or scaffold for bone formation.

Commercially available porous products originate from two sources: hydroxyapatite converted from coral (e.g., Pro Osteon) or animal bone (e.g., Endobon). Other production routes; e.g., burnout techniques (e.g., Fang *et al.*, 1991) and decomposition of hydrogen peroxide (Peelen *et al.*, 1977; Driessen *et al.*, 1982) are not yet used commercially. The optimal type of porosity is still uncertain. The degree of interconnectivity of pores may be more critical than the pore size. Eggl *et al.* (1988) demonstrated improved integration in interconnected 50 – $100\ \mu\text{m}$ pores compared with less connected pores with a size of 200 – $400\ \mu\text{m}$. Similarly Kühne *et al.* (1994) compared two grades of 25–35% porous coralline apatite with average pore sizes of 200 and 500 μm and reported bone ingrowth to be improved in the 500 μm pore sized ceramic. Holmes (1979) suggests that porous coralline apatite when implanted in cortical bone requires interconnections of osteonic diameter for transport of nutrients to maintain bone ingrowth. The findings clearly indicate the importance of thorough characterisation of porous materials before implantation, and Hing (1999) has recommended a range of techniques that should be employed.

Porous materials are weaker than the equivalent bulk form in proportion to the percentage of porosity, so that as the porosity increases, the strength of the material decreases rapidly. Much surface area is also exposed, so that the effects of the environment on decreasing the strength become much more important than for dense, nonporous materials. The aging of porous ceramics, with their subsequent decrease in strength, requires bone ingrowth to stabilize the structure of the implant. Clinical results for non-load-bearing implants are good (Schors and Holmes, 1993).

BIOACTIVE GLASSES AND GLASS-CERAMICS

Certain compositions of glasses, ceramics, glass-ceramics, and composites have been shown to bond to bone (Hench and Ethridge, 1982; Gross *et al.*, 1988; Yamamuro *et al.*, 1990; Hench, 1991; Hench and Wilson, 1993). These materials have become known as bioactive ceramics. Some even more specialized compositions of bioactive glasses will bond to soft tissues as well as bone (Wilson *et al.*, 1981). A common characteristic of bioactive glasses and bioactive ceramics is a time-dependent, kinetic modification of the surface that occurs upon implantation. The surface forms a biologically active carbonated HA layer that provides the bonding interface with tissues.

Materials that are bioactive develop an adherent interface with tissues that resist substantial mechanical forces. In many cases, the interfacial strength of adhesion is equivalent to or greater than the cohesive strength of the implant material or the tissue bonded to the bioactive implant.

Bonding to bone was first demonstrated for a compositional range of bioactive glasses that contained SiO₂, Na₂O, CaO, and P₂O₅ in specific proportions (Hench *et al.*, 1972) (Table 5). There are three key compositional features to these bioactive glasses that distinguish them from traditional soda-lime-silica glasses: (1) less than 60 mol% SiO₂, (2) high Na₂O and CaO content, and (3) a high CaO/P₂O₅ ratio. These features make the surface highly reactive when it is exposed to an aqueous medium.

Many bioactive silica glasses are based upon the formula called 45S5, signifying 45 wt.% SiO₂ (S = the network former) and 5 : 1 ratio of CaO to P₂O₅. Glasses with lower ratios of CaO to P₂O₅ do not bond to bone. However, substitutions in the 45S5 formula of 5–15 wt.% B₂O₃ for SiO₂ or 12.5 wt.% CaF₂ for CaO or heat treating the bioactive glass compositions to form glass-ceramics has no measurable effect on the ability of the material to form a bone bond. However, adding as little as 3 wt.% Al₂O₃ to the 45S5 formula prevents bonding to bone.

The compositional dependence of bone and soft tissue bonding on the Na₂O–CaO–P₂O₅–SiO₂ glasses is illustrated in Fig. 5. All the glasses in Fig. 5 contain a constant 6 wt.% of P₂O₅. Compositions in the middle of the diagram (region A) form a bond with bone. Consequently, region A is termed the bioactive bone-bonding boundary. Silicate glasses within region B (e.g., window or bottle glass, or microscope slides) behave as nearly inert materials and elicit a fibrous capsule at the implant–tissue interface. Glasses within region C are resorbable and disappear within 10 to 30 days of implantation. Glasses within region D are not technically practical and therefore have not been tested as implants.

FIG. 5. Compositional dependence (in wt.%) of bone bonding and soft tissue bonding of bioactive glasses and glass-ceramics. All compositions in region A have a constant 6 wt.% of P_2O_5 . A-W glass ceramic has higher P_2O_5 content (see Table 5 for details). I_B , Index of bioactivity.

The collagenous constituent of soft tissues can strongly adhere to the bioactive silicate glasses that lie within the dashed line region in Fig. 5. The interfacial thicknesses of the hard tissue–bioactive glasses are shown in Fig. 2 for several compositions. The thickness decreases as the bone-bonding boundary is approached.

Gross *et al.* (1988) and Gross and Strunz (1985) have shown that a range of low-alkali (0 to 5 wt.%) bioactive silica glass-ceramics (Ceravital) also bond to bone. They found that small additions of Al_2O_3 , Ta_2O_5 , TiO_2 , Sb_2O_3 , or ZrO_2 inhibit bone bonding (Table 5, Fig. 1). A two-phase silica–phosphate glass-ceramic composed of apatite [$Ca_{10}(PO_4)_6(OH)F_2$] and wollastonite [CaO, SiO_2] crystals and a residual silica glassy matrix, termed A-W glass-ceramic (A-WGC) (Nakamura *et al.*, 1985; Yamamuro *et al.*, 1990; Kokubo, 1993), also bonds with bone. The addition of Al_2O_3 or TiO_2 to the A-W glass-ceramic also inhibits bone bonding, whereas incorporation of a second phosphate phase, B-whitlockite ($3CaO, P_2O_5$), does not.

Another multiphase bioactive phosphosilicate containing phlogopite (Na, K) $Mg_3[AlSi_3O_{10}]F_2$ and apatite crystals bonds to bone even though Al is present in the composition (Höhland and Vogel, 1993). However, the Al^{3+} ions are incorporated within the crystal phase and do not alter the surface reaction kinetics of the material. The compositions of these various bioactive glasses and glass-ceramics are compared in Table 5.

The surface chemistry of bioactive glass and glass-ceramic implants is best understood in terms of six possible types of surface reactions (Hench and Clark, 1978). A high-silica glass may react with its environment by developing only a surface hydration layer. This is called a type I response (Fig. 6). Vitreous silica (SiO_2) and some inert glasses at the apex of region B (Fig. 5) behave in this manner when exposed to a physiological environment.

When sufficient SiO_2 is present in the glass network, the surface layer that forms from alkali–proton exchange can repolymerize into a dense SiO_2 -rich film that protects the glass from further attack. This type II surface (Fig. 6) is characteristic of most commercial silicate glasses, and their biological response of fibrous capsule formation is typical of many within region B in Fig. 5.

SEQUENCE OF INTERFACIAL REACTIONS INVOLVED IN FORMING A BOND BETWEEN TISSUE AND BIOACTIVE GLASS

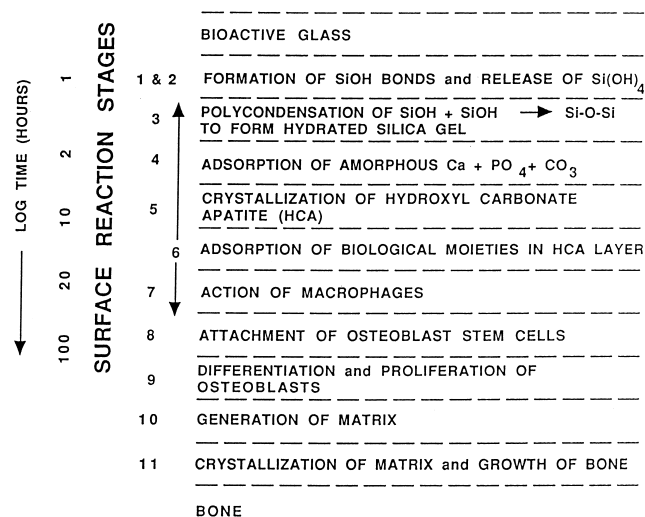

FIG. 6. Types of silicate glass interfaces with aqueous or physiological solutions.

At the other extreme of the reactivity range, a silicate glass or crystal may undergo rapid, selective ion exchange of alkali ions, with protons or hydronium ions leaving a thick but highly porous and nonprotective SiO_2 -rich film on the surface (a type IV surface) (Fig. 6). Under static or slow flow conditions, the local pH becomes sufficiently alkaline ($pH > 19$) that the surface silica layer is dissolved at a high rate, leading to uniform bulk network or stoichiometric dissolution (a type V surface). Both type IV and V surfaces fall into region C of Fig. 5.

Type IIIA surfaces are characteristic of bioactive silicates (Fig. 6). A dual protective film rich in CaO and P_2O_5 forms on top of the alkali-depleted SiO_2 -rich film. When multivalent cations such as Al^{3+} , Fe^{3+} , and Ti^{4+} are present in the glass or solution, multiple layers form on the glass as the saturation of each cationic complex is exceeded, resulting in a type IIIB surface (Fig. 6), which does not bond to tissue.

A general equation describes the overall rate of change of glass surfaces and gives rise to the interfacial reaction profiles shown in Fig. 6. The reaction rate (R) depends on at least four terms (for a single-phase glass). For glass-ceramics, which have several phases in their microstructures, each phase will have a characteristic reaction rate, R_i .

$$R = -k_1 t^{0.5} - k_2 t^{1.0} - k_3 t^{1.0} + k_4 t^y + k_n t^z \quad (1)$$

The first term describes the rate of alkali extraction from the glass and is called a stage 1 reaction. A type II nonbonding glass surface (region B in Fig. 6) is primarily undergoing stage 1 attack. Stage 1, the initial or primary stage of attack, is a process that involves an exchange between alkali ions from the glass and hydrogen ions from the solution, during which the remaining constituents of the glass are not altered. During stage 1, the rate of alkali extraction from the glass is parabolic ($t^{1/2}$) in character.

The second term describes the rate of interfacial network dissolution that is associated with a stage 2 reaction. A type IV surface is a resorbable glass (region C in Fig. 5) and is experiencing a combination of stage 1 and stage 2 reactions. A type V surface is dominated by a stage 2 reaction. Stage 2, the second stage of attack, is a process by which the silica structure breaks down and the glass totally dissolves at the interface. Stage 2 kinetics are linear ($t^{1.0}$).

A glass surface with a dual protective film is designated type IIIA (Fig. 6). The thickness of the secondary films can vary considerably—from as little as 0.01 μm for Al_2O_3 - SiO_2 -rich layers on inactive glasses, to as much as 30 μm for CaO - P_2O_5 -rich layers on bioactive glasses.

A type III surface forms as a result of the repolymerization of SiO_2 on the glass surface by the condensation of the silanols ($\text{Si}-\text{OH}$) formed from the stage 1 reaction. For example:

Stage 3 protects the glass surface. The SiO_2 polymerization reaction contributes to the enrichment of surface SiO_2 that is characteristic of type II, III, and IV surface profiles (Fig. 6). It is described by the third term in Eq. 1. This reaction is interface controlled with a time dependence of $+k_3t^{1.0}$. The interfacial thickness of the most reactive bioactive glasses shown in Fig. 2 is largely due to this reaction.

The fourth term in Eq. 1, $+k_4t^y$ (stage 4), describes the precipitation reactions that result in the multiple films characteristic of type III glasses. When only one secondary film forms, the surface is type IIIA. When several additional films form, the surface is type IIIB.

In stage 4, an amorphous calcium phosphate film precipitates on the silica-rich layer and is followed by crystallization to form carbonated HA crystals. The calcium and phosphate ions in the glass or glass-ceramic provide the nucleation sites for crystallization. Carbonate anions (CO_3^{2-}) substitute for OH^- in the apatite crystal structure to form a carbonate hydroxyapatite similar to that found in living bone. Incorporation of CaF_2 in the glass results in incorporation of fluoride ions in the apatite crystal lattice. Crystallization of carbonate HA occurs around collagen fibrils present at the implant interface and results in interfacial bonding.

In order for the material to be bioactive and form an interfacial bond, the kinetics of reaction in Eq. 1, and especially the rate of stage 4, must match the rate of biomineralization that normally occurs *in vivo*. If the rates in Eq. 1 are too rapid, the implant is resorbable, and if the rates are too slow, the implant is not bioactive.

By changing the compositionally controlled reaction kinetics (Eq. 1), the rates of formation of hard tissue at an implant interface can be altered, as shown in Fig. 1. Thus, the level of bioactivity of a material can be related to the time for more than 50% of the interface to be bonded ($t_{0.5bb}$) [e.g., I_B index of bioactivity: $= (100/t_{0.5bb})$] (Hench, 1988). It is necessary to impose a 50% bonding criterion for an IB since the interface between an implant and bone is irregular (Gross *et al.*, 1988). The initial concentration of macrophages, osteoblasts, chondroblasts, and fibroblasts varies as a function of the fit of the implant and the condition of the bony defect (see Chapters 3 and 4). Consequently, all bioactive implants require an

incubation period before bone proliferates and bonds. The length of this incubation period varies widely, depending on the composition of the implant.

The compositional dependence of IB indicates that there are $isoI_B$ contours within the bioactivity boundary, as shown in Fig. 5 (Hench, 1988). The change of I_B with the $\text{SiO}_2/(\text{Na}_2\text{O} + \text{CaO})$ ratio is very large as the bioactivity boundary is approached. The addition of multivalent ions to a bioactive glass or glass-ceramic shrinks the $isoI_B$ contours, which will contract to zero as the percentage of Al_2O_3 , Ta_2O_5 , ZrO_2 , or other multivalent cations increases in the material. Consequently, the $isoI_B$ boundary shown in Fig. 5 indicates the contamination limit for bioactive glasses and glass-ceramics. If the composition of a starting implant is near the I_B boundary, it may take only a few parts per million of multivalent cations to shrink the I_B boundary to zero and eliminate bioactivity. Also, the sensitivity of fit of a bioactive implant and length of time of immobilization postoperatively depends on the I_B value and closeness to the $I_B = 0$ boundary. Implants near the I_B boundary require more precise surgical fit and longer fixation times before they can bear loads. In contrast, increasing the surface area of a bioactive implant by using them in particulate form for bone augmentation expands the bioactive boundary. Small (<200 μm) bioactive glass granules behave as a partially resorbable implant and stimulate new bone formation (Hench, 1994).

Bioactive implants with intermediate I_B values do not develop a stable soft tissue bond; instead, the fibrous interface progressively mineralizes to form bone. Consequently, there appears to be a critical $isoI_B$ boundary beyond which bioactivity is restricted to stable bone bonding. Inside the critical $isoI_B$ boundary, the bioactivity includes both stable bone and soft-tissue bonding, depending on the progenitor stem cells in contact with the implant. This soft tissue-critical $isoI_B$ limit is shown by the dashed contour in Fig. 5.

The thickness of the bonding zone between a bioactive implant and bone is proportional to its I_B (compare Fig. 1 with Fig. 2). The failure strength of a bioactively fixed bond appears to be inversely dependent on the thickness of the bonding zone. For example, 45S5 Bioglass with a very high I_B develops a gel bonding layer of 200 μm , which has a relatively low shear strength. In contrast, A-W glass-ceramic, with an intermediate I_B value, has a bonding interface in the range of 10–20 μm and a very high resistance to shear. Thus, the interfacial bonding strength appears to be optimum for I_B values of ~ 4 . However, it is important to recognize that the interfacial area for bonding is time dependent, as shown in Fig. 1. Therefore, interfacial strength is time dependent and is a function of such morphological factors as the change in interfacial area with time, progressive mineralization of the interfacial tissues, and resulting increase of elastic modulus of the interfacial bond, as well as shear strength per unit of bonded area. A comparison of the increase in interfacial bond strength of bioactive fixation of implants bonded to bone with other types of fixation is given in Fig. 7 (Hench, 1987).

Clinical applications of bioactive glasses and glass-ceramics are reviewed by Gross *et al.* (1988), Yamamuro *et al.* (1990), and Hench and Wilson (1993) (Table 6). The 8-year history of successful use of Ceravital glass-ceramics in middle ear surgery

(Reck *et al.*, 1988) is especially encouraging, as is the 10-year use of A-W glass-ceramic in vertebral surgery (Yamamuro *et al.*, 1990), the 10-year use of 45S5 Bioglass in endosseous ridge maintenance (Stanley *et al.*, 1996) and middle-ear

replacement, and the 6-year success in repair of periodontal defects (Hench and Wilson, 1996; Wilson, 1994).

CALCIUM PHOSPHATE CERAMICS

Bone typically consists, by weight of 25% water, 15% organic materials and 60% mineral phases. The mineral phase consists primarily of calcium and phosphate ions, with traces of magnesium, carbonate, hydroxyl, chloride, fluoride, and citrate ions. Hence calcium phosphates occur naturally in the body, but they occur also within nature as mineral rocks, and certain compounds can be synthesized in the laboratory. Table 7 summarizes the mineral name, chemical name and composition of various phases of calcium phosphates.

Within the past 20–30 years interest has intensified in the use of calcium phosphates as biomaterials, but only certain compounds are useful for implantation in the body since both their solubility and speed of hydrolysis increase with a decreasing calcium-to-phosphorus ratio. Driessens (1983) stated that those compounds with a Ca/P ratio of less than 1:1 are not suitable for biological implantation.

The main crystalline component of the mineral phase of bone is a calcium-deficient carbonate hydroxyapatite, and various methods have been investigated to produce synthetic hydroxyapatite. The commercial routes are based on aqueous precipitation or conversion from other calcium compounds. Aqueous precipitation is most often performed in one of two ways: a reaction between a calcium salt and an alkaline phosphate (Collin, Hayek and Newsley, 1963; Eanes *et al.*, 1965; Bonel *et al.*, 1987; Young and Holcomb, 1982; Denissen *et al.*, 1980; Jarcho *et al.*, 1976; Kijima and Tsutsumi, 1979) or a reaction between calcium hydroxide or calcium carbonate and phosphoric acid (Mooney, 1961; Irvine, 1981; Nagai *et al.*, 1985; Rao and Boehm, 1974; McDowell *et al.*, 1977; Akao *et al.*, 1981).

Other routes include solid-state processing (Monma *et al.*, 1981; Fowler, 1974; Young and Holcomb, 1982; Rootare *et al.*, 1978; Lehr *et al.*, 1967); hydrolysis (Schleede *et al.*, 1932; Perloff *et al.*, 1956; Morancho *et al.*, 1981; Young and Holcomb, 1982); hydrothermal synthesis (Young and Holcomb, 1982; Fowler, 1974; Roy, 1971; Skinner, 1973; Arends *et al.*, 1979; Perloff and Posner, 1960).

The route and conditions under which synthetic HA is produced will greatly influence its physical and chemical characteristics. Factors that affect the rate of resorption of the implant include physical factors such as the physical features of the material (e.g., surface area, crystallite size), chemical factors such as atomic and ionic substitutions in the lattice, and biological factors such as the types of cells surrounding the implant and location, age, species, sex, and hormone levels.

The thermodynamic stability of the various calcium phosphates is summarized in the form of the phase diagram shown in Fig. 8. The binary equilibrium phase diagram between CaO and P_2O_5 gives an indication of the compounds formed between the two oxides, and by comparing this with Table 7 it is possible to identify the naturally occurring calcium phosphate minerals. The diagram does not indicate the phase boundaries of apatite due to the absence of hydroxyl groups.

TABLE 7 Calcium Phosphates

Ca : P	Mineral name	Formula	Chemical name

**FIG. 8.** Phase equilibrium diagram of calcium phosphates in a water atmosphere. Shaded area is processing range to yield HA-containing implants. (After K. de Groot, 1988. *Ann. N. Y. Acad. Sci.* 523: 227.)**FIG. 9.** X-ray diffraction of hydroxyapatite.

However, from the binary diagram an indication may be obtained of the stability of other calcium phosphates with temperature.

The stoichiometry of HA is highly significant where thermal processing of the material is required. Slight imbalances in the stoichiometric ratio of calcium and phosphorus in HA (from the standard molar ratio of 1.67), can lead to the appearance of either α or β -tricalcium phosphate on heat treatment. Many early papers concerning the production and processing of HA powders reported problems in avoiding the formation of these extraneous phases (Jarcho *et al.*, 1976; De With *et al.*, 1981a, b; Peelen *et al.*, 1978). However, using stoichiometric hydroxyapatite it should be possible to sinter, without phase purity problems, at temperatures in excess of 1300°C.

X-ray diffraction (Fig. 9) and infra-red spectroscopy (Fig. 10) should be used to reveal the phase purity and level of hydroxylation of HA. Kijima and Tsutsumi (1979) used these techniques to study hydroxyapatite sintered at different temperatures and reported that after sintering at 900°C, the

**FIG. 10.** Typical FT-IR spectrum for HA.

material was fully hydroxylated, but after sintering at temperatures higher than this, dehydroxylation occurred. Dehydration of HA, produced by processes such as high temperature solid state reaction, result in the formation of oxyhydroxyapatite: $\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_{2-2x}\text{O}_x\text{V}_x$ (where V is a hydroxyl vacancy). Hydroxyapatite has a $P6_3/m$ space group: This signifies that the lattice is primitive Bravais, there is a sixfold axis parallel to the c axis and a $1/2$ ($3/6$) translation along the length of the c axis (a screw axis) with a mirror plane situated perpendicular to the screw axis and the c axis. The a and c parameters for hydroxyapatite are 0.9418 nm and 0.6884 nm, respectively.

The structure assumed by any solid is such that, on an atomic level, the configuration of the constituents is of the lowest possible energy. In phosphates, this energy requirement results in the formation of discrete subunits within the structure and the PO_4^{3-} group forms a regular tetrahedron with a central P^{5+} ion and O^{2-} ions at the four corners. In a similar manner, the $(\text{OH})^-$ groups are also ionically bonded. In terms of the volume occupied, the oxygen ions exceed all other elements in phosphates. Any other elements present may therefore be considered as filling the interstices, with the exact position being determined by atomic radius and charge (See Fig. 11).

The hydroxyapatite lattice contains two kinds of calcium positions; columnar and hexagonal. There is a net total of four "columnar calcium" ions that occupy the $[1/3, 2/3, 0]$ and $[1/3, 2/3, 1/2]$ lattice points. The "hexagonal calcium" ions are located on planes parallel to the basal plane at $c = 1/4$ and $c = 3/4$ and the six PO_4^{3-} tetrahedra are also located on these planes. The $(\text{OH})^-$ groups are located in columns parallel to the c axis, at the corners of the unit cell, which may be viewed as passing through the centers of the triangles formed by the "hexagonal calcium" ions. Successive hexagonal calcium triangles are rotated through 60° (See Fig. 12).

Defects and impurities in hydroxyapatite may be identified as either substitutional or as discrete, extraneous crystalline phases (as discussed above). Methods of detection of impurities include X-ray diffraction, infrared spectroscopy, and spectrochemical analysis. It is important to make a full spectrochemical analysis of hydroxyapatite since contact with any metal

FIG. 11. Structure of hydroxyapatite projected on the x,y plane, adapted from Kay *et al.*, 1964 (Hing, 1995).

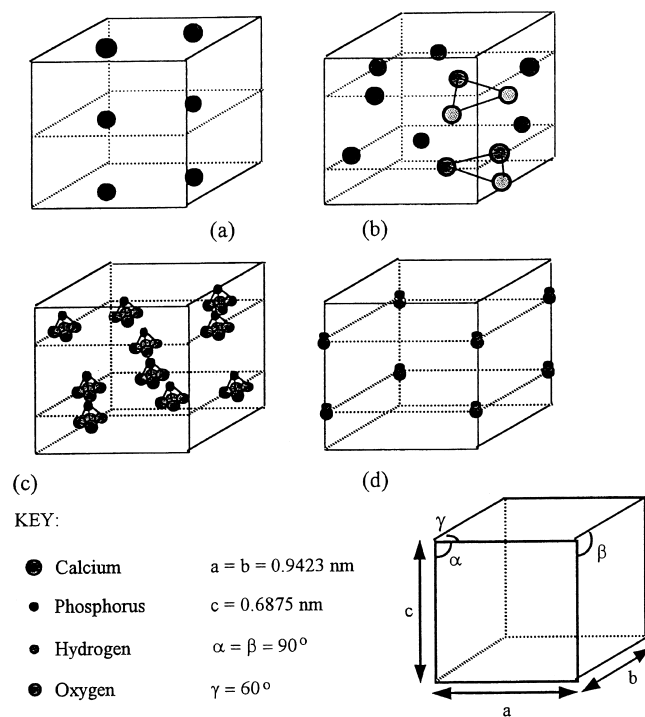

FIG. 12. Theoretical positions of the ionic species within the unit cell of hydroxyapatite (Hing, 1995).

ions during production can lead to high levels of impurities in the product. Typical data for one commercial hydroxyapatite powder are shown in Table 8.

Ions that may be incorporated into the HA structure, either intentionally or unintentionally, include carbonate ions (substituting for hydroxyl or phosphate groups), fluoride ions (substituting for hydroxyl groups), silicon, or silicate ions (substituting for phosphorus or phosphate groups) and magnesium ions substituting for calcium, e.g., Newsley, 1963; Le Geros, 1965; Barralet, 1997; Jha *et al.*, 1998; Gibson *et al.*, 1999).

The presence of carbonate may be observed directly, using infrared spectroscopy, in the form of weak peaks at between 870 and 880 cm^{-1} and a stronger doublet between 1460 and 1530 cm^{-1} , and also through alterations in the hydroxyapatite

TABLE 8 Trace Elements in a Commercial Hydroxyapatite

Trace element	ppm
Al	600
Cu	1
Fe	1000
Ge	100
Mg	2000
Mn	300
Na	3000
Pb	4
Si	500
Ti	30

TABLE 9 Typical Mechanical Properties of Dense Hydroxyapatite Ceramics

Theoretical density	3.156 g cm ³
Hardness	500–800 HV, 2000–3500 Knoop
Tensile strength	40–100 MPa
Bend strength	20–80 MPa
Compressive strength	100–900 MPa
Fracture toughness	approx. 1 Mpa m ^{0.5}
Young's modulus	70–120 GPa

lattice parameters from X-ray diffraction (Rootare and Craig, 1978; LeGeros, 1965; Barralet *et al.*, 1997). The substitution of electronegative anions such as fluorine and chlorine for (OH)⁻ has also been reported to alter the lattice parameters of the material (e.g., Young and Elliot, 1966; Kay *et al.*, 1964; see also Elliot, 1994).

Hydroxyapatite may be processed as a ceramic using compaction (die pressing, isostatic pressing, slip casting, etc.) followed by solid-state sintering (discussed earlier in this chapter). When reporting methods for the production and sintering of hydroxyapatite powders it is very important to adequately characterize the morphology of the product including the surface area, particle size distribution, mean particle size, and physical appearance of the powders, since this will greatly influence the handling and processing characteristics of the material (Best and Bonfield, 1994). There is great deal of variation in the reported mechanical performance of dense hydroxyapatite ceramics, dependent on phase purity, density and grain size, but the properties cited generally fall in the range shown in Table 9.

CALCIUM PHOSPHATE COATINGS

The clinical application of calcium phosphate ceramics is largely limited to non-major-load-bearing parts of the skeleton because of their inferior mechanical properties, and it was partly for this reason that interest was directed toward the use of calcium phosphate coatings on metallic implant substrates. A very good review of techniques for the production of calcium phosphates was given by Wolke *et al.* in 1998. Many techniques are available for the deposition of hydroxyapatite coatings, including electrophoresis, sol-gel routes, electrochemical routes, biomimetic routes, and sputter techniques, but the most popular commercial routes are those based on plasma spraying. In plasma spraying, an electric arc is struck between two electrodes and stream of gases is passed through the arc. The arc converts the gases into a plasma with a speed of up to 400 m/sec and a temperature within the arc of 20,000 K. The ceramic powder is suspended in the carrier gas and fed into the plasma where it can be fired at a substrate. There are many variables in the process including the gases used, the electrical settings, the nozzle/substrate separation and the morphology, particle size, and particle size distribution of the powder. Because of the very high temperatures but very short

times involved, the behavior of the hydroxyapatite powder particle is somewhat different than might be predicted in an equilibrium phase diagram. However, according to the particular conditions used, it is likely that at least a thin outer layer of the powder particle will be in a molten state and will undergo some form of phase transformation, but by careful control of the operating variables the transformed material should represent a relatively small volume fraction of the coating and the product should maintain the required phase purity and crystallinity (Cook *et al.*, 1988; Mayer *et al.*, 1986; Wolke *et al.*, 1992).

A number of factors influence the properties of the resulting coating, including coating thickness (this will influence coating adhesion and fixation—the agreed optimum now seems to be 50–100 μm; Soballe *et al.*, 1993 and de Groot *et al.*, 1987), crystallinity (this affects the dissolution and biological behavior; Klein *et al.*, 1994a, b; Clemens, 1995; Le Geros *et al.*, 1992), biodegradation (affected by phase purity, chemical purity, porosity, crystallinity), and adhesion strength (these may range between 5 and 65 MPa (97)).

The mechanical behavior of calcium phosphate ceramics strongly influences their application as implants. Tensile and compressive strength and fatigue resistance depend on the total volume of porosity. Porosity can be in the form of micropores (< 1 μm diameter, due to incomplete sintering) or macropores (> 100 μm diameter, created to permit bone growth). The dependence of compressive strength (σ_c) and total pore volume (V_p) is described in de Groot *et al.* (1990) by:

$$\sigma_c = 700 \exp -5V_p \quad (\text{in MPa}), \quad (3)$$

where V_p is in the range of 0–0.5.

Tensile strength depends greatly on the volume fraction of microporosity (V_m):

$$\sigma_t = 220 \exp -20V_m (\text{in MPa}). \quad (4)$$

The Weibull factor (n) of HA implants is low in physiological solutions ($n = 12$), which indicates low reliability under tensile loads. Consequently, in clinical practice, calcium phosphate bioceramics should be used (1) as powders; (2) in small, unloaded implants such as in the middle ear; (3) with reinforcing metal posts, as in dental implants; (4) as coatings (e.g., composites); or (5) in low-loaded porous implants where bone growth acts as a reinforcing phase.

The bonding mechanism of dense HA implants appears to be very different from that described above for bioactive glasses. The bonding process for HA implants is described by Jarcho (1981). A cellular bone matrix from differentiated osteoblasts appears at the surface, producing a narrow amorphous electron-dense band only 3 to 5 μm wide. Between this area and the cells, collagen bundles are seen. Bone mineral crystals have been identified in this amorphous area. As the site matures, the bonding zone shrinks to a depth of only 0.05 to 0.2 μm (Fig. 2). The result is normal bone attached through a thin epitaxial bonding layer to the bulk implant. TEM image analysis of dense HA bone interfaces show an almost perfect epitaxial alignment of some of the growing bone crystallites with the apatite crystals in the implant. A consequence of this ultrathin bonding zone is a very high gradient in elastic modulus at the bonding interface between HA and bone. This is one of

the major differences between the bioactive apatites and the bioactive glasses and glass-ceramics. The implications of this difference for the implant interfacial response to Wolff's law is discussed in Hench and Ethridge (1982, Chap. 14).

RESORBABLE CALCIUM PHOSPHATES

Resorption or biodegradation of calcium phosphate ceramics is caused by three factors:

- 1 Physiochemical dissolution, which depends on the solubility product of the material and local pH of its environment. New surface phases may be formed, such as amorphous calcium phosphate, dicalcium phosphate dihydrate, octacalcium phosphate, and anionic-substituted HA.
- 2 Physical disintegration into small particles as a result of preferential chemical attack of grain boundaries.
- 3 Biological factors, such as phagocytosis, which causes a decrease in local pH concentrations (de Groot and Le Geros, 1988).

Ideally, one would wish for a replacement material to be slowly resorbed by the body once its task of acting as a scaffold for new bone has been completed. Degradation or resorption of calcium phosphates *in vivo* occurs by a combination of phagocytosis of particles and the production of acids. However, when selecting a resorbable material for implantation, care must be taken to match the rate of resorption with that of the expected bone tissue regeneration. Where the solubility of calcium phosphates is higher than the rate of tissue regeneration, they will not be of use to fill bone defects. As mentioned previously, the rate of dissolution increases with decreasing calcium-to-phosphorus ratio, and consequently, tricalcium phosphate, with a Ca:P ratio of 1.5, is more rapidly resorbed than hydroxyapatite. Tricalcium phosphate has four polymorphs, α β γ and super α . The γ polymorph is a high pressure phase and the super α polymorph is observed at temperatures above approximately 1500°C (Nurse *et al.*, 1959). Therefore the most frequently observed polymorphs in bioceramics are α and β -TCP. X-ray diffraction studies indicate that the β polymorph transforms to the α polymorph at temperatures between 1120°C and 1290°C (Gibson *et al.*, 1996).

In the 1980s, the idea of a new bone substitute material was introduced and the materials were referred to as calcium phosphate bone cements. These materials offer the potential for *in situ* molding and injectability. There are a variety of different combinations of calcium compounds (e.g., α -tricalcium phosphate and dicalcium phosphate) that are used in the formulation of these bone cements, but the end product is normally based on a calcium-deficient hydroxyapatite (Fernandez *et al.*, 1998, 1999a, b).

All calcium phosphate ceramics biodegrade to varying degrees in the following order: increasing rate HA.

The rate of biodegradation increases as:

1. Surface area increases (powders > porous solid > dense solid)
2. Crystallinity decreases

3. Crystal perfection decreases
4. Crystal and grain size decrease
5. There are ionic substitutions of CO_2^{-3} , Mg^{2+} , and Sr^{2+} in HA

Factors that tend to decrease the rate of biodegradation include (1) F^- substitution in HA, (2) Mg^{2+} substitution in β -TCP, and (3) lower β -TCP/HA ratios in biphasic calcium phosphates.

CLINICAL APPLICATIONS OF HA

Calcium phosphate-based bioceramics have been used in medicine and dentistry for nearly 20 years (Hulbert *et al.*, 1987; de Groot, 1983, 1988; de Groot *et al.*, 1990; Jarcho, 1981; Le Geros, 1988; Le Geros and Le Geros, 1993). Applications include dental implants, periodontal treatment, alveolar ridge augmentation, orthopedics, maxillofacial surgery, and otolaryngology (Table 6).

Most authors agree that HA is bioactive, and it is generally agreed that the material is osseointegrative, where osseointegration is the ability of a material to encourage bone growth along its surface when placed in the vicinity of viable bone or differentiated bone-forming cells. A good recent review of *in vitro* and *in vivo* data for calcium phosphates has been prepared by Hing *et al.* (1998), who observed that there are a large number of "experimental parameters," including specimen, host, and test parameters, which need to be carefully controlled in order to allow adequate interpretation of data.

Hydroxyapatite has been used clinically in a range of different forms and applications. It has been utilised as a dense, sintered ceramic for middle ear implant applications (van Blitterswijk, 1990) and alveolar ridge reconstruction and augmentation (Quin and Kent, 1984; Cranin *et al.*, 1987), in porous form (Smiler and Holmes, 1987; Bucholz *et al.*, 1987), as granules for filling bony defects in dental and orthopaedic surgery (Aoki, 1994; Fujishiro, 1997; Oonishi *et al.*, 1990; Froum *et al.*, 1986; Galgut *et al.*, 1990; Wilson and Low, 1992), and as a coating on metal implants (Cook *et al.*, 1992a, b; De Groot, 1987).

Another successful clinical application for hydroxyapatite has been in the form of a filler in a polymer matrix. The original concept of a bioceramic polymer composite was introduced by Bonfield *et al.* (1981) and the idea was based on the concept that cortical bone itself comprises an organic matrix reinforced with a mineral component. The material developed by Bonfield and co-workers contains up to 50 vol % hydroxyapatite in a polyethylene matrix, has a stiffness similar to that of cortical bone, has high toughness, and has been found to exhibit bone bonding *in vivo*. The material has been used as an orbit implant for orbital floor fractures and volume augmentation (Tanner *et al.*, 1994) and is now used in middle ear implants, commercialized under the trade name HAPEX (Bonfield, 1996).

2.11 PYROLYTIC CARBON FOR LONG-TERM MEDICAL IMPLANTS

Robert B. More, Axel D. Haubold, and Jack C. Bokros

INTRODUCTION

Carbon materials are ubiquitous and of great interest because the majority of substances that make up living organisms are carbon compounds. Although many engineering materials and biomaterials are based on carbon or contain carbon in some form, elemental carbon itself is also an important and very successful biomaterial. Furthermore, there exists enough diversity in structure and properties for elemental carbons to be considered as a unique class of materials beyond the traditional molecular carbon focus of organic chemistry, polymer chemistry, and biochemistry. Through a serendipitous interaction between researchers during the late 1960s the outstanding blood compatibility of a special form of elemental pyrolytic carbon deposited at high temperature in a fluidized bed was discovered. The material was found to have not only remarkable blood compatibility but also the structural properties needed for long-term use in artificial heart valves (LaGrange *et al.*, 1969). The blood compatibility of pyrolytic carbon was recognized empirically using the Gott vena cava ring test. This test involved implanting a small tube made of a candidate material in a canine vena cava and observing the development of thrombosis within the tube in time. Prior to pyrolytic carbon, only surfaces coated with graphite, benzylalkonium chloride, and heparin would resist thrombus formation when exposed to blood for long periods. The incorporation of pyrolytic carbon in mechanical heart valve implants was declared “an exceptional event” (Sadeghi, 1987) because it

FIG. 1. Allotropic crystalline forms of carbon: diamond, graphite, and fullerene.

added the durability and stability needed for heart valve prostheses to endure for a patient's lifetime. The objective of this chapter is to present the elemental pyrolytic carbon materials currently used in the fabrication of medical devices and to describe their manufacture, characterization, and properties.

ELEMENTAL CARBON

Elemental carbon is found in nature as two crystalline allotrophic forms: graphite and diamond. Elemental carbon also occurs as a spectrum of imperfect, turbostratic crystalline forms that range in degree of crystallinity from amorphous to the perfectly crystalline allotropes. Recently a third crystalline form of elemental carbon, the fullerene structure, has been discovered. The crystalline polymorphs of elemental carbon are shown in Fig. 1.

The properties of the elemental carbon crystalline forms vary widely according to their structure. Diamond with its tetrahedral sp^3 covalent bonding is one of the hardest materials known. In the diamond crystal structure, covalent bonds of length 1.54 Å connect each carbon atom with its four nearest neighbors. This tetrahedral symmetry repeats in three dimensions throughout the crystal (Pauling, 1964). In effect, the crystal is a giant isotropic covalently bonded molecule; therefore, diamond is very hard.

Graphite with its anisotropic layered in-plane hexagonal covalent bonding and interplane van der Waals bonding structure is a soft material. Within each planar layer, each carbon atom forms two single bonds and one double bond with its three nearest neighbors. This bonding repeats in-plane to form a giant molecular (graphene) sheet. The in-plane atomic bond length is 1.42 Å, which is a resonant intermediate (Pauling, 1964) between the single-bond length of 1.54 Å and the double-bond length of 1.33 Å. The planer layers are held together by relatively weak van der Waals bonding at a distance of 3.4 Å, which is more than twice the 1.42-Å bond length (Pauling, 1964). Graphite has low hardness and a lubricating property

because the giant molecular sheets can readily slip past one another against the van der Waals bonding. Nevertheless, although large-crystallite-size natural graphite is used as a lubricant, some artificially produced graphites can be very abrasive if the crystallite sizes are small and randomly oriented.

Fullerenes have yet to be produced in bulk, but their properties on a microscale are entirely different from those of their crystalline counterparts. Fullerenes and nanotubes consist of a graphene layer that is rolled up or folded (Sattler, 1995) to form a tube or ball. These large molecules, C_{60} and C_{70} fullerenes and (C_{60+18j}) nanotubes, are often mentioned in the literature (Sattler, 1995) along with more complex multilayer “onion skin” structures.

There exist many possible forms of elemental carbon that are intermediate in structure and properties between those of the allotropes diamond and graphite. Such “turbostratic” carbons occur as a spectrum of amorphous through mixed amorphous, graphite-like and diamond-like to the perfectly crystalline allotropes (Bokros, 1969). Because of the dependence of properties upon structure, there can be considerable variability in properties for the turbostratic carbons. Glassy carbons and pyrolytic carbons, for example, are two turbostratic carbons with considerable differences in structure and properties. Consequently, it is not surprising that carbon materials are often misunderstood through oversimplification. Properties found in one type of carbon structure can be totally different in another type of structure. Therefore it is very important to specify the exact nature and structure when discussing carbon.

PYROLYTIC CARBON (PyC)

The biomaterial known as pyrolytic carbon is not found in nature: it is manmade. The successful pyrolytic carbon biomaterial was developed at General Atomic during the late 1960s using a fluidized-bed reactor (Bokros, 1969). In the original terminology, this material was considered a low-temperature isotropic carbon (LTI carbon). Since the initial clinical implant of a pyrolytic carbon component in the DeBakey–Surgitool mechanical valve in 1968, 95% of the mechanical heart valves implanted worldwide have at least one structural component made of pyrolytic carbon. On an annual basis this translates into approximately 500,000 components (Haubold, 1994). Pyrolytic carbon components have been used in more than 25 different prosthetic heart valve designs since the late 1960s and have accumulated a clinical experience on the order of 16 million patient-years. Clearly, pyrolytic carbon is one of the most successful, critical biomaterials both in function and application. Among the materials available for mechanical heart valve prostheses, pyrolytic carbon has the best combination of blood compatibility, physical and mechanical properties, and durability. However, the blood compatibility of pyrolytic carbon in heart-valve applications is not perfect; chronic anticoagulant therapy is needed for patients with mechanical heart valves. Whether the need for anticoagulant therapy arises from the biocompatible properties of the material itself or from the particular hydrodynamic interaction of a given device and the blood remains to be resolved.

FIG. 2. Fluidized-bed reactor schematic.

The term “pyrolytic” is derived from “pyrolysis,” which is thermal decomposition. Pyrolytic carbon is formed from the thermal decomposition of hydrocarbons such as propane, propylene, acetylene, and methane, in the absence of oxygen. Without oxygen the typical decomposition of the hydrocarbon to carbon dioxide and water cannot take place; instead a more complex cascade of decomposition products occurs that ultimately results in a “polymerization” of the individual carbon atoms into large macroatomic arrays.

Pyrolysis of the hydrocarbon is normally carried out in a fluidized-bed reactor such as the one shown in Fig. 2. A fluidized-bed reactor typically consists of a vertical tube furnace that may be induction or resistance heated to temperatures of 1000 to 2000°C (Bokros, 1969). Reactor diameters ranging from 2 cm to 25 cm have been used; however, the most common size used for medical devices has a diameter of about 10 cm. These high-temperature reactors are expensive to operate, and the reactor size limits the size of device components to be produced.

Small refractory ceramic particles are placed into the vertical tube furnace. When a gas is introduced into the bottom of the tube furnace, the gas causes the particle bed to expand: Interparticle spacing increases to allow for the flow of the gas. Particle mixing occurs and the bed of particles begins to “flow” like a fluid. Hence the term “fluidized bed.” Depending upon the gas flow rate and volume, this expansion and mixing can be varied from a gentle bubbling bed to a violent spouting bed. An oxygen-free, inert gas such as nitrogen or helium is used to fluidize the bed, and the source hydrocarbon is added to the gas stream when needed.

At a sufficiently high temperature, pyrolysis or thermal decomposition of the hydrocarbon can take place. Pyrolysis products range from free carbon and gaseous hydrogen to a mixture of C_xH_y decomposition species. The pyrolysis reaction

is complex and is affected by the gas flow rate, composition, temperature and bed surface area. Decomposition products, under the appropriate conditions, can form gas-phase nucleated droplets of carbon/hydrogen, which condense and deposit on the surfaces of the wall and bed particles within the reactor (Bokros, 1969). Indeed, the fluidized-bed process was originally developed to coat small (200–500 micrometer) diameter spherical particles of uranium/thorium carbide or oxide with pyrolytic carbon. These coated particles were used as the fuel in the high temperature gas-cooled nuclear reactor (Bokros, 1969).

Pyrolytic carbon coatings produced in vertical-tube reactors can have a variety of structures such as laminar or isotropic, granular, or columnar (Bokros, 1969). The structure of the coating is controlled by the gas flow rate (residence time in the bed), hydrocarbon species, temperature and bed surface area. For example, an inadequately fluidized or static bed will produce a highly anisotropic, laminar pyrolytic carbon (Bokros, 1969).

Control of the first three parameters (gas flow rate, hydrocarbon species, and temperature) is relatively easy. However, until recently, it was not possible to measure the bed surface area while the reactions were taking place. As carbon deposits on the particles in the fluidized bed, the diameter of the particles increases. Hence the surface area of the bed changes, which in turn influences the subsequent rate of carbon deposition. As surface area increases, the coating rate decreases since a larger surface area now has to be coated with the same amount of carbon available. Thus the process is not in equilibrium. The static-bed process was adequate to coat nuclear fuel particles without attempting to control the bed surface area, because such thin coatings (25 to 50 μm thick) did not appreciably affect the bed surface area.

It was later found that larger objects could be suspended within the fluidized bed of small ceramic particles and also become uniformly coated with carbon. This finding led to the demand for thicker, structural coatings, an order of magnitude thicker (250 to 500 μm). Bed surface area control and stabilization became an important factor (Akins and Bokros, 1974) in achieving the goal of thicker, structural coatings. In particular, with the discovery of the blood-compatible properties of pyrolytic carbon (LaGrange *et al.*, 1969), thicker structural coatings with consistent and uniform mechanical properties were needed to realize the application to mechanical heart-valve components. Quasi-steady-state conditions as needed to prolong the coating reaction were achieved empirically by removing coated particles and adding uncoated particles to the bed while the pyrolysis reaction was taking place (Akins and Bokros, 1974). However, the rates of particle addition and removal were based upon little more than good guesses.

Three of the four parameters that control carbon deposition could be accurately measured and controlled, but a method to measure and control bed surface area was lacking. Thus, the quasi-steady-state process was more of an art than a science. If too many coated particles were removed, the bed became too small to support the larger components within it and the bed collapsed. If too few particles were removed, the rate of deposition decreased, and the desired amount of coating was not achieved in the anticipated time. Furthermore, there were

considerable variations in the mechanical properties of the coating from batch to batch. It was found that in order to consistently achieve the hardness needed for wear resistance in prosthetic heart valve applications, it was necessary to add a small amount of β -silicon carbide to the carbon coating. The dispersed silicon carbide particles within the pyrolytic carbon matrix added sufficient hardness to compensate for potential variations in the properties of the pyrolytic carbon matrix. The β -silicon carbide was obtained from the pyrolysis of methyltrichlorosilane, CH_3SiCl_3 . For each mole of silicon carbide produced, the pyrolysis of methyltrichlorosilane also produces 3 moles of hydrogen chloride gas. Handling and neutralization of this corrosive gas added substantial complexity and cost to an already complex process. Nevertheless, this process allowed consistency for the successful production of several million components for use in mechanical heart valves.

A process has been developed and patented that allows precise measurement and control of the bed surface area. A description of this process is given in the patent literature and elsewhere (Emken *et al.*, 1993, 1994; Ely *et al.*, 1998). With precise control of the bed surface area it is no longer necessary to include the silicon carbide. Elimination of the silicon carbide has produced a stronger, tougher, and more deformable pure pyrolytic carbon. Historically, pure carbon was the original objective of the development program because of the potential for superior biocompatibility (LaGrange *et al.*, 1969). Furthermore, the enhanced mechanical and physical properties of the pure pyrolytic carbon now possible with the improved process control allows prosthesis design improvements in the hemodynamic contribution to thromboresistance (Ely *et al.*, 1998).

Structure of Pyrolytic Carbons

X-ray diffraction patterns of the biomedical-grade fluidized-bed pyrolytic carbons are broad and diffuse because of the small crystallite size and imperfections. In silicon-alloyed pyrolytic carbon, a diffraction pattern characteristic of the β form of silicon carbide also appears in the diffraction pattern along with the carbon bands. The carbon diffraction pattern indicates a turbostratic structure (Kaae and Wall, 1996) in which there is order within carbon layer planes, as in graphite; but, unlike graphite, there is no order between planes. This type of turbostratic structure is shown in Fig. 3 compared to that of graphite. In the disordered crystalline structure, there may be lattice vacancies and the layer planes are curved or kinked. The ability of the graphite layer planes to slip is inhibited, which greatly increases the strength and hardness of the pyrolytic carbon relative to that of graphite. From the Bragg equation, the pyrolytic carbon layer spacing is reported to be 3.48 \AA , which is larger than the 3.35 \AA graphite layer spacing (Kaae and Wall, 1996). The increase in layer spacing relative to graphite is due to both the layer distortion and the small crystallite size, and is common feature for turbostratic carbons. From the Scherrer equation the crystallite size is typically 25–40 \AA (Kaae and Wall, 1996).

During the coating reaction, gas-phase nucleated droplets of carbon/hydrogen form that condense and deposit on the surfaces of the reactor wall and bed particles within the reactor.

FIG. 3. Structures of (A) diamond, (B) graphite, and (C) turbostratic pyrolytic carbon.

These droplets aggregate, grow, and form the coating. When viewed with high-resolution transmission electron microscopy, a multitude of near-spherical polycrystalline growth features are evident as shown in Fig. 4 (Kaae and Wall, 1996). These growth features are considered to be the basic building blocks of the material, and the shape and size are related to the deposition mechanism. In the silicon-alloyed carbon small silicon carbide particles are present within the growth features as shown in Fig. 5. Based on a crystallite size of 33 \AA , each growth feature contains about 3×10^9 crystallites. Although the material is quasi-crystalline on a fine level, the crystallites are very small and randomly oriented in the fluidized bed pyrolytic carbons so that overall the material exhibits isotropic behavior.

Glassy carbon, also known as vitreous carbon or polymeric carbon, is another turbostratic carbon form that has been proposed for use in long-term implants. However, its strength is low and the wear resistance is poor. Glassy carbons are quasi-crystalline in structure and are named 'glassy' because the fracture surfaces closely resemble those of glass (Haubold *et al.*, 1981).

Vapor-deposited carbons are also used in heart-valve applications. Typically, the coatings are thin ($< 1 \text{ \mu m}$) and may be applied to a variety of materials in order to confer the biochemical characteristics of turbostratic carbon. Some examples are vapor-deposited carbon coatings on heart-valve sewing cuffs and metallic orifice components (Haubold *et al.*, 1981).

FIG. 4. Electron micrograph of pure pyrolytic carbon microstructure showing near-spherical polycrystalline growth features formed during deposition (Kaae and Wall, 1996).

FIG. 5. Electron micrograph of silicon-alloyed pyrolytic carbon microstructure showing near-spherical polycrystalline growth features formed during deposition (Kaae and Wall, 1996). Small silicon carbide particles are shown in concentric rings in the growth features.

Mechanical Properties

Mechanical properties of pure pyrolytic carbon, silicon-alloyed pyrolytic carbons and glassy carbon are given in Table 1. Pyrolytic carbon flexural strength is high enough to provide the necessary structural stability for a variety of implant applications and the density is low enough to allow for components to move easily under the applied forces of circulating blood. With respect to orthopedic applications, Young's modulus is in the range reported for bone (Reilly and Burstein, 1974; Reilly *et al.*, 1974), which allows for

TABLE 1 Mechanical Properties of Biomedical Carbons

Property	Pure PyC	Typical Si-alloyed PyC	Typical glassy carbon
Flexural strength (MPa)	493.7 ± 12	407.7 ± 14.1	175
Young's modulus (GPa)	29.4 ± 0.4	30.5 ± 0.65	21
Strain-to-failure (%)	1.58 ± 0.03	1.28 ± 0.03	
Fracture toughness (MPa √m)	1.68 ± 0.05	1.17 ± 0.17	0.5–0.7
Hardness (DPH, 500 g load)	235.9 ± 3.3	287 ± 10	150
Density (g/cm ³)	1.93 ± 0.01	2.12 ± 0.01	<1.54
CTE (10–6 cm/cm °C)	6.5	6.1	
Silicon content (%)	0	6.58 ± 0.32	0
Wear resistance	Excellent	Excellent	Poor

compliance matching. Relative to metals and polymers, the pyrolytic carbon strain-to-failure is low; it is a nearly ideal linear elastic material and requires consideration of brittle material principles in component design. Strength levels vary with the effective stressed volume or stressed area as predicted by classical Weibull statistics (De Salvo, 1970). The flexural strengths cited in Table 1 are for specimens tested in four-point bending, third-point loading (More *et al.*, 1993) with effective stressed volumes of 1.93 mm³. The pyrolytic carbon material Weibull modulus is approximately 10 (More *et al.*, 1993).

Fracture toughness levels reflect the brittle nature of the material, but the fluidized-bed isotropic pyrolytic carbons are remarkably fatigue resistant. Recent fatigue studies indicate the existence of a fatigue threshold that is very nearly the single-cycle fracture strength (Gilpin *et al.*, 1993; Ma and Sines, 1996, 1999, 2000). Fatigue-crack propagation studies indicate very high Paris-Law fatigue exponents, on the order of 80, and display clear evidence of a fatigue-crack propagation threshold (Ritchie *et al.*, 1990; Beavan *et al.*, 1993; Cao, 1996).

Crystallographic mechanisms for fatigue-crack initiation, as occur in metals, do not exist in the pyrolytic carbons (Haubold *et al.*, 1981). In properly designed and manufactured components, and in the absence of externally induced damage, fatigue does not occur in pyrolytic-carbon mechanical heart-valve components. In the 30 years of clinical experience, there have been no clear instances of fatigue failure. Few pyrolytic carbon component fractures have occurred, less than 60 out of more than 4 million implanted components (Haubold, 1994), and most are attributable to induced damage from handling or cavitation (Kelpetko *et al.*, 1989; Kafesjian *et al.*, 1994; Richard and Cao, 1996).

Wear resistance of the fluidized-bed pyrolytic carbons is excellent. The strength, stability, and durability of pyrolytic carbon are responsible for the extension of mechanical-valve lifetimes from less than 20 years to more than the recipient's expected lifetime (Wieting, 1996; More and Silver, 1990; Schoen, 1983; Schoen *et al.*, 1982).

Pyrolytic carbon in heart-valve prostheses is often used in contact with metals, either as a carbon disk in a metallic

valve orifice or as a carbon orifice stiffened with a metallic ring. Carbon falls with the noble metals in the galvanic series (Haubold *et al.*, 1981), the sequence being silver, titanium, graphite, gold, and platinum. Carbon can accelerate corrosion when coupled to less noble metals *in vivo*. However, testing using mixed potential corrosion theory and potentiostatic polarization has determined that no detrimental effects occur when carbon is coupled with titanium or cobalt–chrome alloys (Griffin *et al.*, 1983; Thompson *et al.*, 1979). Carbon couples with stainless steel alloys are not recommended.

STEPS IN THE FABRICATION OF PYROLYTIC CARBON COMPONENTS

To convert a gaseous hydrocarbon into a shiny, polished black component for use in the biological environment is not a trivial undertaking. Furthermore, because of the critical importance of long-term implants to a recipient's health, all manufacturing operations are performed to stringent levels of quality assurance under the auspices of U.S. Food and Drug Administration Good Manufacturing Practices and International Standards Organization ISO-9000 regulations. As in the case of fabrication of metallic implants, numerous steps are involved. Pyrolytic carbon is not machined from a block of material, as is the case with most metallic implants, nor is it injection or reactive molded, as are many polymeric devices. An overview of the processing steps leading to a finished pyrolytic carbon coated component for use in a medical device is shown in Fig. 6 and is further described in the following sections.

Substrate Material

Since pyrolytic carbon is a coating, it must be deposited on an appropriately shaped, preformed substrate (preform). Because the pyrolysis process takes place at high temperatures, the choice of substrates is severely limited. Only a few of the refractory materials such as tantalum or molybdenum/rhenium alloys and graphite can withstand the conditions at which the pyrolytic carbon coating is produced. Some refractory metals have been used in heart-valve components; for example, Mo/Re preforms were coated to make the struts for the Beall-Surgitool mitral valve. It is important for the thermal expansion characteristics of the substrate to closely match those of the applied coating. Otherwise, upon cooling of the coated part to room temperature the coating will be highly stressed and can spontaneously crack. For contemporary heart-valve applications, fine-grained isotropic graphite is the most commonly used substrate. This substrate graphite can be doped with tungsten in order to provide radioopacity for X-ray visualizations of the implants. The graphite substrate does not impart structural strength. Rather, it provides a dimensionally stable platform for the pyrolytic carbon coating both at the reaction temperature and at room temperature.

Preform

Once the appropriate substrate material has been selected and prior to making a preform, it must be inspected to ensure that the material meets the desired specifications. Typically, the strength and density of the starting material are measured. Thermal expansion is ordinarily validated and monitored through process control. The preform, which is an undersized replica of the finished component, is normally machined using conventional machining methods. Because the fine-grained isotropic graphite is very abrasive, standard machine tools have given way to diamond-plated or single-point diamond tools. In the case of heart valves, numerical control machining methods are often required to maintain critical component dimensional tolerances. After the preform is completed, it is inspected to ensure that its dimensions fall within the specified tolerances and that it contains no visible flaws or voids.

Coating

Generally numerous preforms are coated in one furnace run. A batch to be coated is made up of substrates from a single lot of preforms. Such batch processing by lot is required in order to maintain “forward and backward” traceability. In other words, ultimately it is necessary to know all of the components that were prepared using a specific material lot, given either the starting material lot number (forward) or given the specific component serial number (backward). The number of parts that can be coated in one furnace run is dictated by the

Steps in the fabrication of pyrolytic carbon components

FIG. 6. Schematic of manufacturing processing steps.

FIG. 7. Metallographic mount cross section of heat valve component. The light-colored pyrolytic carbon layer is coated over the interior, darker colored granular-appearing graphite substrate.

size of the furnace and the size and weight of the parts to be coated. The batch of substrates is placed within the fluidized bed in the vertical tube furnace and is coated to the desired thickness. Coating times are generally on the order of a few hours, but the entire cycle (heat-up, coating, and cool-down) may take as long as a full day.

A statistical sample from each coating lot is taken for analysis. At this point, typical measurements include coating thickness, microhardness and microstructure. The microhardness, and microstructure are determined from a metallographically prepared cross section of the coated component taken perpendicular to plane of deposition. Thus, this test is destructive. An example of a metallographically prepared cross section of a pyrolytic carbon component is shown in Fig. 7.

Machine to Size

The components used to manufacture medical devices have strict dimensional requirements. Because of the inability, until recently, to precisely measure and control bed size and indirectly coating thickness, the preforms were generally coated more thickly than necessary to ensure adequate pyrolytic carbon coating thickness on the finished part. The strict dimensional requirements were then achieved through precision grinding or other machining operations. Because pyrolytic carbon is very hard, conventional machine tools again cannot be used. Diamond-plated grinding wheels and other diamond tooling are required. The dimensions of final machined parts are again verified.

Polish

The surface of as-deposited, machined and polished components is shown in Fig. 8. It was found early on in experiments (LaGrange *et al.*, 1969; Haubold *et al.*, 1981; Sawyer *et al.*, 1975) that clean polished pyrolytic carbon surfaces

FIG. 8. Scanning electron microscope micrographs of (A) as-coated and (B) as-polished surfaces.

of tubes when placed within the vasculature of experimental animals accumulated minimal if any thrombus and certainly less than pyrolytic carbon tubes with the as-deposited surface. Consequently, the surfaces of pyrolytic carbon have historically been polished, either manually or mechanically, using fine diamond or aluminum oxide pastes and slurries. The surface finish achieved has roughness measured on the scale of nanometers. As can be seen from Table 2 (More and Haubold, 1996), the surfaces of polished pyrolytic carbon (30–50 nm) are an order of magnitude smoother than the as-deposited surfaces (300–500 nm).

Once the desired surface quality is achieved, components are again inspected. The final component inspection may include measurement of dimensions, X-ray inspection in two orientations to verify coating thickness, and visual inspection for surface quality and flaws. In many cases, automated inspection methods with computer-controlled coordinate measurement machines are used. X-ray inspection can be used to ensure that minimum coating thickness requirements are met. Two orthogonal views ensure that machining and grinding of

As-coated slab	389.07	503.72	

^aComponents/prepared by: On-X/Medical Carbon Research Institute, Austin, TX; Sorin/Sorin Biomedica, Saluggia, Italy; SJM/Saint Jude Medical, Saint Paul, MN; CMI (SJM)/CarboMedics, Austin, TX; DeBakey-S/CarboMedics, San Diego (circa 1968). "Clinical" was from as-packaged valve; "nonclinical" lacks component traceability.

the coating was achieved uniformly and that the coating is symmetrical. The machining and grinding operation after coating is not without the risk of inducing cracks or flaws in the coating, which may subsequently affect the service life of the component. Such surface flaws are detected visually or with the aid of dye-penetrant techniques. Components may also be proof-tested to detect and eliminate components with subsurface flaws. With the advent of bed size control, which allows coating to exact final dimensions, the concerns about flaws introduced during the machining and grinding operation have been eliminated.

The polished and inspected components, thus prepared, are now ready for assembly into devices, or are packaged and sterilized in the case of stand-alone devices. Shown in Fig. 9 are the three pyrolytic carbon components for a bileaflet mechanical heart valve. The components were selected and matched for assembly using the data generated from the final dimensional inspection to achieve the dimensional requirements specified in the device design. In Fig. 10, the pyrolytic carbon components for a replacement metacarpophalangeal total joint prosthesis are shown.

Assembly

The multiple components of a mechanical heart must be assembled. The brittleness of pyrolytic carbon poses a significant assembly problem. Because the strain-to-failure is on the order of 1.28 to 1.58%, there is a limited range of deformation that can be applied in order to achieve a proper fit. Relative fit between the components defines the capture and the range of motion for components that move to actuate valve opening and closing. Furthermore, component obstructive bulk and tolerance gaps are critical to hemodynamic performance.

In designs that use a metallic orifice, the metallic components are typically deformed in order to insert the pyrolytic

**FIG. 9.** Components for On-X bileaflet heart valve.**FIG. 10.** Replacement metacarpophalangeal total joint prosthesis components, Ascension Orthopedics, Austin TX.

carbon occluder disk. For the all-carbon bileaflet designs, the carbon orifice must be deflected in order to insert the leaflets. As the valve diameter decreases and as the section modulus of the orifice design increases, the orifice stiffness increases. The possibility of damage or fracture during assembly was a limiting factor in early orifice design. For this reason, the orifices in valve designs using silicon-alloyed pyrolytic carbon were simple cylindrical geometries, and the smallest sizes limited to the equivalent of a 19-mm-diameter tissue annulus. The simple cylindrical orifice designs are often reinforced with a metallic stiffening ring that is shrunk on after assembly. The stiffening ring ensures that physiological loading will not produce deflections that can inhibit valve action or result in leaflet escape.

The increased strain-to-failure of pure pyrolytic carbon, relative to the silicon-alloyed carbon, allows designs with more complex orifice section moduli. This allows designers to utilize hydrodynamically efficient shapes such as flared inlets and to incorporate external stiffening bands that eliminate the need for a metallic stiffening ring. The increased strain-to-failure of On-X carbon has been used to advantage in the On-X mechanical heart valve design (Ely *et al.*, 1998).

Cleaning and Surface Chemistry

Pyrolytic carbon surface chemistry is important because the manufacturing and cleaning operations to which a component is subjected can change and redefine the surface that is presented to the blood. Oxidation of carbon surfaces can produce surface contamination that detracts from blood compatibility (LaGrange *et al.*, 1969; Bokros *et al.*, 1969). Historically, the initial examinations of pyrolytic carbon biocompatibility assumed de facto that the surface needed to be treated with a thromboresistant agent such as heparin (Bokros *et al.*, 1969). It was found, however, that the non-heparin-coated surface was actually more blood compatible than the treated surface. Hence, the efforts toward surface coating with heparin were abandoned.

In general it is desired to minimize the surface oxygen and any other non-carbon surface contaminants. From X-ray photoelectron spectroscopy (XPS) analyses, a typical heart valve component surface has 76–86% C, 12–21% O, 0–2% Si, and 1–2% Al (More and Haubold, 1996; King *et al.*, 1981; Smith and Black, 1984). Polishing compounds tend to contain alumina and some alumina particles may become imbedded in the carbon surface. Other contaminants that may be introduced at low levels < 2% each are Na, B, Cl, S, Mg, Ca, Zn, and N. The XPS carbon 1s peak when scanned at high resolution can be deconvoluted to determine carbon oxidations states. The carbon 1s peak will typically consist primarily of hydrocarbon-like carbon (60–81%), ether alcohol/ester-like carbon (10–24%), ketone-like carbon (0–6%), and ester/acid-like carbon (1–12%) (More and Haubold, 1996). Each manufacturing, cleaning and sterilizing operation potentially redefines the surface. The effect of modified surface chemistry on blood compatibility is not well characterized, so this adds a level of uncontrolled variability when considering the blood compatibility of pyrolytic-carbon heart-valve materials from different manufacturing sources and different investigators. In general, the presence of oxygen and surface contaminants should be eliminated.

BIOCOMPATIBILITY OF PYROLYTIC CARBON

The suitability of a material for use in an implant is a complex issue. Biocompatibility testing is the focus of other

chapters. In the case of pyrolytic carbon, its successful history interfacing with blood in mechanical heart valves attests to its suitability for this application. A note of caution, however, is in order. Until about a decade ago, the pyrolytic carbon used so successfully in mechanical heart valves was produced by a single manufacturer. The material, many applications in the biological environment, and the processes for producing the material were all patented. Since the expiration of the last of these patents in 1989, other sources for pyrolytic carbon have appeared that are copies of the original General Atomic material. When considering alternative carbon materials, it is important to recognize that the proper combination of physical, mechanical, and blood-compatible properties is required for the success of the implant application. Furthermore, because there are a number of different possible pyrolysis processes, it should be recognized that each can result in different microstructures with different properties. Just because a material is carbon, a turbostratic carbon, or a pyrolytic carbon does not qualify its use in a long-term human implant (Haubold and Ely, 1995). For example, pyrolytic carbons prepared by chemical vapor deposition processes, other than the fluidized-bed process, are known to exhibit anisotropy, nonhomogeneity, and considerable variability in mechanical properties (Agafonov *et al.*, 1999). Although these materials may exhibit biocompatibility, the potential for variability in structural stability and durability may lead to valve dysfunction.

The original General Atomic-type fluidized-bed pyrolytic carbons all demonstrate negligible reactions in the standard Tripartite and ISO 10993-1 type biocompatibility tests. Results from such tests are given in Table 3 (Ely *et al.*, 1998). Pure pyrolytic carbon is so non-reactive that it can serve as a negative control for these tests.

It is believed that pyrolytic carbon owes its demonstrated blood compatibility to its inertness and to its ability to quickly absorb proteins from blood without triggering a protein denaturing reaction. Ultimately, the blood compatibility is thought to be a result of the protein layer formed upon the carbon surface. Baier observed that pyrolytic carbon surfaces have a relatively high critical surface tension of 50 dyn/cm, which immediately drops to 28 to 30 dyn/cm following exposure to blood (Baier *et al.*, 1970). The quantity of sorbed protein was thought to be an important factor for blood compatibility. Lee and Kim (1974) quantified the amount of radiolabeled

TABLE 3 Biological Testing of Pure PyC

Test description	Protocol	Results

FIG. 11. Fibrinogen and albumin adsorption on pyrolytic carbon (PyC) and Silastic silicone rubber.

proteins sorbed from solutions of mixture proteins (albumin, fibrinogen, and gamma-globulin). While pyrolytic carbon does absorb albumin, it also absorbs considerable quantity of fibrinogen as shown in Fig. 11. As can be seen in Fig. 11, the amount of fibrinogen absorbed on pyrolytic carbon surfaces is far greater than the amount of albumin on these surfaces and is comparable to the amount of fibrinogen that sorbed on silicone rubber. The mode of albumin absorption, however, appears to be drastically different for these two materials. Albumin sorbs immediately on the pyrolytic carbon surfaces, whereas the buildup of fibrinogen is much slower. In the case of silicone rubber, both proteins sorb at a much slower rate. It appears that the mode of protein absorption is important and not the total amount sorbed.

Nyilas and Chiu (1978) studied the interaction of plasma proteins with foreign surfaces by measuring directly the heats of absorption of selected proteins onto such surfaces using microcalorimetric techniques. They found that the heats of absorption of fibrinogen, up to the completion of first monolayer coverage, are a factor of 8 smaller on pyrolytic carbon surfaces than on the known thrombogenic control (glass) surface as shown in Fig. 12. Furthermore, the measured net heats of absorption of gamma globulin on pyrolytic carbon were about 15 times smaller than those on glass. They concluded that low heats of absorption onto a foreign surface imply small interaction forces with no conformational changes of the proteins that might trigger the clotting cascade. It appears that a layer of continuously exchanging blood proteins in their unaltered state "masks" the pyrolytic carbon surfaces from appearing as a foreign body.

There is further evidence that the minimally altered sorbed protein layers on pyrolytic carbon condition blood compatibility. Salzman *et al.* (1977), for example, observed a significant difference in platelet reaction with pyrolytic carbon beads in packed columns prior to and after pretreatment with albumin. With no albumin preconditioning treatment, platelet retention by the columns was high, but the release of platelet constituents was low. However, with albumin pretreatment, platelet retention and the release of constituents was minimal.

FIG. 12. Integral heat of sorption for fibrinogen on glass and fibrinogen on PyC at two different temperatures (Nyilas and Chiu, 1978).

The foregoing observations led to the view that pyrolytic carbon owes its demonstrated blood compatibility to its inertness and to its ability to quickly absorb proteins from blood without triggering a protein-denaturing reaction (Haubold *et al.*, 1981; Nyilas and Chiu, 1978). However, the assertion that pyrolytic carbon is an inert material and induces minimal conformational changes in adsorbed protein was reexamined by Feng and Andrade (1994). Using differential scanning calorimetry and a variety of proteins and buffers, they found that pyrolytic carbon surfaces denatured all of the

proteins studied. They concluded that whether or not a surface denatures protein cannot be the sole criteria for blood compatibility. Their suggestion was that the specific proteins and the sequence in which they are denatured may be important. For example, it was suggested that pyrolytic carbon may first adsorb and denature albumin, which forms a layer that subsequently passivates the surface and inhibits thrombosis.

Chinn *et al.* (1994) reexamined the adsorption of albumin and fibrinogen on pyrolytic carbon surfaces and noted that relative large amounts of fibrinogen were adsorbed and speculated that the adsorbed fibrinogen was rapidly converted to a non-elutable form. If the elutable form is more reactive to platelets than the nonelutable form, then the nonelutable protein layer may contribute to the passivating effect.

Work on visualizing the carbon surface and platelet adhesion done by Goodman *et al.* (1995) using low-accelerating-voltage scanning electron microscopy, along with critical-point drying techniques, has discovered that the platelet spreading on pyrolytic carbon surfaces is more extensive than previously observed (Haubold *et al.*, 1981). However, platelet loading was in a static flow situation that does not model the physiological flow that a heart valve is subjected to. Hence, this approach cannot resolve kinetic effects on platelet adhesion. However, Okazaki, Tweden, and co-workers observed adherent platelets on valves following implantation in sheep that were not treated with anticoagulants (Okazaki *et al.*, 1997). There were no instances of valve thrombosis even though platelets were present on some of the valve surfaces. But, the relevance of this observation to clinical valve thromboses is not clear because human patients with mechanical heart valves undergo chronic anticoagulant therapy (Edmunds, 1987) and have a hemostatic system different from that of sheep.

A more contemporary version of the mechanism of pyrolytic carbon blood compatibility might be to reject the assumption that the surface is inert, as it is now thought by some that no material is totally inert in the body (Williamis, 1998), and to accept that the blood-material interaction is preceded by a complex, interdependent, and time-dependent series of interactions between the plasma proteins and the surface (Hanson, 1998) that is as yet poorly understood. To add to the confusion, it must also be recognized that much of the forementioned conjecture depends on the assumption that all of the carbon surfaces studied were in fact pure and comparable to one another.

CONCLUSION

Because the blood compatibility of pyrolytic carbon in mechanical heart valves is not perfect, anticoagulant therapy is required for mechanical heart valve patients. However, pyrolytic carbon has been the most successful material in heart valve applications because it offers excellent blood and tissue compatibility which, combined with the appropriate set of physical and mechanical properties and durability, allows for practical implant device design and manufacture. Improvements in biocompatibility are desired, of course, because when heart valves and other implants are used, a deadly or disabling disease is often treated by replacing it with a less pathological,

more manageable chronic condition. Ideally, an implant should not lead to a chronic condition.

It is important to recognize that the mechanism for the blood compatibility of pyrolytic carbons is not fully understood, nor is the interplay between the biomaterial itself, design-related hemodynamic stresses, and the ultimate biological reaction. The elucidation of the mechanism for blood and tissue compatibility of pyrolytic carbon remains a challenge.

It is also worth restating that the suitability of carbon materials from new sources for long-term implants is not assured simply because the material is carbon. Elemental carbon encompasses a broad spectrum of possible structures and mechanical properties. Each new candidate carbon material requires a specific assessment of biocompatibility based on its own merits and not by reference to the historically successful General Atomic-type pyrolytic carbons.

2.12 COMPOSITES

Claudio Migliaresi and Harold Alexander

INTRODUCTION

The word *composite* means “consisting of two or more distinct parts.” At the atomic level, materials such as metal alloys

and polymeric materials could be called composite materials in that they consist of different and distinct atomic groupings. At the microstructural level (about 10^{-4} to 10^{-2} cm), a metal alloy such as a plain-carbon steel containing ferrite and pearlite could be called a composite material since the ferrite and pearlite are distinctly visible constituents as observed in the optical microscope. At the molecular and microstructural level, tissues such as bone and tendon are certainly composites with a number of levels of hierarchy.

In engineering design a composite material usually refers to a material consisting of constituents in the micro- to macro-size range, favoring the macrosize range. For the purpose of discussion in this chapter, composites can be considered materials consisting of two or more chemically distinct constituents, on a macroscale, having a distinct interface separating them. This definition encompasses the fiber and particulate composite materials of primary interest as biomaterials. Such composites consist of one or more discontinuous phases embedded within a continuous phase. The discontinuous phase is usually harder and stronger than the continuous phase and is called the *reinforcement* or *reinforcing material*, whereas the continuous phase is termed the *matrix*.

Properties of composites are strongly influenced by the properties of their constituent materials, their distribution and content, and the interaction among them. The composite properties may be the volume fraction sum of the properties of the constituents, or the constituents may interact in a synergistic way due to geometrical orientation so as to provide properties in the composite that are not accounted for by a simple volume fraction sum. Thus in describing a composite material, besides specifying the constituent materials and their properties, one needs to specify the geometry of the reinforcement, their concentration, distribution, and orientation.

Most composite materials are fabricated to provide desired mechanical properties such as strength, stiffness, toughness, and fatigue resistance. Therefore, it is natural to study together the composites that have a common strengthening mechanism. The strengthening mechanism strongly depends upon the geometry of the reinforcement. Therefore, it is quite convenient to classify composite materials on the basis of the geometry of a representative unit of reinforcement. Figure 1 shows a commonly accepted classification scheme.

With regard to this classification, the distinguishing characteristic of a particle is that it is nonfibrous in nature. It may be spherical, cubic, tetragonal, or of other regular or irregular shape, but it is approximately equiaxial. A fiber is characterized by its length being much greater than its cross-sectional dimensions. Particle-reinforced composites are sometimes referred to as *particulate composites*. Fiber-reinforced composites are, understandably, called *fibrous composites*. *Laminates* are composite structures made by stacking laminae of fiber composites oriented to produce a structural element. Characteristics, number, and orientation of laminae are such as to match specific design requirements.

Fibers are much more mechanically effective than particles, and polymer-fiber composites can reach stiffness and strength comparable to those of metals and even higher.

Moreover, whereas particle-reinforced composites are isotropic, fiber-reinforced composites are basically anisotropic. Properties in different directions can be in most cases designed to match specific requirements.

At the molecular and microstructural level, tissues such as bone and tendon or vessels are certainly composites with a number of levels of hierarchy. Their properties are highly anisotropic, and the only possibility to mimic them is to use composites.

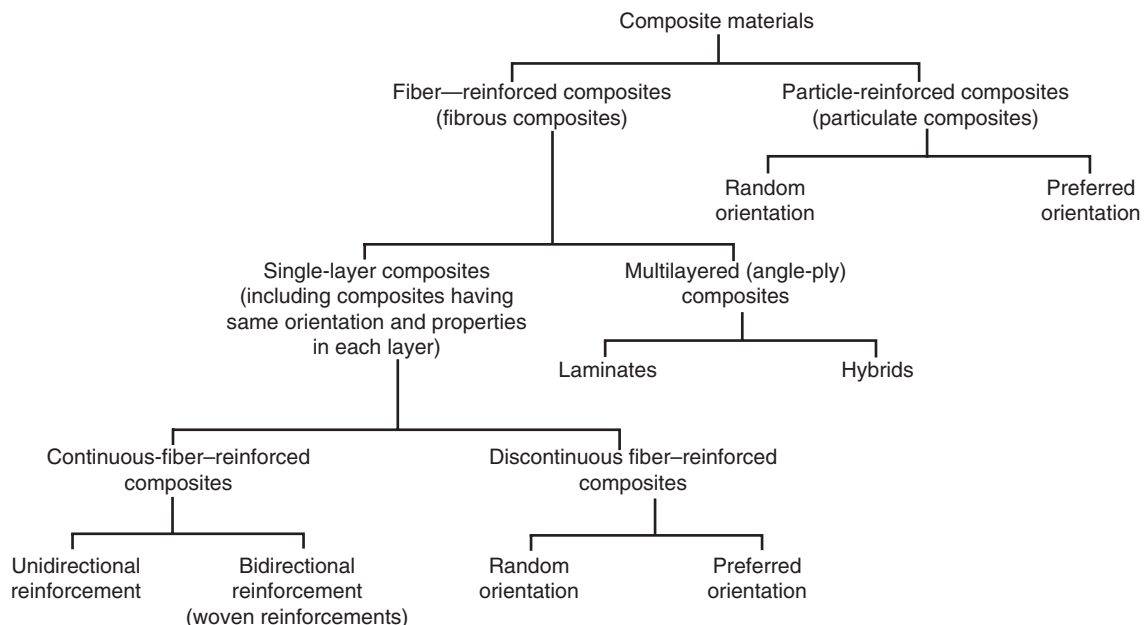

FIG. 1. Classification of composite materials. (From Agarwal and Broutman, 1980.)

Failure of a composite material implant can expose fibers or particles to the surrounding biological environment. In many cases failure in composites is preceded by the failure of the interface between filler and matrix, this being due to idrothermal aging or stresses exceeding the interface strength. Sterilization methods or conditions can play an important role.

As with all biomaterials, the question of biocompatibility (tissue response to the composite) is paramount. Being composed of two or more materials, composites provide enhanced probability of causing adverse tissue reactions. Also, the fact that one constituent (the reinforcement) usually has dimensions on the cellular scale always leaves open the possibility of cellular ingestion of particulate debris that can result in either the production of tissue-lysing enzymes or transport into the lymph system.

Although durability and biocompatibility can be considered major issues in a composite medical device, composites offer unique advantages in terms of design ability and fabrication. These advantages can be used to construct isocompliant arterial prostheses (Gershon *et al.*, 1990, 1992), intervertebral disks duplicating the natural structure (Ambrosio *et al.*, 1996), or fixation plates and nails with controlled stiffness (Veerabagu *et al.*, 2003)

For some applications, moreover, radiolucency is considered to be a further potential advantage. An example is external or internal fracture fixation devices not shielding the bone fracture site from the X-ray radiography.

Design flexibility, strength, and lightweight have made polymeric composite materials, mostly carbon fiber reinforced, the ideal materials also for orthotic aids able to return walking and even athletic performances to impaired people (Dawson, 2000).

REINFORCING SYSTEMS

The main reinforcing materials that have been used in biomedical composites are carbon fibers, polymer fibers, ceramics, and glasses. Depending upon the application, the reinforcements have been either inert or absorbable.

Carbon Fiber

Carbon fiber is a lightweight, flexible, high-strength, high-tensile-modulus material produced by the pyrolysis of organic precursor fibers, such as rayon, polyacrylonitrile (PAN), and pitch in an inert environment. The term carbon is often indifferently interchanged with the term graphite, but carbon and graphite fibers differ in the temperature of fabrication, thermal treatment, and the content of carbon (93–95% for carbon fibers and more than 99% for graphite fibers). Because of their low density (depending on the precursor from 1.7 to 2.1 g/cm³) and high mechanical properties (elastic modulus up to 900 GPa and strength up to 4.5 GPa, depending on the precursor and on the fabrication process—hence they can be much stiffer and stronger than steel!) these fibers are used in composites in a variety of applications demanding lightness and high mechanical properties. Their disadvantage is that carbon fibers have poor shear strength.

In medicine, several commercial products have used carbon fibers. Some of the first devices, however, have experienced severe negative effects and have been recalled from the market. Two examples are:

- Short carbon fiber reinforced UHMWPE for orthopedic applications. The assumption was that increase of strength and decrease of creep would increase the bearing longevity. The favorable indications of the laboratory wear tests contrasted with the *in vivo* results: Many patients presented with osteolysis and failure of the tibial inserts (Kurtz *et al.*, 1999).
- In the 1980s carbon fibers have been used to develop a scaffolding device to induce tendon or ligament repair. The low shear strength of fibers caused fiber breakage and the formation of harmful debris. A resorbable polymeric coating was somewhat successful in preventing carbon fiber breakage and localizing debris. However, because of poor performance and permanent wear debris in the joint, the carbon fiber device was not approved by the FDA for ACL reconstruction (Dunn, 1998).

In spite of these early failures, however, carbon fibers display unique properties for the fabrication of load-bearing medical devices.

Polymer Fibers

Whereas carbon fibers have been used for their superior mechanical properties, polymer fibers are not comparably strong or stiff as reinforcements for other polymers, with the possible exceptions of aramid fibers or ultrahigh-molecular-weight polyethylene (UHMWPE) fibers. For biomedical applications, biocompatibility, of course, and high strength and fatigue resistance are compulsory, while stiffness is a design parameter to be adapted to the specific conditions. This is why for some applications PET fibers have been used. In addition, thanks to their absorbability, not to their mechanical superiority, certain absorbable fibers have been employed.

- *Aramid* is the generic name for aromatic polyamide fibers. The most well known aramids are Kevlar and Nomex (DuPont trademarks), and Twaron (made by Teijin/Twaron of Japan). Kevlar is produced by spinning a sulfuric acid/poly(*p*-phenylene terephthalamide) solution through an air layer into a coagulating water bath. Aramid fibers are light (density = 1.44 g/cm³), stiff (the modulus can go up to 190 GPa), and strong (tensile strength about 3.6 GPa); moreover, they resist impact and abrasion damage. A negative point that can be relevant for biomedical applications is that aramid fibers absorb moisture, and worth noting is their poor compressive strength, about 1/8 of the tensile strength. Aramid fiber composites are used commercially where high tensile strength and stiffness, damage resistance, and resistance to fatigue and stress rupture are important. In medicine, these composites have not seen extensive use, due perhaps to some concerns about their biocompatibility or long-term fate. Main applications have been in dentistry

(Pourdeyhimi *et al.*, 1986; Vallittu, 1996) and ligament prostheses (Wening *et al.*, 1994).

- Commercially available high-strength, high-modulus polyethylene fibers include Spectra from Honeywell Performance Fibers (Colonial Heights, VA), Dyneema from DSM (Heerlen, The Netherlands), and Toyobo fibers from Toyobo (Shiga, Japan). UHMWPE fibers are produced by a gel-spinning technique starting from an approximately 2–8 wt.% solution of the ultrahigh-molecular-weight polymer ($M_w > 10^6$) in a common solvent, such as decalin. Spinning at 130–140°C and hot drawing at very high draw ratios produces fibers with the highest specific strength of all commercial fibers available to date. UHMWPE fibers possess high modulus and strength, besides displaying light weight (density about 0.97 g/cm³) and high energy dissipation ability, compared to other fibers. In addition PE fibers resist abrasion and do not absorb water. However, the chemical properties of UHMWPE fibers are such that few resins bond well to the fiber surfaces, and so the structural properties expected from the fiber properties are often not fully realized in a composite. The low melting point of the fibers (about 147°C) impedes high-temperature fabrication. Bulk UHMWPE has extensive applications in medicine for the fabrication of bearings for joint prostheses, displaying excellent biocompatibility but with lifetime restricted by its wear resistance. Polyethylene fibers are used to reinforce acrylic resins for application in dentistry (Ladizesky *et al.*, 1994; Karaman *et al.*, 2002; Brown, 2000), or to make intervertebral disk prostheses (Kotani *et al.*, 2002). They have been also used for the fabrication of ligament augmentation devices (Guidoin *et al.*, 2000).
- Dacron is the name commonly used to indicate poly(ethylene terephthalate) fibers. These fibers have several biomedical uses, most in cardiovascular surgery for arterial grafts. Poly(ethylene terephthalate) fibers, however, have been proposed in orthopedics for the fabrication of artificial tendons or ligaments (Kolarik *et al.*, 1981) and ligament augmentation devices, as fibers or fabrics alone, or imbedded in different matrices in composites. Other proposed applications include soft-tissue prostheses, intervertebral disks (Ambrosio *et al.*, 1996), and plastic surgery applications.
- Polylactic and polyglycolic acid and their copolymers are the principal biodegradable polymers used for the fabrication of biodegradable fibers. These fibers have been used for a number of years in absorbable sutures. Properties of these fibers depend upon several factors, such as crystallinity degree, molecular weight, and purity (Migliaresi and Fambri, 1997). Fibers and tissues have been proposed for ligament reconstruction (Durselen *et al.*, 2001) or as scaffolds for tissue engineering applications (Lu and Mikos, 1996). They also have been employed in composites, in combination with parent biodegradable matrices. Examples are the intramedullary biodegradable pins and plates (Vert *et al.*, 1986, Middleton and Tipton, 2000) and biodegradable scaffolds for bone regeneration (Vacanti *et al.*, 1991, Kellomaki *et al.*, 2000).

Ceramics

A number of different ceramic materials have been used to reinforce biomedical composites. Since most biocompatible ceramics, when loaded in tension or shear, are relatively weak and brittle materials compared to metals, the preferred form for this reinforcement has usually been particulate. These reinforcements have included various calcium phosphates, aluminum- and zinc-based phosphates, glass and glass-ceramics, and bone mineral. Minerals in bone are numerous. In the past, bone has been defatted, ground, and calcined or heated to yield a relatively pure mix of the naturally occurring bone minerals. It was recognized early that this mixture of natural bone mineral was poorly defined and extremely variable. Consequently, its use as an implant material was limited.

The calcium phosphate ceramic system has been the most intensely studied ceramic system. Of particular interest are the calcium phosphates having calcium-to-phosphorus ratios of 1.5–1.67. Tricalcium phosphate and hydroxyapatite form the boundaries of this compositional range. At present, these two materials are used clinically for dental and orthopedic applications. Tricalcium phosphate has a nominal composition of $\text{Ca}_3(\text{PO}_4)_2$. The common mineral name for this material is whitlockite. It exists in two crystallographic forms, α - and β -whitlockite. In general, it has been used in the β -form.

The ceramic hydroxyapatite has received a great deal of attention. Hydroxyapatite is, of course, the major mineral component of bone. The nominal composition of this material is $\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$.

Tricalcium phosphates and hydroxyapatite are commonly referred as bioceramics, i.e., bioactive ceramics. The definition refers to their ability to elicit a specific biological response that results in the formation of bond between the tissues and material (Hench *et al.*, 1971). Hydroxyapatite ceramic and tricalcium phosphates are used in orthopedics and dentistry alone or in combination with other substances, or also as coating of metal implants. The rationale behind the use of bioceramics in combination with polymeric matrix for composites is in their ability to enhance the integration in bone, while improving the device mechanical properties. An example are the HA-PE composites developed by Bonfield (Bonfield, 1988; Bonfield *et al.*, 1998), and today commercialized with the name of HAPEX (Smith & Nephew ENT, Memphis, TN).

Glasses

Glass fibers are used to reinforce plastic matrices to form structural composites and molding compounds. Commercial glass fiber plastic composite materials have the following favorable characteristics: high strength-to-weight ratio; good dimensional stability; good resistance to heat, cold, moisture, and corrosion; good electrical insulation properties; ease of fabrication; and relatively low cost. De Santis *et al.* (2000) have stacked glass and carbon/PEI laminae to manufacture a hip prosthesis with constant tensile modulus but with bending modulus increasing in the tip-head direction. An isoelastic intramedullary nail made of PEEK and chopped glass fibers has been evaluated by Lin *et al.* (1997), and glass fibers have been

used to increase the mechanical properties of acrylic resins for applications in dentistry (Chen *et al.*, 2001).

Zimmerman *et al.* (1991) and Lin (1986) introduced an absorbable polymer composite reinforced with an absorbable calcium phosphate glass fiber. This allowed for the fabrication of a completely absorbable composite implant material. Commercial glass fiber produced from a lime–aluminum–borosilicate glass typically has a tensile strength of about 3 GPa and a modulus of elasticity of 72 GPa. Lin (1986) estimates the absorbable glass fiber to have a modulus of 48 GPa, comparing favorably with the commercial fiber. The tensile strength, however, was significantly lower, approximately 500 MPa.

MATRIX SYSTEMS

Ceramic matrix or metal matrix composites have important technological applications, but their use is restricted to specific cases (e.g., cutting tools, power generation equipment, process industries, aerospace), with just a few examples for biomedical applications (e.g., calcium phosphate bone cements).

Most biomedical composites have polymeric matrices, mostly thermoplastic, bioabsorbable or not.

The most common matrices are synthetic nonabsorbable polymers. By far the largest literature exists for the use of polysulfone, poly(ether ether ketone) (PEEK), ultrahigh-molecular-weight polyethylene (UHMWPE), polytetrafluoroethylene (PTFE), poly(methyl methacrylate) (PMMA), and hydrogels. These matrices, reinforced with carbon fibers, polyethylene fibers, and ceramics, have been used as prosthetic hip stems, fracture fixation devices, artificial joint bearing surfaces, artificial tooth roots, and bone cements. Also, epoxy composite materials have been used. However, because of concerns about the toxicity of monomers (Morrison *et al.*, 1995) the research activity on epoxy composite for implantable devices gradually decreased.

Materials used and some examples of proposed applications are reported in Table 1.

Not all the proposed systems underwent clinical trial and only some of them are today regularly commercialized.

A review on biomedical applications of composites is in Ramakrishna *et al.* (2001).

Absorbable composite implants can be produced from absorbable α -polyester materials such as polylactic and polyglycolic polymers. Previous work has demonstrated that for most applications, it is necessary to reinforce these polymers to obtain adequate mechanical strength. Poly(glycolic acid) (PGA) was the first biodegradable polymer synthesized (Frazza and Schmitt, 1971). It was followed by poly(lactic acid) (PLA) and copolymers of the two (Gilding and Reed, 1979). These α -polyesters have been investigated for use as sutures and as implant materials for the repair of a variety of osseous and soft tissues. Important biodegradable polymers include poly(ortho esters), synthesized by Heller and co-workers (Heller *et al.*, 1980), and a class of bioerodable dimethyl-trimethylene carbonates (DMTMCs) (Tang *et al.*, 1990). A good review of absorbable polymers by Barrows (1986) included poly(lactic acid), poly(glycolic acid), poly(lactide-co-glycolide), polydioxanone, poly(glycolide-co-trimethylene

carbonate), poly(ethylene carbonate), poly(iminocarbonates), polycaprolactone, polyhydroxybutyrate, poly(amino acids), poly(ester amides), poly(ortho esters), poly(anhydrides), and cyanoacrylates. The more recent review by Middleton and Tipton (2000) focused on biodegradable polymers suited for orthopedic applications, mainly poly(glycolic acid) and poly(lactic acid). The authors examined chemistry, fabrication, mechanisms, degradation, and biocompatibility of different polymers and devices.

Natural-origin absorbable polymers have also been utilized in biomedical composites. Purified bovine collagen, because of its biocompatibility, resorbability, and availability in a well-characterized implant form, has been used as a composite matrix, mainly as a ceramic composite binder (Lemons *et al.*, 1984). A commercially available fibrin adhesive (Bochlogyros *et al.*, 1985) and calcium sulfate (Alexander *et al.*, 1987) have similarly been used for this purpose.

Reis *et al.* (1998) proposed alternative biodegradable systems to be used in temporary medical applications. These systems are blends of starch with various thermoplastic polymers. They were proposed for a large range of applications such as temporary hard-tissue replacement, bone fracture fixation, drug delivery devices, or tissue engineering scaffolds.

FABRICATION OF COMPOSITES

Composite materials can be fabricated with different technologies. Some of them are peculiar for the type of filler (particle, short or long fiber) and matrix (thermoplastic or thermosetting). Some make use of solvents whose residues could affect the material biocompatibility, hence not being applicable for the fabrication of biomedical composites. The selection of the most appropriate manufacturing technology is also influenced by the relatively low volumes of the production, compared to other applications, and by the relatively low dominance of the manufacturing cost over the overall cost of the device.

Some biomedical composites, moreover, are fabricated “*in situ*.” This is the case of composite bone cements.

The most common fabrication technologies for composites are:

1. Hand lay up
2. Spray up
3. Compression molding
4. Resin transfer molding
5. Injection molding
6. Filament winding
7. Pultrusion

In principle all of the listed technologies could be used for the fabrication of biomedical composites. Only some of them, however, have found practical use.

Fabrication of Particle-Reinforced Composites

Injection molding, compression molding, and extrusion are the most common fabrication technologies for biomedical particulate composites. In some applications composites

Legenda: PMMA, polymethylmethacrylate; PSU, polysulfone; PP, polypropylene; PE, polyethylene; PBT, poly(butylene terephthalate); PEEK, poly(ether ether ketone); PLLA, poly(L-lactic acid); PGA, poly(glycolic acid); PU, polyurethane; PET, poly(ethylene terephthalate); Bis-GMA, bis-glycidil dimethacrylate; PEI, poly(ether-imide); PEG, poly(ethylene glycol); PLGA, lactic acid-glycolic acid copolymer; PDLLA, poly(D,L-lactic acid); CL, poly(ϵ -caprolactone acid); PELA, ethylene oxide/lactic acid copolymer; CF, carbon fibers; GF, glass fibers; HA, hydroxyapatite; UHMWPE, ultrahigh-molecular-weight polyethylene; TCP, tricalcium phosphate; KF, Kevlar fibers.

are manufactured *in situ*. This is the case of dental restorative composites and particle-reinforced bone cements.

Fabrication of Fiber-Reinforced Composites

Fiber-reinforced composites are produced commercially by one of two classes of fabrication techniques: open or closed molding. Most of the open-molding techniques are not appropriate to biomedical composites because of the character of the matrices used (mainly thermoplastics) and the need to produce materials that are resistant to water intrusion.

Consequently, the simplest techniques, the hand lay-up and spray-up procedures, are seldom, if ever, used to produce biomedical composites. The two open-molding techniques that may find application in biomedical composites are the vacuum bag-autoclave process and the filament-winding process.

Vacuum Bag–Autoclave Process

This process is used to produce high-performance laminates, usually of fiber-reinforced epoxy. Composite materials produced by this method are currently used in aircraft and aerospace applications. The first step in this process, and indeed

many other processes, is the production of a “prepreg.” This basic structure is a thin sheet of matrix imbedded with uniaxially oriented reinforcing fibers. When the matrix is epoxy, it is prepared in the partially cured state. Pieces of the prepreg sheet are cut out and placed on top of each other on a shaped tool to form a laminate. The layers, or plies, may be placed in different directions to produce the desired strength and stiffness.

After the laminate is constructed, the tooling and attached laminate are vacuum-bagged, with a vacuum being applied to remove entrapped air from the laminated part. Finally, the vacuum bag enclosing the laminate and the tooling is put into an autoclave for the final curing of the epoxy resin. The conditions for curing vary depending upon the material, but the carbon fiber–epoxy composite material is usually heated at about 190°C at a pressure of about 700 kPa. After being removed from the autoclave, the composite part is stripped from its tooling and is ready for further finishing operations. This procedure is potentially useful for the production of fracture fixation devices and total hip stems.

Filament-Winding Process

Another important open-mold process to produce high-strength hollow cylinders is the filament-winding process. In this process, the fiber reinforcement is fed through a resin bath and then wound on a suitable mandrel (Fig. 2). When sufficient layers have been applied, the wound mandrel is cured. The molded part is then stripped from the mandrel. The high degree of fiber orientation and high fiber loading with this method produce extremely high tensile strengths. Biomedical applications

for this process include intramedullary rods for fracture fixation, prosthetic hip stems, ligament prostheses, intervertebral disks, and arterial grafts.

Closed-Mold Processes

There are many closed-mold methods used for producing fiber-reinforced plastic materials. The methods of most importance to biomedical composites are compression and injection molding and continuous pultrusion. In compression molding, the previously described prepregs are arranged in a two-piece mold that is then heated under pressure to produce the laminated part. This method is particularly useful for use with thermoplastic matrices. In injection molding the fiber–matrix mix is injected into a mold at elevated temperature and pressure. The finished part is removed after cooling. This is an extremely fast and inexpensive technique that has application to chopped fiber–reinforced thermoplastic composites. It offers the possibility to produce composite devices, such as bone plates and screws, at much lower cost than comparable metallic devices.

Continuous pultrusion is a process used for the manufacture of fiber-reinforced plastics of constant cross section such as structural shapes, beams, channels, pipe, and tubing. In this process, continuous-strand fibers are impregnated in a resin bath and then are drawn through a heated die, which determines the shape of the finished stock (Fig. 3). Highly oriented parts cut from this stock can then be used in other structures or they can be used alone in such applications as intramedullary rodding or pin fixation of bone fragments.

FIG. 2. Filament-winding process for producing fiber-reinforced composite materials.

FIG. 3. The pultrusion process for producing fiber-reinforced polymer composite materials. Fibers impregnated with polymer are fed into a heated die and then are slowly drawn out as a cured composite material with a constant cross-sectional shape.

MECHANICAL AND PHYSICAL PROPERTIES OF COMPOSITES

Continuous Fiber Composites

Laminated continuous fiber-reinforced composites are described from either a micro- or macromechanical point of view. Micromechanics is the study of composite material behavior wherein the interaction of the constituent materials is examined on a local basis. Macromechanics is the study of composite material behavior wherein the material is presumed homogeneous and the effects of the constituent materials are detected only as averaged apparent properties of the composite. Both the micromechanics and macromechanics of experimental laminated composites will be discussed.

Micromechanics

There are two basic approaches to the micromechanics of composite materials: the mechanics of materials and the elasticity approach. The mechanics-of-materials approach embodies the concept of simplifying assumptions regarding the hypothesized behavior of the mechanical system. It is the simpler of the two and the traditional choice for micromechanical evaluation. The most prominent assumption made in the mechanics-of-materials approach is that strains in the fiber direction of a unidirectional fibrous composite are the same in the fibers and the matrix. This assumption allows the planes to remain parallel to the fiber direction. It also allows the longitudinal normal strain to vary linearly throughout the member with the distance from the neutral axis. Accordingly, the stress will also have a linear distribution.

Some other important assumptions are as follows:

1. The lamina is macroscopically homogeneous, linearly elastic, orthotropic, and initially stress-free.
2. The fibers are homogeneous, linearly elastic, isotropic, regularly spaced, and perfectly aligned.
3. The matrix is homogeneous, linearly elastic, and isotropic.

In addition, no voids are modeled in the fibers, the matrix or between them.

The mechanical properties of a lamina are determined by fiber orientation. The most often used laminate coordinate system has the length of the laminate in the x direction and the width in the y direction. The principal fiber direction is the 1 direction, and the 2 direction is normal to that. The angle between the x and 1 directions is ϕ . A counterclockwise rotation of the 1–2 system yields a positive ϕ .

The mechanical properties of the lamina are dependent on the material properties and the volume content of the constituent materials. The equations for the mechanical properties of a lamina in the 1–2 directions are:

$$E_1 = E_f V_f + E_m V_m \quad (1)$$

$$E_2 = \frac{E_f E_m}{V_m E_f} + V_f E_m \quad (2)$$

$$\nu_{12} = V_m \nu_m + V_f \nu_f \quad (3)$$

$$\nu_{21} E_1 = \nu_{12} E_2 \quad (4)$$

$$G_{12} = \frac{G_f G_m}{V_m G_f} + V_f G_m \quad (5)$$

$$V_m = 1 - V_f \quad (6)$$

where E is Young's modulus, G is the shear modulus, V is the volume fraction, ν is Poisson's ratio, and subscripts f and m represent fiber and matrix properties, respectively. These equations are based on the law of mixtures for composite materials.

Macromechanics of a Lamina

The generalized Hooke's law relating stresses to strains is

$$\sigma_i = C_{ij} \varepsilon_j \quad ij = 1, 2, \dots, 6 \quad (7)$$

where σ_i = stress components, C_{ij} = stiffness matrix, and ε_j = strain components. An alternative form of the stress-strain relationship is

$$\varepsilon_{ij} = S_{ij} \sigma_i \quad ij = 1, 2, \dots, 6 \quad (8)$$

where S_{ij} = compliance matrix.

Given that $C_{ij} = C_{ji}$, the stiffness matrix is symmetric, thus reducing its population of 36 elements to 21 independent constants. We can further reduce the matrix size by assuming the laminae are orthotropic. There are nine independent constants for orthotropic laminae. In order to reduce this three-dimensional situation to a two-dimensional situation for plane stress, we have

$$\tau_3 = 0 = \sigma_{23} = \sigma_{13} \quad (9)$$

thus reducing the stress-strain relationship to

$$\begin{bmatrix} \varepsilon_1 \\ \varepsilon_2 \\ \gamma_{12} \end{bmatrix} = \begin{bmatrix} S_{11} & S_{12} & 0 \\ S_{21} & S_{22} & 0 \\ 0 & 0 & S_{66} \end{bmatrix} \begin{bmatrix} \sigma_1 \\ \sigma_2 \\ \tau_{12} \end{bmatrix} \quad (10)$$

The stress-strain relation can be inverted to obtain

$$\begin{bmatrix} \sigma_1 \\ \sigma_2 \\ \tau_{12} \end{bmatrix} = \begin{bmatrix} Q_{11} & Q_{12} & 0 \\ Q_{21} & Q_{22} & 0 \\ 0 & 0 & Q_{66} \end{bmatrix} \begin{bmatrix} \varepsilon_1 \\ \varepsilon_2 \\ \gamma_{12} \end{bmatrix} \quad (11)$$

where Q_{ij} are the reduced stiffnesses. The equations for these stiffnesses are

$$Q_{11} = \frac{E_1}{1 - \nu_{21} \nu_{12}} \quad (12)$$

$$Q_{12} = \frac{\nu_{12} E_2}{1 - \nu_{12} \nu_{21}} = \frac{\nu_{21} E_1}{1 - \nu_{12} \nu_{21}} = Q_{21} \quad (13)$$

$$Q_{22} = \frac{E_2}{1 - \nu_{21} \nu_{12}} \quad (14)$$

$$Q_{66} = G_{12} \quad (15)$$

The material directions of the lamina may not coincide with the body coordinates. The equations for the transformation of stresses in the 1–2 direction to the x - y direction are

$$\begin{bmatrix} \sigma_x \\ \sigma_y \\ \tau_{xy} \end{bmatrix} = [T^{-1}] \cdot \begin{bmatrix} \sigma_1 \\ \sigma_2 \\ \tau_{12} \end{bmatrix} \quad (16)$$

where $[T^{-1}]$ is

$$[T^{-1}] = \begin{vmatrix} \cos^2 \Phi & \sin^2 \Phi & -2 \sin \Phi \cos \Phi \\ \sin^2 \Phi & \cos^2 \Phi & 2 \sin \Phi \cos \Phi \\ \sin \Phi \cos \Phi & -\sin \Phi \cos \Phi & \cos^2 \Phi - \sin^2 \Phi \end{vmatrix} \quad (17)$$

The x and 1 axes form angle Φ . This matrix is also valid for the transformation of strains,

$$\begin{vmatrix} \varepsilon_x \\ \varepsilon_y \\ \frac{1}{2}\gamma_{xy} \end{vmatrix} = [T^{-1}] \cdot \begin{vmatrix} \varepsilon_1 \\ \varepsilon_2 \\ \frac{1}{2}\gamma_{12} \end{vmatrix} \quad (18)$$

Finally, it can be demonstrated that

$$\begin{vmatrix} \sigma_x \\ \sigma_y \\ \tau_{xy} \end{vmatrix} = [\bar{Q}_{ij}] \cdot \begin{vmatrix} \varepsilon_x \\ \varepsilon_y \\ \gamma_{xy} \end{vmatrix} \quad (19)$$

where $[\bar{Q}_{ij}]$ is the transformed reduced stiffness. The transformed reduced stiffness matrix is

$$[\bar{Q}_{ij}] = \begin{vmatrix} \bar{Q}_{11} & \bar{Q}_{12} & \bar{Q}_{16} \\ \bar{Q}_{21} & \bar{Q}_{22} & \bar{Q}_{26} \\ \bar{Q}_{16} & \bar{Q}_{26} & \bar{Q}_{66} \end{vmatrix} \quad (20)$$

where,

$$\begin{aligned} \bar{Q}_{11} &= Q_{11} \cos^4 \Phi + Q_{22} \sin^4 \Phi \\ &\quad + 2(Q_{12} + 2Q_{66}) \sin^2 \Phi \cos^2 \Phi \end{aligned} \quad (21)$$

$$\begin{aligned} \bar{Q}_{22} &= Q_{11} \sin^4 \Phi + Q_{22} \cos^4 \Phi \\ &\quad + 2(Q_{12} + 2Q_{66}) \sin^2 \Phi \cos^2 \Phi \end{aligned} \quad (22)$$

$$\begin{aligned} \bar{Q}_{12} &= (Q_{11} + Q_{22} - 4Q_{66}) \sin^2 \Phi \cos^2 \Phi \\ &\quad + Q_{12} (\sin^4 \Phi + \cos^4 \Phi) \end{aligned} \quad (23)$$

$$\begin{aligned} \bar{Q}_{66} &= (Q_{11} + Q_{22} - 2Q_{12} - 2Q_{66}) \sin^2 \Phi \cos^2 \Phi \\ &\quad + Q_{66} (\sin^4 \Phi + \cos^4 \Phi) \end{aligned} \quad (24)$$

$$\begin{aligned} \bar{Q}_{16} &= (Q_{11} - Q_{12} - 2Q_{66}) \sin \Phi \cos^3 \Phi \\ &\quad - (Q_{22} - Q_{12} - 2Q_{66}) \sin^3 \Phi \cos \Phi \end{aligned} \quad (25)$$

$$\begin{aligned} \bar{Q}_{26} &= (Q_{11} - Q_{12} - 2Q_{66}) \sin^3 \Phi \cos \Phi \\ &\quad - (Q_{22} - Q_{12} - 2Q_{66}) \sin \Phi \cos^3 \Phi \end{aligned} \quad (26)$$

$\bar{Q}_{16} = \bar{Q}_{26} = 0$ for a laminated symmetric composite.

The transformation matrix $[T^{-1}]$ and the transformed reduced stiffness matrix $[\bar{Q}_{ij}]$ are very important matrices in the macromechanical analysis of both laminae and laminates. These matrices play a key role in determining the effective in-plane and bending properties and how a laminate will perform when subjected to different combinations of forces and moments.

Macromechanics of a Laminate

The development of the A , B , and D matrices for laminate analysis is important for evaluating the forces and moments to which the laminate will be exposed and in determining the stresses and strains of the laminae. As given in Eq. (19),

$$(\sigma_k) = [\bar{Q}_{ij}] (\varepsilon_k) \quad (27)$$

where σ = normal stresses, ε = normal strains, and $[\bar{Q}_{ij}]$ = stiffness matrix. The A , B , and D matrices are equivalent to the following:

$$[A_{ij}] = \sum_{k=1}^n (\bar{Q}_{ij})_k (h_k - h_{k-1}) \quad (28)$$

$$[B_{ij}] = \frac{1}{2} \sum_{k=1}^n (\bar{Q}_{ij})_k (h_k^2 - h_{k-1}^2) \quad (29)$$

$$[D_{ij}] = \frac{1}{3} \sum_{k=1}^n (\bar{Q}_{ij})_k (h_k^3 - h_{k-1}^3) \quad (30)$$

The matrix $[A]$ is called the *extensional stiffness matrix* because it relates the resultant forces to the midplane strains, while matrix $[D]$ is called the *bending stiffness matrix* because it relates the resultant moments to the laminate curvature. The so called *coupling stiffness matrix*, $[B]$, accounts for coupling between bending and extension, which means that normal and shear forces acting at the laminate midplane are causing laminate curvature or that bending and twisting moments are accompanied by midplane strain.

The letter k denotes the number of laminae in the laminate with a maximum number (N). The letter h represents the distances from the neutral axis to the edges of the respective laminae. A standard procedure for numbering laminae is used where the 0 lamina is at the bottom of a plate and the K th lamina is at the top.

The resultant laminate forces and moments are:

$$\begin{vmatrix} N_x \\ N_y \\ N_{xy} \end{vmatrix} = [A_{ij}] \cdot \begin{vmatrix} \varepsilon_x \\ \varepsilon_y \\ \gamma_{xy} \end{vmatrix} + [B_{ij}] \cdot \begin{vmatrix} k_x \\ k_y \\ k_{xy} \end{vmatrix} \quad (31)$$

$$\begin{vmatrix} M_x \\ M_y \\ M_{xy} \end{vmatrix} = [B_{ij}] \cdot \begin{vmatrix} \varepsilon_x \\ \varepsilon_y \\ \gamma_{xy} \end{vmatrix} + [D_{ij}] \cdot \begin{vmatrix} k_x \\ k_y \\ k_{xy} \end{vmatrix} \quad (32)$$

The k vector represents the respective curvatures of the various planes. The resultant forces and moments of a loaded composite can be analyzed given the ABD matrices. If the laminate is assumed symmetric, the force equation reduces to

$$\begin{vmatrix} N_x \\ N_y \\ N_{xy} \end{vmatrix} = [A_{ij}] \cdot \begin{vmatrix} \varepsilon_x \\ \varepsilon_y \\ \gamma_{xy} \end{vmatrix} \quad (33)$$

Once the laminate strains are determined, the stresses in the xy direction for each lamina can be calculated. The most useful information gained from the ABD matrices involves the determination of generalized in-plane and bending properties of the laminate.

In a generic laminate, normal stresses N_x and/or N_y (or thermal stresses or liquid sorption) will cause deformations in the directions x and/or y , but also shear strains, unless A_{16} and A_{26} of the extensional stiffness matrix are equal to 0. These coefficients become 0 if the laminate is balanced, i.e., has the same number of laminae oriented at Φ and $-\Phi$.

Moreover, in a generic laminate, normal or shear stresses will produce bending, and bending or twisting will cause mid-plane strains. The coupling between bending and extension can be eliminated if the coefficients of the B_{ij} matrix are equal to zero, that is, if the laminate is fabricated symmetric with respect to its midplane.

The equivalent elastic constants ($E_x, E_y, G_{xy}, \nu_{xy}$) of a symmetric and balanced laminate can be easily evaluated from the A_{ij} coefficients (Barbero, 1998):

$$E_x = \frac{1}{h} \frac{A_{11}A_{22} - A_{12}^2}{A_{22}} \quad (34)$$

$$E_y = \frac{1}{h} \frac{A_{11}A_{22} - A_{12}^2}{A_{11}} \quad (35)$$

$$\nu_{xy} = \frac{A_{12}}{A_{22}} \quad (36)$$

$$G_{xy} = \frac{1}{h} A_{66} \quad (37)$$

In the equations above h is the total thickness of the laminate.

Short-Fiber Composites

A distinguishing feature of the unidirectional laminated composites discussed above is that they have higher strength and modulus in the fiber direction, and thus their properties are amenable to alteration to produce specialized laminates. However, in some applications, unidirectional multiple-ply laminates may not be required. It may be advantageous to have isotropic laminae. An effective way of producing an isotropic lamina is to use randomly oriented short fibers as the reinforcement. Of course, molding compounds consisting of short fibers that can be easily molded by injection or compression molding may be used to produce generally isotropic composites. The theory of stress transfer between fibers and matrix in short-fiber composites goes beyond this text; it is covered in detail by Agarwal and Broutman (1980). However, the longitudinal and transverse moduli (E_L and E_T , respectively) for an aligned short-fiber lamina can be derived from the generalized Halpin-Tsai equations (Halpin and Kardos, 1976), as:

$$\frac{E_L}{E_m} = \frac{1 + ((2l/d)\eta_L V_f)}{1 - \eta_L V_f} \quad (38)$$

$$\frac{E_T}{E_m} = \frac{1 + 2\eta_T V_f}{1 - \eta_T V_f} \quad (39)$$

$$\eta_L = \frac{E_f/E_m - 1}{E_f/E_m + 2(l/d)} \quad (40)$$

$$\eta_T = \frac{E_f/E_m - 1}{E_f/E_m + 2} \quad (41)$$

FIG. 4. Variations of longitudinal modulus of short-fiber composites against aspect ratio for different fiber volume fractions ($E_f/E_m = 20$).

In the previous equations E_m is the elastic modulus of the matrix, l and d are the fiber length and diameter respectively, and V_f is the fiber volume fraction.

For a ratio of fiber to matrix modulus of 20, the variation of longitudinal modulus of an *aligned* short-fiber lamina as a function of fiber aspect ratio, l/d , for different fiber volume fractions is shown in Fig. 4. It can be seen that approximately 85% of the modulus obtainable from a continuous fiber lamina is attainable with an aspect ratio of 20.

The problem of predicting properties of *randomly oriented* short-fiber composites is more complex. The following empirical equation can be used to predict the modulus of composites containing fibers that are randomly oriented in a plane:

$$E_{\text{random}} = \frac{3}{8} E_L + \frac{5}{8} E_T \quad (42)$$

where E_L and E_T are respectively the longitudinal and transverse moduli of an aligned short-fiber composite having the same fiber aspect ratio and fiber volume fraction as the composite under consideration. Moduli E_L and E_T can either be determined experimentally or calculated using Eqs. 38 and 39.

Particulate Composites

The reinforcing effect of particles on polymers was first recognized for rubbery matrices during studies of the effect of carbon black on the properties of natural rubber.

Several models have been introduced to predict the effect of the addition of particles to a polymeric matrix, starting from the equation developed by Einstein in 1956 to predict the viscosity of suspensions of rigid spherical inclusions. The paper by Ahmed and Jones (1990) well reviews theories developed to predict strength and modulus of particulate composites. One of the most versatile equation predicting the shear modulus of composites of polymers and spherical fillers is due to Kerner (1956):

$$G_c = G_m \left(1 + \frac{V_f}{V_m} \frac{15(1 - \nu_m)}{8 - 10\nu_m} \right) \quad (43)$$

FIG. 5. Variation of the Young's modulus of hydroxyapatite-polyethylene composites modulus with volume fraction: experimental values, \square , and predicted values before and after the application of the statistical model; \blacksquare , primary; \triangle , equal strain; \blacktriangle , equal stress (from Guild and Bonfield, 1993).

A more generalized form was developed by Nielsen (1974),

$$M_c = M_m \frac{1 + ABV_f}{1 - B\psi V_f} \quad (44)$$

where M_c is any modulus—shear, Young's or bulk- of the composite, the constant A takes into account for the filler geometry and the Poisson's ratio of the matrix and the constant B depends on the relative moduli of the filler (M_f) and the matrix (M_m). The function Ψ depends on the particle packing fraction.

By using a finite element analysis method Guild and Bonfield (1993) predicted the elastic modulus of hydroxyapatite-polyethylene reinforced composites for various filler content. Their result (Fig. 5) indicated a good agreement between theoretical and experimental data, except at higher hydroxyapatite volume fraction.

While elastic modulus of a particulate composites increases with the filler content, strength decreases in tension and increases in compression. Size and shape of the inclusion play an important role, with a higher stress concentration cause

by irregularly shaped inclusions. For spherical particles, tensile strength can be predicted by the equation (Nicolais and Narkis, 1971):

$$\sigma_{cu} = \sigma_{mu} (1 - 1.21V_f^{2/3}) \quad (45)$$

where σ_{cu} and σ_{mu} are tensile strength of composite and matrix, respectively.

ABSORBABLE MATRIX COMPOSITES

Absorbable matrix composites have been used in situations where absorption of the matrix is desired. Matrix absorption may be desired to expose surfaces to tissue or to release admixed materials such as antibiotics or growth factors (drug release) (Yasko *et al.*, 1992). However, the most common reasons for the use of this class of matrices for composites has been to accomplish time-varying mechanical properties and assure complete dissolution of the implant, eliminating long-term biocompatibility concerns. A typical clinical example is fracture fixation (Daniels *et al.*, 1990; Tormala, 1992).

Fracture Fixation

Rigid internal fixation of fractures has conventionally been accomplished with metallic plates, screws, and rods. During the early stages of fracture healing, rigid internal fixation maintains alignment and promotes primary osseous union by stabilization and compression. Unfortunately, as healing progresses, or after healing is complete, rigid fixation may cause bone to undergo stress protection atrophy. This can result in significant loss of bone mass and osteoporosis. Additionally, there may be a basic mechanical incompatibility between the metal implants and bone. The elastic modulus of cortical bone ranges from 17 to 24 GPa, depending upon age and location of the specimen, while the commonly used alloys have moduli ranging from 110 GPa (titanium alloys) to 210 GPa (316L steel). This large difference in stiffness can result in disproportionate load sharing, relative motion between the implant and bone upon loading, as well as high stress concentrations at bone-implant junctions.

Another potential problem is that the alloys currently used corrode to some degree. Ions so released have been reported to cause adverse local tissue reactions as well as allogenic responses, which in turn raises questions of adverse effects on bone mineralization as well as adverse systemic responses such as local tumor formation (Martin *et al.*, 1988). Consequently, it is usually recommended that a second operation be performed to remove hardware.

The advantages of absorbable devices are thus twofold. First, the devices degrade mechanically with time, reducing stress protection and the accompanying osteoporosis. Second, there is no need for secondary surgical procedures to remove absorbable devices. The state of stress at the fracture site gradually returns to normal, allowing normal bone remodeling.

Absorbable fracture fixation devices have been produced from poly(L-lactic acid) polymer, poly(glycolic acid) polymer, and polydioxanone. An excellent review of the mechanical properties of biodegradable polymers was prepared by Daniels and co-workers (Daniels *et al.*, 1990; see Figs. 6 and 7).

FIG. 6. Representative flexural strengths of absorbable polymer composites (from Daniels *et al.*, 1990).

FIG. 7. Representative flexural moduli of absorbable polymer composites (from Daniels *et al.*, 1990).

FIG. 8. Scanning electron micrograph of laminae buckling and delamination (D) between lamina in a carbon fiber-reinforced PLA fracture fixation plate (from Zimmerman *et al.*, 1987).

Their review revealed that unreinforced biodegradable polymers are initially 36% as strong in tension as annealed stainless steel, and 54% in bending, but only 3% as stiff in either test mode. With fiber reinforcement, highest initial strengths exceeded those of stainless steel. Stiffness reached 62% of stainless steel with nondegradable carbon fibers, 15% with degradable inorganic fibers, but only 5% with degradable polymeric fibers.

Most previous work on absorbable composite fracture fixation has been performed with PLLA polymer. PLLA possesses three major characteristics that make it a potentially attractive biomaterial:

1. It degrades in the body at a rate that can be controlled.
2. Its degradation products are nontoxic, biocompatible, easily excreted entities. PLA undergoes hydrolytic deesterification to lactic acid, which enters the lactic acid cycle of metabolites. Ultimately it is metabolized to carbon dioxide and water and is excreted.
3. Its rate of degradation can be controlled by mixing it with poly(glycolic acid) polymer.

Poly(L-lactic acid) polymer reinforced with randomly oriented chopped carbon fiber was used to produce partially degradable bone plates (Corcoran *et al.*, 1981). It was demonstrated that the plates, by virtue of the fiber reinforcement, exhibited mechanical properties superior to those of pure polymer plates. *In vivo*, the matrix degraded and the plates lost rigidity, gradually transferring load to the healing bone. However, the mechanical properties of such chopped fiber

plates were relatively low; consequently, the plates were only adequate for low-load situations. Zimmerman *et al.* (1987) used composite theory to determine an optimum fiber layup for a long fiber composite bone plate. Composite analysis suggested the mechanical superiority of a $0^\circ/\pm 45^\circ$ laminae layup. Although the $0^\circ/\pm 45^\circ$ carbon/poly(lactic acid) composite possessed adequate initial mechanical properties, water absorption and subsequent delamination degraded the properties rapidly in an aqueous environment (Fig. 8). The fibers did not chemically bond to the matrix.

In an attempt to develop a totally absorbable composite material, a calcium-phosphate-based glass fiber has been used to reinforce poly(lactic acid). Experiments were pursued to determine the biocompatibility and *in vitro* degradation properties of the composite (Zimmerman *et al.*, 1991). These studies showed that the glass fiber-PLA composite was biocompatible, but its degradation rate was too high for use as an orthopedic implant.

Shikinami and Okuno (2001), have produced miniplates, rods, and screws made of hydroxyapatite poly(L-lactide). These composites have been principally applied for indications such as repair of bone fracture in bone grafting and osteotomy, exhibiting total resorbability and osteological bioactivity while retaining sufficient stiffness high stiffness retainable for a long period of time to achieve bony union. These plates are commercialized with the name of Fixsorb-MX.

Furukawa *et al.* (2000b) have investigated the *in vivo* biodegradation behavior of hydroxyapatite/poly(L-lactide) composite rods implanted *sub cutem* and in the intramedullary

cavities of rabbits, showing that after 25 weeks of *sub cutem* implantation rods maintained a bending strength higher than 200 MPa. Their conclusion was that such a strength was sufficient for application of the rods in the fixation of human bone fractures.

By using a sintering technique, Tormala *et al.* (1988) have produced self-reinforced PGA (SR-PGA) rods that have been used in the treatment of fractures and osteotomies. Afterwards, by using the same technique, self-reinforced PLLA (SR-PLLA) pins and screws have been produced. The higher initial mechanical properties of SR-PLGA are counterbalanced by their faster decrease with respect to the SR-PLLA material, which has a slower degradation rate and is reabsorbed in 12–16 months. These products are commercially available.

NONABSORBABLE MATRIX COMPOSITES

Nonabsorbable matrix composites are generally used as biomaterials to provide specific mechanical properties unattainable with homogeneous materials. Particulate and chopped-fiber reinforcement has been used in bone cements and bearing surfaces to stiffen and strengthen these structures.

For fracture fixation, reduced-stiffness carbon-fiber-reinforced epoxy bone plates to reduce stress-protection osteoporosis have been made. These plates have also been entered into clinical use, but were found to not be as reliable or biocompatible as stainless steel plates. Consequently, they have not generally been accepted in clinical use. By far the most studied, and potentially most valuable use of nonabsorbable composites has been in total joint replacement.

Total Joint Replacement

Bone resorption in the proximal femur leading to aseptic loosening is an all-too-common occurrence associated with the implantation of metallic femoral hip replacement components. It has been suggested that proximal bone loss may be related to the state of stress and strain in the femoral cortex. It has long been recognized that bone adapts to functional stress by remodeling to reestablish a stable mechanical environment. When applied to the phenomenon of bone loss around implants, one can postulate that the relative stiffness of the metallic component is depriving bone of its accustomed load. Clinical and experimental results have shown the significant role that implant elastic characteristics play in allowing the femur to attain a physiologically acceptable stress state. Femoral stem stiffness has been indicated as an important determinant of cortical bone remodeling (Cheal *et al.*, 1992). Composite materials technology offers the ability to alter the elastic characteristics of an implant and provide a better mechanical match with the host bone, potentially leading to a more favorable bone remodeling response.

Using different polymer matrices reinforced with carbon fiber, a large range of mechanical properties is possible. St. John (1983) reported properties for $\pm 15^\circ$ laminated test specimens (Table 2) with moduli ranging from 18 to 76 GPa.

TABLE 2 Typical Mechanical Properties of Polymer–Carbon Composites (Three-Point Bending)

Polymer	Ultimate strength (MPa)	Modulus (GPa)
PMMA	772	55
Polysulfone	938	76
Epoxy		
Stycast	535	30
Hysol	207	24
Polyurethane	289	18

However, the best reported study involved a novel press-fit device constructed of carbon fiber/polysulfone composite (Magee *et al.*, 1988). The femoral component designed and used in this study utilized composite materials with documented biologic profiles. These materials demonstrated strength commensurate with a totally unsupported implant region and elastic properties commensurate with a fully bone-supported implant region. These properties were designed to produce constructive bone remodeling. The component contained a core of unidirectional carbon/polysulfone composite enveloped with a bidirectional braided layer composed of carbon/polysulfone composite covering the core. These regions were encased in an outer coating of pure polysulfone (Fig. 9). Finite-element stress analysis predicted that this construction would cause minimal disruption of the normal stresses in the intact cortical bone. Canine studies carried out to 4 years showed a favorable bone remodeling response. The authors proposed that implants fabricated from carbon/polysulfone composites should have the potential for use in load-bearing

FIG. 9. Construction details of a femoral stem of a composite total hip prosthesis. (From Magee *et al.*, 1988.)

applications. An implant with appropriate elastic properties provides the opportunity for the natural bone remodeling response to enhance implant stability.

Adam *et al.* (2002) reported on the revision of 51 epoxy resin/carbon fiber composite press fit-hip prostheses implanted in humans. Their result showed that within 6 years 92% of the prostheses displayed aseptic loosening, i.e., did not induce bone ongrowth. Authors attributed the failure to the smoothness of the stem surface. No osteolysis or wear or inflammatory reaction were, however, observed.

Different fibers matrices and fabrication technologies have been proposed for the fabrication of hip prostheses. Reviews of materials and methods are in Ramakrishna *et al.* (2001) and in de Oliveira Simopes and Marques (2001).

CONCLUSIONS

Biomedical composites have demanding properties that allow few, if any, “off the shelf” materials to be used. The designer must almost start from scratch. Consequently, few biomedical composites are yet in general clinical use. Those that have been developed to date have been fabricated from fairly primitive materials with simple designs. They are simple laminates, chopped fiber, or particulate reinforced systems with no attempts made to react or bond the phases together. Such bonding may be accomplished by altering the surface texture of the filler or by the introduction of coupling agents: molecules that can react with both filler and matrix. However, concerns about the biocompatibility of coupling agents and the high development costs of surface texture alteration procedures have curtailed major developments in this area. It is also possible to provide three-dimensional reinforcement with complex fiber weaving and impregnation procedures now regularly used in high-performance aerospace composites. Unfortunately, the high development costs associated with these techniques have restricted their application to biomedical composites.

Because of the high development costs and the small-volume market available, few biomedical materials have, to date, been designed specifically for biomedical use. Biomedical composites, because of their unique requirements, are probably be the first general class of materials developed exclusively for implantation purposes.

2.13 NONFOULING SURFACES

Allan S. Hoffman and Buddy D. Ratner

INTRODUCTION

“Nonfouling” surfaces (NFSs) refer to surfaces that resist the adsorption of proteins and/or adhesion of cells. They are also loosely referred to as protein-resistant surfaces and “stealth” surfaces. It is generally acknowledged that surfaces that strongly adsorb proteins will generally bind cells, and that surfaces that resist protein adsorption will also resist cell adhesion. It is also generally recognized that hydrophilic surfaces are more likely to resist protein adsorption, and that hydrophobic surfaces usually will adsorb a monolayer of tightly adsorbed protein. Exceptions to these generalizations exist, but, overall, they are accurate statements.

An important area for NFSs focuses on bacterial biofilms. Bacteria are believed to adhere to surfaces via a “conditioning film” of molecules (often proteins) that adsorbs first to the surface. The bacteria stick to this conditioning film and begin to exude a gelatinous slime layer (the biofilm) that aids in their protection from external agents (for example, antibiotics). Such layers are particularly troublesome in devices such as urinary catheters and endotracheal tubes. However, they also form on vascular grafts, hip joint prostheses, heart valves, and other long-term implants where they can stimulate significant inflammatory reaction to the infected device. If the conditioning film

can be inhibited, bacterial adhesion and biofilm formation can also be reduced. NFSs offer this possibility.

NFSs have medical and biotechnology uses as blood-compatible materials (where they may resist fibrinogen adsorption and platelet attachment), implanted devices, urinary catheters, diagnostic assays, biosensors, affinity separations, microchannel flow devices, intravenous syringes and tubing, and nonmedical uses as biofouling-resistant heat exchangers and ship bottoms. It is important to note that many of these uses involve *in vivo* implants or extracorporeal devices, and many others involve *in vitro* diagnostic assays, sensors, and affinity separations. As well as having considerable medical and economic importance, nonfouling surfaces offer important experimental and theoretical insights into one of the important phenomena in biomaterials science, protein adsorption. Hence, they have been the subject of many investigations. Aspects of nonfouling surfaces are addressed in many other chapters of this textbook including the chapters on water at interfaces (Chapter 1.5), surface modification (Chapter 2.14) and protein adsorption (Chapter 3.2).

The majority of the literature on non-fouling surfaces focuses on surfaces containing the relatively simple polymer poly(ethylene glycol) or PEG:

When n is in the range of 15 to 3500 (molecular weights of approximately 400–100,000), the PEG designation is used. When molecular weights are greater than 100,000, the molecule is commonly referred to as poly(ethylene oxide) (PEO). Where n is in the range of 2–15, the term oligo(ethylene glycol) (oEG) is often used. An interesting article on the origins of the use of PEG to enhance the circulation time of proteins in the body has recently been published by Davis (2002). Other natural and synthetic polymers besides PEG show nonfouling behavior, and they will also be discussed in this chapter.

BACKGROUND

The published literature on protein and cell interactions with biomaterial surfaces has grown significantly in the past 30 years, and the following concepts have emerged:

- It is well established that hydrophobic surfaces have a strong tendency to adsorb proteins irreversibly (Horbett and Brash, 1987, 1995; Hoffman, 1986). The driving force for this action is most likely the unfolding of the protein on the surface, accompanied by release of many hydrophobically structured water molecules from the interface, leading to a large entropy gain for the system (Hoffman, 1999). Note that adsorbed proteins can be displaced from the surface by solution phase proteins (Brash *et al.*, 1974).
- It is also well known that at low ionic strengths cationic proteins bind to anionic surfaces and anionic proteins bind to cationic surfaces (Hoffman, 1999; Horbett and Hoffman, 1975). The major thermodynamic driving force for these actions is a combination of ion-ion

coulombic interactions, accompanied by an entropy gain due to the release of counterions along with their waters of hydration. However, these interactions are diminished at physiologic conditions by shielding of the protein ionic groups at the 0.15 *N* ionic strength (Horbett and Hoffman, 1975). Still, lysozyme, a highly charged cationic protein at physiologic pH, strongly binds to hydrogel contact lenses containing anionic monomers (see Bohnert *et al.*, 1988, and Chapter 7.10, for discussion of class IV contact lenses).

- It has been a common observation that proteins tend to adsorb in monolayers, i.e., proteins do not adsorb non-specifically onto their own monolayers (Horbett, 1993). This is probably due to retention of hydration water by the adsorbed protein molecules, preventing close interactions of the protein molecules in solution with the adsorbed protein molecules. In fact, adsorbed protein films are, in themselves, reasonable nonfouling surfaces with regard to other proteins (but not necessarily to cells).
- Many studies have been carried out on surfaces coated with physically or chemically immobilized PEG, and a conclusion was reached that the PEG molecular weight should be above a minimum of ca.2000 in order to provide good protein repulsion (Mori *et al.*, 1983; Gombotz *et al.*, 1991; Merrill, 1992). This seems to be the case whether PEG is chemically bound as a side chain of a polymer that is grafted to the surface (Mori *et al.*, 1983), is bound by one end to the surface (Gombotz *et al.*, 1991; Merrill, 1992), or is incorporated as segments in a cross-linked network (Merrill, 1992). The minimum MW was found to be ca. 500–2000, depending on packing density (Mori *et al.*, 1983; Gombotz *et al.*, 1991; Merrill, 1992).
- The mechanism of protein resistance by the PEG surfaces may due to be a combination of factors, including the resistance of the polymer coil to compression due to its desire to retain the volume of a random coil (called “entropic repulsion” or “elastic network” resistance) plus the resistance of the PEG molecule to release both bound and free water from within the hydrated coil (called “osmotic repulsion”) (Gombotz *et al.*, 1991; Antonsen and Hoffman, 1992). The size of the adsorbing protein and its resistance to unfolding may also be an important factor determining the extent of adsorption on any surface (Lim and Herron, 1992). The thermodynamic principles governing the adsorption of proteins onto surfaces involve a number of enthalpic and entropic terms favoring or resisting adsorption. These terms are summarized in Table 1. The major factors favoring adsorption will be the entropic gain of released water and the enthalpy loss due to cation–anion attractive interactions between ionic protein groups and surface groups. The major factors favoring resistance to protein adsorption will be the retention of bound water, plus, in the case of an immobilized hydrophilic polymer, entropic and osmotic repulsion of the polymer coils.
- In spite of the evidence for a PEG molecular weight effect, excellent protein resistance can be achieved with very

TABLE 1 Thermodynamics of Protein Adsorption

		Favoring adsorption
ΔH_{ads}	(-)	VdW interactions (short-range)
	(-)	ion-ion interactions (long-range)
ΔS_{ads}	(+)	desorption of many H ₂ O's
	(+)	unfolding of protein
		Opposing adsorption
ΔH_{ads}	(+)	dehydration (interface between surface and protein)
	(+)	unfolding of protein
	(+)	chain compression (PEO)
ΔS_{ads}	(-)	adsorption of protein
	(-)	protein hydrophobic exposure
	(-)	chain compression (PEO)
	(-)	osmotic repulsion (PEO)

short chain PEGs (OEGs) and PEG-like surfaces (Lopez *et al.*, 1992; Sheu *et al.*, 1993).

- Surface-assembled monolayers (SAMs) of lipid-oligoEG molecules have been studied, and it has been found that at least about 50% of the surface should be covered before significant resistance to protein adsorption is observed (Prime and Whitesides, 1993). This suggests that protein resistance by OEG-coated surfaces may be related to a “cooperativity” between the hydrated, short OEG chains in the “plane of the surface,” wherein the OEG chains interact together to bind water to the surface, in a way that is similar to the hydrated coil and its osmotic repulsion, as described above. It has also been observed that a minimum of 3 EG units are needed for highly effective protein repulsion (Harder *et al.*, 1998). Based on all of these observations, one may describe the mechanism as being related to the conformation of the individual oligoEG chains, along with their packing density in the SAM. It has been proposed that helical or amorphous oligoEG conformations lead to stronger water-oligoEG interactions than an all-trans oligoEG conformation (Harder *et al.*, 1998).

Packing density of the nonfouling groups on the surface is difficult to measure and often overlooked as an important factor in preparing nonfouling surfaces. Nevertheless, one may conclude that the one common factor connecting all nonfouling surfaces is their resistance to release of bound water molecules from the surface. Water may be bound to surface groups by both hydrophobic (structured water) and hydrophilic (primarily via hydrogen bonds) interactions, and in the latter case, the water may be H-bonded to neutral polar groups, such as hydroxyl (-OH) or ether (-C-O-C-) groups, or it may be polarized by ionic groups, such as -COO⁻ or -NH₃⁺. *The overall conclusion from all of the above observations is that resistance to protein adsorption at biomaterial interfaces is directly related to resistance of interfacial groups to the release of their bound waters of hydration.*

Based on these conclusions, it is obvious why the most common approaches to reducing protein and cell binding to biomaterial surfaces have been to make them more hydrophilic.

This has been accomplished most often by chemical immobilization of a hydrophilic polymer (such as PEG) on the biomaterial surface by one of the following methods: (a) using UV or ionizing radiation to graft copolymerize a hydrophilic monomer onto surface groups; (b) depositing such a polymer from the vapor of a precursor monomer in a gas discharge process; or (c) directly immobilizing a preformed hydrophilic polymer on the surface using radiation or gas discharge processes. Other approaches to make surfaces more hydrophilic have included the physical adsorption of surfactants or chemical derivatization of surface groups with neutral polar groups such as hydroxyls, or with negatively charged groups (especially since most proteins and cells are negatively charged) such as carboxylic acids or their salts, or sulfonates. Gas discharge has been used to covalently bind nonfouling surfactants such as Pluronic polyols to polymer surfaces (Sheu *et al.*, 1993), and it has also been used to deposit an “oligoEG-like” coating from vapors of triglyme or tetraglyme (Lopez *et al.*, 1992). More recently, a hydrophilic polymer containing phosphorylcholine zwitterionic groups along its backbone has been extensively studied for its nonfouling properties (Iwasaki *et al.*, 1999). Coatings of many hydrogels including poly(2-hydroxyethyl methacrylate) and polyacrylamide show reasonable nonfouling behavior. There have also been a number of naturally occurring biomolecules such as albumin, casein, hyaluronic acid, and mucin that have been coated on surfaces and have exhibited resistance to nonspecific adsorption of proteins. Naturally occurring ganglioside lipid surfactants having saccharide head groups have been used to make “stealth” liposomes (Lasic and Needham, 1995). One paper even suggested that the protein resistance of PEGylated surfaces is related to the “partitioning” of albumin into the PEG layers, causing those surfaces to “look like native albumin” (Vert and Domurado, 2000).

Recently, SAMs presenting an interesting series of head-group molecules that can act as H-bond acceptors but not as H-bond donors have been shown to yield surfaces with unexpected protein resistance (Chapman *et al.*, 2000; Ostuni *et al.*, 2001; Kane *et al.*, 2003). Interestingly, PEG also fits in this category of H-bond acceptors but not donors. However, this generalization does not explain all nonfouling surfaces, especially a report in which mannitol groups with H-bond donor -OH groups were found to be nonfouling (Luk *et al.*, 2000). Another hypothesis proposes that the functional groups that impart a nonfouling property are kosmotropes, order-inducing molecules (Kane *et al.*, 2003). Perhaps because of the ordered water surrounding these molecules, they cannot penetrate the ordered water shell surrounding proteins so strong intermolecular interactions between surface group and protein cannot occur. An interesting kosmotrope molecule with good nonfouling ability described in this paper is taurine, H₃N⁺(CH₂)₂SO₃⁻. Table 2 summarizes some of the different compositions that have been applied as nonfouling surfaces.

It is worthwhile to mention some computational papers (supported by some experiments) that offer new insights and ideas on NFSs (Lim and Herron, 1992; Pertsin *et al.*, 2002; Pertsin and Grunze, 2000). Also, many new experimental methods have been applied to study the mechanism of nonfouling surfaces including neutron reflectivity to measure the

TABLE 2 “Nonfouling” Surface Compositions

Synthetic Hydrophilic Surfaces

- PEG polymers and surfactants
- Neutral polymers
 - Poly(2-hydroxyethyl methacrylate)
 - Polyacrylamide
 - Poly(*N*-vinyl-2-pyrrolidone)
 - Poly(*N*-isopropyl acrylamide) (below 31°C)
- Anionic polymers
- Phosphoryl choline polymers
- Gas discharge-deposited coatings (especially from PEG-like monomers)
- Self-assembled *n*-alkyl molecules with oligo-PEG head groups
- Self-assembled *n*-alkyl molecules with other polar head groups

Natural Hydrophilic Surfaces

- Passivating proteins (e.g., albumin and casein)
- Polysaccharides (e.g., hyaluronic acid)
- Liposaccharides
- Phospholipid bilayers
- Glycoproteins (e.g., mucin)

water density in the interfacial region (Schwendel *et al.*, 2003), scanning force microscopy (Feldman *et al.*, 1999), and sum frequency generation (Zolk *et al.*, 2000).

Finally, it should be noted that bacteria tend to adhere and colonize almost any type of surface, perhaps even many protein-resistant NFSs. However, the best NFSs can provide acute resistance to bacteria and biofilm build-up better than most surfaces (Johnston *et al.*, 1997). Resistance to bacterial adhesion remains an unsolved problem in surface science. Also, it has been pointed out that susceptibility of PEGs to oxidative damage may reduce their utility as nonfouling surfaces in real-world situations (Kane *et al.*, 2003).

CONCLUSIONS AND PERSPECTIVES

It is remarkable how many different surface compositions appear to be nonfouling. Although it is difficult to be sure about the existence of a unifying mechanism for this action, it appears that the major factor favoring resistance to protein adsorption will be the retention of bound water by the surface molecules, plus, in the case of an immobilized hydrophilic polymer, entropic and osmotic repulsion by the polymer coils. Little is known about how long a nonfouling surface will remain nonfouling *in vivo*. Longevity and stability for nonfouling biomaterials remains an uncharted frontier. Defects (e.g., pits, uncoated areas) in NFSs may provide “footholds” for bacteria and cells to begin colonization. Enhanced understanding of how to optimize the surface density and composition of NFSs will lead to improvements in quality and fewer microdefects. Finally, it is important to note that a clean, “nonfouled” surface may not always be desirable. In the case of cardiovascular implants or devices, emboli may be shed when such

a surface is exposed to flowing blood (Hoffman *et al.*, 1982). This can lead to undesirable consequences, even though (or perhaps especially because) the surface is an effective nonfouling surface. In the case of contact lenses, a protein-free lens may seem desirable, but there are concerns that such a lens will not be comfortable. Although biomaterials scientists can presently create surfaces that are nonfouling for a period of time, applying such surfaces must take into account the specific application, the biological environment, and the intended service life.

2.14 PHYSICOCHEMICAL SURFACE MODIFICATION OF MATERIALS USED IN MEDICINE

Buddy D. Ratner and Allan S. Hoffman

INTRODUCTION

Much effort goes into the design, synthesis, and fabrication of biomaterials and devices to ensure that they have the appropriate mechanical properties, durability, and functionality. To cite a few examples, a hip joint should withstand high stresses, a hemodialyzer should have the requisite permeability characteristics, and the pumping bladder in an artificial heart should flex for millions of cycles without failure. The bulk structure of the materials governs these properties.

The biological response to biomaterials and devices, on the other hand, is controlled largely by their surface chemistry and structure (see Chapters 1.4 and 9.4). The rationale for the surface modification of biomaterials is therefore straightforward: to retain the key physical properties of a biomaterial while modifying only the outermost surface to influence the biointeraction. If such surface modification is properly effected, the mechanical properties and functionality of the device will be unaffected, but the bioresponse related to the tissue–device interface will be improved or modulated.

Materials can be surface-modified by using biological, mechanical, or physicochemical methods. Many biological surface modification schemes are covered in Chapter 2.16. Generalized examples of physicochemical surface modifications, the focus of this chapter, are illustrated schematically in Fig. 1. Surface modification with Langmuir–Blodgett (LB) films has elements of both biological modification and physicochemical modification. LB films will be discussed later in this chapter. Some applications for surface modified biomaterials are listed in Table 1. Physical and chemical surface modification methods, and the types of materials to which they can be applied, are listed in Table 2. Methods to modify or create surface texture or roughness will not be explicitly covered here, though chemical patterning of surfaces will be addressed.

GENERAL PRINCIPLES

Surface modifications fall into two categories: (1) chemically or physically altering the atoms, compounds, or molecules in the existing surface (chemical modification, etching, mechanically roughening), or (2) overcoating the existing surface with a material having a different composition (coating, grafting, thin film deposition) (Fig. 1). A few general principles provide guidance when undertaking surface modification:

Thin Surface Modifications

Thin surface modifications are desirable. The modified zone at the surface of the material should be as thin as possible. Modified surface layers that are too thick can change the mechanical and functional properties of the material.

Surface Modification Possibilities

Unmodified surface

Overcoat

- Solvent coat
- Grafted or adsorbed surface layer
- Metallization
- Sprayed hydroxyapatite (flame or electrostatic)

Surface gradient

- Graft
- Interpenetrating network
- Ion implant

Self assembled film, Langmuir-Blodgett overlayer

- N-Alkyl thiols on gold
- N-Alky silanes on silica
- N-Alky phosphates on Ti
- Multilayers are possible

Surface active bulk additive

Surface chemical reaction

- Oxidation
- Fluorination
- Silanization

Etching and roughening

Surface chemical reaction is also frequently observed

Polyelectrolyte multilayer films

FIG. 1. Schematic representations of methods to modify surfaces.

TABLE 1 Some Physicochemically Surface-Modified Biomaterials

To modify blood compatibility
Octadecyl group attachment to surfaces (albumin affinity)
Silicone-containing block copolymer additive
Plasma fluoropolymer deposition
Plasma siloxane polymer deposition
Radiation grafted hydrogel
Chemically modified polystyrene for heparin-like activity
To influence cell adhesion and growth
Oxidized polystyrene surface
Ammonia plasma-treated surface
Plasma-deposited acetone or methanol film
Plasma fluoropolymer deposition (reduce endothelial adhesion to IOLs)
To control protein adsorption
Surface with immobilized poly(ethylene glycol) (reduce adsorption)
Treated ELISA dish surface (increase adsorption)
Affinity chromatography column
Surface cross-linked contact lens (reduce adsorption)
To improve lubricity
Plasma treatment
Radiation grafting (hydrogels)
Interpenetrating polymeric networks
To improve wear resistance and corrosion resistance
Ion implantation
Diamond deposition
Anodization
To alter transport properties
Polyelectrolyte grafting
To modify electrical characteristics
Polyelectrolyte grafting
Magnetron sputtering of titanium

Thick coatings are also more subject to delamination and cracking. How thin should a surface modification be? Ideally, alteration of only the outermost molecular layer (3–10 Å) should be sufficient. In practice, thicker films than this will be necessary since it is difficult to ensure that the original surface is uniformly covered when coatings and treatments are so thin. Also, extremely thin layers may be more subject to surface reversal (see later discussion) and mechanical erosion. Some coatings intrinsically have a specific thickness. For example, the thickness of LB films is related to the length of the amphiphilic molecules that form them (25–50 Å). Other coatings, such as poly(ethylene glycol) protein-resistant layers, may require a minimum thickness (a dimension related to the molecular weight of chains) to function. In general, surface modifications should be the minimum thickness needed for uniformity, durability, and functionality, but no thicker. This is often experimentally defined for each system.

Delamination Resistance

The surface-modified layer should be resistant to delamination and cracking. Resistance to delamination is achieved

by covalently bonding the modified region to the substrate, intermixing the components of the substrate and the surface film at an interfacial zone (for example, an interpenetrating network), applying a compatibilizing (“primer”) layer at the interface, or incorporating appropriate functional groups for strong intermolecular adhesion between a substrate and an overlayer (Wu, 1982).

Surface Rearrangement

Surface rearrangement can readily occur. It is driven by a thermodynamic minimization of interfacial energy and enhanced by molecular mobility. Surface chemistries and structures can “switch” because of diffusion or translation of surface atoms or molecules in response to the external environment (see Chapter 1.4 and Fig. 2 in that chapter). A newly formed surface chemistry can migrate from the surface into the bulk, or molecules from the bulk can diffuse to cover the surface. Such reversals occur in metallic and other inorganic systems, as well as in polymeric systems. Terms such as “reconstruction,” “relaxation,” and “surface segregation” are often used to describe mobility-related alterations in surface structure and chemistry (Ratner and Yoon, 1988; Garbassi *et al.*, 1989; Somorjai, 1990, 1991). The driving force for these surface changes is a minimization of the interfacial energy. However, sufficient atomic or molecular mobility must exist for the surface changes to occur in reasonable periods of time. For a modified surface to remain as it was designed, surface reversal must be prevented or inhibited. This can be done by cross-linking, sterically blocking the ability of surface structures to move, or by incorporating a rigid, impermeable layer between the substrate material and the surface modification.

Surface Analysis

Surface modification and surface analysis are complementary and sequential technologies. The surface-modified region is usually thin and consists of only minute amounts of material. Undesirable contamination can readily be introduced during modification reactions. The potential for surface reversal to occur during surface modification is also high. The surface reaction should be monitored to ensure that the intended surface is indeed being formed. Since conventional analytical methods are often insufficiently sensitive to detect surface modifications, special surface analytical tools are called for (Chapter 1.4).

Commercializability

The end products of biomaterials research are devices and materials that are manufactured to exacting specifications for use in humans. A surface modification that is too complex will be difficult and expensive to commercialize. It is best to minimize the number of steps in a surface modification process and to design each step to be relatively insensitive to small changes in reaction conditions.

METHODS FOR MODIFYING THE SURFACES OF MATERIALS

General methods to modify the surfaces of materials are illustrated in Fig. 1, with many examples listed in Table 2. A few of the more widely used of these methods will be briefly described. Some of the conceptually simpler methods such as solution coating of a polymer onto a substrate or metallization by sputtering or thermal evaporation will not be elaborated upon here.

Chemical Reaction

There are hundreds of chemical reactions that can be used to modify the chemistry of a surface. Chemical reactions, in the context of this article, are those performed with reagents that react with atoms or molecules at the surface, but do not overcoat those atoms or molecules with a new layer. Chemical reactions can be classified as nonspecific and specific.

Nonspecific reactions leave a distribution of different functional groups at the surface. An example of a nonspecific surface chemical modification is the chromic acid oxidation

of polyethylene surfaces. Other examples include the corona discharge modification of materials in air; radio-frequency glow discharge (RFGD) treatment of materials in oxygen, argon, nitrogen, carbon dioxide, or water vapor plasmas; and the oxidation of metal surfaces to a mixture of suboxides.

Specific chemical surface reactions change only one functional group into another with a high yield and few side reactions. Examples of specific chemical surface modifications for polymers are presented in Fig. 2. Detailed chemistries of biomolecule immobilization are described in Chapter 2.16.

Radiation Grafting and Photografting

Radiation grafting and related methods have been widely applied for the surface modification of biomaterials starting in the late 1960s (Hoffman *et al.*, 1972), and comprehensive review articles are available (Ratner, 1980; Hoffman, 1981; Hoffman *et al.*, 1983; Stannett, 1990; Safrany, 1997). The earliest applications, particularly for biomedical applications, focused on attaching chemically reactable groups ($-OH$, $-COOH$, $-NH_2$, etc) to the surfaces of relatively inert hydrophobic polymers. Within this category, three types of

FIG. 2. A diagram of a capacitively coupled RF plasma reactor. Important experimental variables are indicated in bold type-face. Zone 1 shows gas storage and mixing. Zone 2 shows components that power the reactor. Zone 3 highlights components of the vacuum system.

reactions can be distinguished: grafting using ionizing radiation sources (most commonly, a cobalt-60 or cesium-137 gamma radiation source) (Dargaville *et al.*, 2003), grafting using UV radiation (photografting) (Srinivasan and Lazare, 1985; Matsuda and Inoue, 1990; Dunkirk *et al.*, 1991; Swanson, 1996), and grafting using high-energy electron beams (Singh and Silverman, 1992). In all cases, similar processes occur. The radiation breaks chemical bonds in the material to be grafted, forming free radicals, peroxides, or other reactive species. These reactive surface groups are then exposed to a monomer. The monomer reacts with the free radicals at the surface and propagates as a free radical chain reaction incorporating other monomers into a surface grafted polymer. Electron beams and gamma radiation sources are also used for biomedical device sterilization (see Chapter 9.2).

These high-energy surface modification technologies are strongly dependent on the source energy, the radiation dose rate, and the amount of the dose absorbed. Gamma sources have energies of roughly 1 MeV (1 eV = 23.06 kcal/mol). Typical energies for electron beam processing are 5–10 MeV. UV radiation sources are of much lower energy (<6 eV). Radiation dose rates are low for UV and gamma and very high for electron beams. The amount of energy absorbed is measured in units of grays (Gy) where 1 kilogray (kGy) = 1000 joules/kilogram. Units of megarads (MR) are often used for gamma sources; 1 MR = 1×10^6 ergs/gram = 10 kGy.

Three distinct reaction modes can be described: (a) In the mutual irradiation method, the substrate material is immersed

in an oxygen-free solution (monomer \pm solvent) that is then exposed to the radiation source. (b) The substrate materials can also be exposed to the radiation under an inert atmosphere or at low temperatures (to stabilize free radicals). In this case, the materials are later contacted with a monomer solution to initiate the graft process. (c) Finally, the exposure to the radiation can take place in air or oxygen, leading to the formation of peroxide groups on the surface. Heating the material to be grafted in the presence of monomer, or addition of a redox reactant (e.g., Fe^{2+}) that will decompose the peroxide groups to form free radicals, can initiate the graft polymerization (in O_2 -free conditions).

Graft layers formed by energetic irradiation of the substrate are often thick ($>1 \mu\text{m}$) and composed of relatively high-molecular-weight polymer chains. However, they are typically well-bonded to the substrate material. Since many polymerizable monomers are available, a wide range of surface chemistries can be created. Mixtures of monomers can form unique graft copolymers (Ratner and Hoffman, 1980). For example, the hydrophilic/hydrophobic ratio of surfaces can be controlled by varying the ratio of a hydrophilic and a hydrophobic monomer in the grafting mixture (Ratner and Hoffman, 1980; Ratner *et al.*, 1979).

Photoinitiated grafting (usually with visible or UV light) represents a unique subcategory of surface modifications in which there is growing interest. There are many approaches to effect this photoinitiated covalent coupling. For example, a phenyl azide group can be converted to a highly reactive

nitrene upon UV exposure. This nitrene will quickly react with many organic groups. If a synthetic polymer is prepared with phenyl azide side groups and this polymer is exposed simultaneously to UV light and a substrate polymer or polymeric medical device, the polymer containing the phenyl azide side groups will be immobilized to the substrate (Matsuda and Inoue, 1990). Another method involves the coupling of a benzophenone molecule to a hydrophilic polymer (Dunkirk *et al.*, 1991). In the presence of UV irradiation, the benzophenone is excited to a reactive triplet state that can abstract a hydrogen leading to radical cross-linking.

Radiation, electron beam, and photografting have frequently been used to bond hydrogels to the surfaces of hydrophobic polymers (Matsuda and Inoue, 1990; Dunkirk *et al.*, 1991). Electron beam grafting of *N*-isopropyl acrylamide to polystyrene has been used to create a new class of temperature-dependent surfaces for cell growth (Kwon *et al.*, 2000) (also see Chapter 2.6). The protein interactions (Horbett and Hoffman, 1975), cell interactions (Ratner *et al.*, 1975; Matsuda and Inoue, 1990), blood compatibility (Chapiro, 1983; Hoffman *et al.*, 1983), and tissue reactions (Greer *et al.*, 1979) of hydrogel graft surfaces have been investigated.

RFGD Plasma Deposition and Other Plasma Gas Processes

RFGD plasmas, as used for surface modification, are low-pressure ionized gas environments typically at ambient (or slightly above ambient) temperature. They are also referred to as glow discharge or gas discharge depositions or treatments. Plasmas can be used to modify existing surfaces by ablation or etching reactions or, in a deposition mode, to overcoat surfaces (Fig. 1). Good review articles on plasma deposition and its application to biomaterials are available (Yasuda and Gazicki, 1982; Hoffman, 1988; Ratner *et al.*, 1990; Chu *et al.*, 2002; Kitching *et al.*, 2003). Some biomedical applications of plasma-modified biomaterials are listed in Table 3.

The application of RFGD plasma surface modification in biomaterials development is steadily increasing. Because such coatings and treatments have special promise for improved biomaterials, they will be emphasized in this chapter. The specific advantages of plasma-deposited films (and to some extent, plasma-treated surfaces) for biomedical applications are:

1. They are conformal. Because of the penetrating nature of a low-pressure gaseous environment in which mass transport is governed by both molecular (line-of-sight) diffusion and convective diffusion, complex geometric shapes can be treated.
2. They are free of voids and pinholes. This continuous barrier structure is suggested by transport studies and electrical property studies (Charlson *et al.*, 1984).
3. Plasma-deposited polymeric films can be placed upon almost any solid substrate, including metals, ceramics, and semiconductors. Other surface-grafting or surface-modification technologies are highly dependent upon the chemical nature of the substrate.
4. They exhibit good adhesion to the substrate. The energetic nature of the gas-phase species in the plasma

Unique film chemistries can be produced. The chemical structure of the polymeric overlayer films generated from the plasma environment usually cannot be synthesized by conventional chemical methods. 6. They can serve as excellent barrier films because of their pinhole-free and dense, cross-linked nature. 7. Plasma-deposited layers generally show low levels of leachables. Because they are highly cross-linked, plasma-deposited films contain negligible amounts of low-molecular-weight components that might lead to an adverse biological reaction. They can also prevent leaching of low-molecular-weight material from the substrate. 8. These films are easily prepared. Once the apparatus is set up and optimized for a specific deposition, treatment of additional substrates is rapid and simple. 9. The production of plasma depositions is a mature technology. The microelectronics industry has made extensive use of inorganic plasma-deposited films for many years (Sawin and Reif, 1983; Nguyen, 1986). 10. Plasma surface modifications, although they are chemically complex, can be characterized by infrared (IR) (Inagaki <i>et al.</i>, 1983; Haque and Ratner, 1988; Krishnamurthy <i>et al.</i>, 1989), nuclear magnetic resonance (NMR) (Kaplan and Dilks, 1981), electron spectroscopy for chemical analysis (ESCA) (Chilkoti <i>et al.</i>, 1991a), chemical derivatization studies (Everhart and Reilly, 1981; Gombotz and Hoffman, 1988; Griesser and Chatelier, 1990; Chilkoti <i>et al.</i>, 1991a), and static secondary ion mass spectrometry (SIMS) |

(Chilkoti *et al.*, 1991b, 1992; Johnston and Ratner, 1996).

11. Plasma-treated surfaces are sterile when removed from the reactor, offering an additional advantage for cost-efficient production of medical devices.

It would be inappropriate to cite all these advantages without also discussing some of the disadvantages of plasma deposition and treatment for surface modification. First, the chemistry produced on a surface is often ill-defined. For example, if tetrafluoroethylene gas is introduced into the reactor, polytetrafluoroethylene will not be deposited on the surface. Rather, a complex, branched fluorocarbon polymer will be produced. This scrambling of monomer structure has been addressed in studies dealing with retention of monomer structure in the final film (Lopez and Ratner, 1991; Lopez *et al.*, 1993; Panchalingham *et al.*, 1993). Second, the apparatus used to produce plasma depositions can be expensive. A good laboratory-scale reactor will cost \$10,000–30,000, and a production reactor can cost \$100,000 or more. Third, uniform reaction within long, narrow pores can be difficult to achieve. Finally, contamination can be a problem and care must be exercised to prevent extraneous gases and pump oils from entering the reaction zone. However, the advantages of plasma reactions outweigh these potential disadvantages for many types of modifications that cannot be accomplished by other methods.

The Nature of the Plasma Environment

Plasmas are atomically and molecularly dissociated gaseous environments. A plasma environment contains positive ions, negative ions, free radicals, electrons, atoms, molecules, and photons (visible and UV). Typical conditions within the plasma include an electron energy of 1–10 eV, a gas temperature of 25–60°C, an electron density of 10^{-9} to $10^{-12}/\text{cm}^3$, and an operating pressure of 0.025–1.0 torr.

A number of processes can occur on the substrate surface that lead to the observed surface modification or deposition. First, a competition takes place between deposition and etching by the high-energy gaseous species (ablation) (Yasuda, 1979). When ablation is more rapid than deposition, no deposition will be observed. Because of its energetic nature, the ablation or etching process can result in substantial chemical and morphological changes to the substrate.

A number of mechanisms have been postulated for the deposition process. The reactive gaseous environment and UV emission may create free radical and other reactive species on the substrate surface that react with and polymerize molecules from the gas phase. Alternately, reactive small molecules in the gas phase could combine to form higher-molecular-weight units or particulates that may settle or precipitate onto the surface. Most likely, the depositions observed are formed by some combination of these two processes.

Production of Plasma Environments for Deposition

Many experimental variables relating both to reaction conditions and to the substrate onto which the deposition is

placed affect the final outcome of the plasma deposition process (Fig. 2). A diagram of a typical inductively coupled radio frequency plasma reactor is presented in Fig. 2. The major sub-systems that make up this apparatus are a gas introduction system (control of gas mixing, flow rate, and mass of gas entering the reactor), a vacuum system (measurement and control of reactor pressure and inhibition of backstreaming of molecules from the pumps), an energizing system to efficiently couple energy into the gas phase within the reactor, and a reactor zone in which the samples are treated. Radio-frequency, acoustic, or microwave energy can be coupled to the gas phase. Devices for monitoring the molecular weight of the gas-phase species (mass spectrometers), the optical emission from the glowing plasma (spectrometers), and the deposited film thickness (ellipsometers, vibrating quartz crystal microbalances) are also commonly found on plasma reactors. Technology has been developed permitting atmospheric-pressure plasma deposition (Massines *et al.*, 2000; Klages *et al.*, 2000). Another important development is “reel-to-reel” (continuous) plasma processing, opening the way to low-cost treatment of films, fibers, and tubes.

RFGD Plasmas for the Immobilization of Molecules

Plasmas have often been used to introduce organic functional groups (e.g., amine, hydroxyl) on a surface that can be activated to attach biomolecules (see Chapter 2.16). Certain reactive gas environments can also be used for directly immobilizing organic molecules such as surfactants. For example, a poly(ethylene glycol)-*n*-alkyl surfactant will adsorb to polyethylene via the propylene glycol block. If the polyethylene surface with the adsorbed surfactant is briefly exposed to an argon plasma, the *n*-alkyl chain will be cross-linked, thereby leading to the covalent attachment of pendant poly(ethylene glycol) chains (Sheu *et al.*, 1992).

High-Temperature and High-Energy Plasma Treatments

The plasma environments described above are of relatively low energy and low temperature. Consequently, they can be used to deposit organic layers on polymeric or inorganic substrates. Under higher energy conditions, plasmas can effect unique and important inorganic surface modifications on inorganic substrates. For example, flame-spray deposition involves injecting a high-purity, relatively finely divided (~100 mesh) metal powder into a high-velocity plasma or flame. The melted or partially melted particles impact the surface and rapidly solidify (see Chapter 2.9). An example of thermal spray coating on titanium is seen in Gruner (2001).

Silanization

Silane treatments of surfaces involve a liquid-phase chemical reaction and are straightforward to perform and low cost. A typical silane surface modification reaction is illustrated in Fig. 4. Silane reactions are most often used to modify hydroxylated surfaces. Since glass, silicon, germanium, alumina, and quartz surfaces, as well as many metal oxide surfaces, are rich in

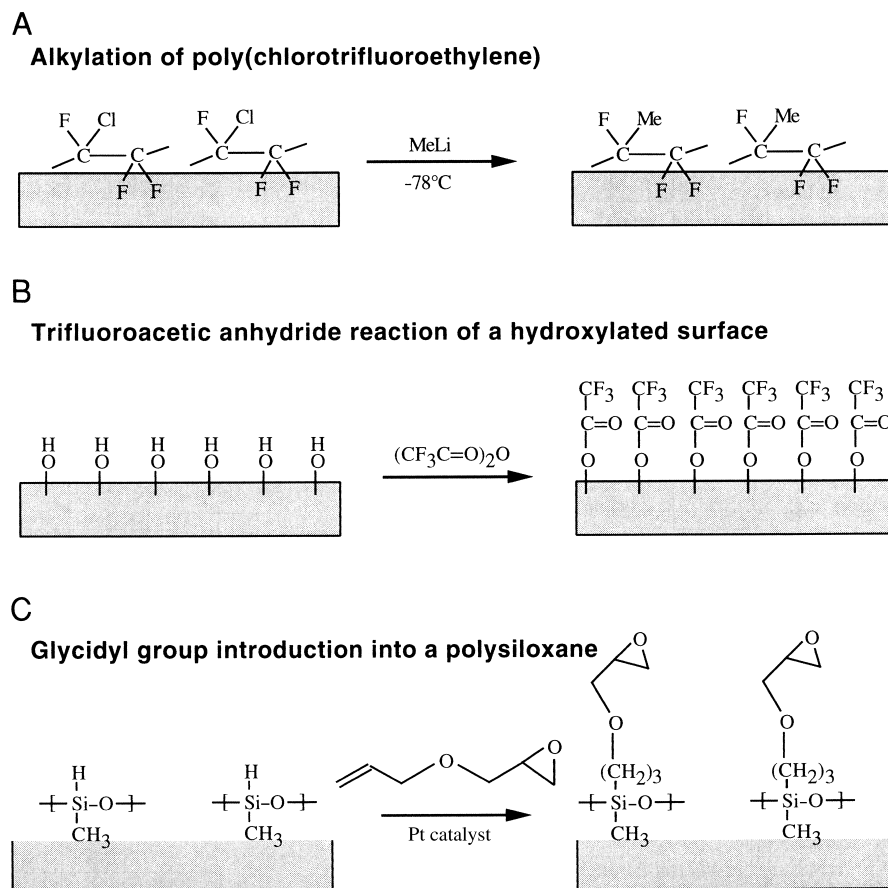

FIG. 3. Some specific chemical reactions to modify surfaces.

hydroxyl groups, silanes are particularly useful for modifying these materials. Numerous silane compounds are commercially available, permitting a broad range of chemical functionalities to be incorporated on surfaces (Table 4). The advantages of silane reactions are their simplicity and stability, attributed to their covalent, cross-linked structure. However, the linkage between a silane and an hydroxyl group is also readily subject to basic hydrolysis, and film breakdown under some conditions must be considered (Wasserman *et al.*, 1989).

Silanes can form two types of surface film structures. If only surface reaction occurs (perhaps catalyzed by traces of adsorbed surface water), a structure similar to that shown in Fig. 4 can be formed. However, if more water is present, a thicker silane layer can be formed consisting of both Si-O groups bonded to the surface and silane units participating in a "bulk," three-dimensional, polymerized network. The initial stages in the formation of a thicker silane film are suggested by the further reaction of the group at the right side of Fig. 4D with solution-phase silane molecules. Without careful control of silane liquid purity, water concentration, and reaction conditions, thicker silane films can be rough and inhomogeneous.

A new class of silane-modified surfaces based upon monolayer silane films and yielding self-assembled, highly ordered

structures is of particular interest in precision engineering of surfaces (Pomerantz *et al.*, 1985; Maoz *et al.*, 1988; Heid *et al.*, 1996). These self-assembled monolayers are described in more detail later in this chapter.

Many general reviews and basic science studies on surface silanization are available (Arkles, 1977; Plueddemann, 1980; Rye *et al.*, 1997). Applications for silanized surface-modified biomaterials are on the increase and include cell attachment (Matsuzawa *et al.*, 1997; Hickman and Stenger, 1994), biomolecule and polymer immobilization (Xiao *et al.*, 1997; Mao *et al.*, 1997), nonfouling surfaces (Lee and Laibinis, 1998), surfaces for DNA studies (Hu *et al.*, 1996), biomineralization (Archibald *et al.*, 1996), and model surfaces for biointeraction studies (Jenney and Anderson, 1999).

Ion Beam Implantation

The ion-beam method injects accelerated ions with energies ranging from 10^1 to 10^6 eV ($1 \text{ eV} = 1.6 \times 10^{-19}$ joules) into the surface zone of a material to alter its surface properties. It is largely, but not exclusively, used with metals and other inorganics such as ceramics, glasses, and semiconductors. Ions formed from most of the atoms in the periodic table

FIG. 4. The chemistry of a typical silane surface modification reaction. (A) A hydroxylated surface is immersed in a non-aqueous solution containing *n*-propyl trimethoxysilane (nPTMS). (B) One of the methoxy groups of the nPTMS couples with a hydroxyl group releasing methanol. (C) Two of the methoxy groups on another molecule of the nPTMS have reacted, one with a hydroxyl group and the other with a methoxy group from the first nPTMS molecule. (D) A third nPTMS molecule has reacted only with a methoxy group. This molecule is tied into the silane film network, but is not directly bound to the surface.

	$-\text{CH}_2\text{CH}_2-\text{C}_6\text{H}_5$

can be implanted, but not all provide useful modifications to the surface properties. Important potential applications for biomaterial surfaces include modification of hardness (wear), lubricity, toughness, corrosion, conductivity, and bioreactivity.

If an ion with kinetic energy greater than a few electron volts impacts a surface, the probability that it will enter the surface

is high. The impact transfers much energy to a localized surface zone in a very short time interval. Some considerations for the ion implantation process are illustrated in Fig. 5. These surface changes must be understood quantitatively for engineering of modified surface characteristics. Many review articles and books are available on ion implantation processes and their application for tailoring surface properties (Picraux and Pope, 1984; Colligon, 1986; Sioshansi, 1987; Nastasi *et al.*, 1996).

Specific examples of biomaterials that have been surface altered by ion implantation processes are plentiful. Iridium was ion implanted in a Ti-6Al-4V alloy to improve corrosion resistance (Buchanan *et al.*, 1990). Nitrogen implanted into titanium greatly reduces wear (Sioshansi, 1987). The ion implantation of boron and carbon into type 316L stainless steel improves the high cycle fatigue life of these alloys (Sioshansi, 1987). Silver ions implanted into polystyrene permit cell attachment (Tsuji *et al.*, 1998).

Langmuir-Blodgett Deposition

The Langmuir-Blodgett (LB) deposition method overcoats a surface with one or more highly ordered layers of surfactant molecules. Each of the molecules that assemble into this

FIG. 5. Some considerations for the ion implantation process.

layer contains a polar “head” group and a nonpolar “tail” group. The deposition of an LB film using an LB trough is illustrated schematically in Fig. 6. By withdrawing the vertical plate through the air–water interface, and then pushing the plate down through the interface, keeping the surface film at the air–water interface compressed at all times (as illustrated in Fig. 6), multilayer structures can be created. Some compounds that form organized LB layers are shown in Fig. 7. The advantages of films deposited on surfaces by this method are their high degree of order and uniformity. Also, since a wide range of chemical structures can form LB films, there are many options for incorporating new chemistries at surfaces. The stability of LB films can be improved by cross-linking or internally polymerizing the molecules after film formation, often through double bonds in the alkyl portion of the chains (Meller *et al.*, 1989). A number of research groups have investigated LB films for biomedical applications (Hayward and Chapman, 1984; Bird *et al.*, 1989; Cho *et al.*, 1990; Heens *et al.*, 1991). A unique cross between silane thin films and LB layers has been developed for biomedical surface modification (Takahara *et al.*, 2000). Many general reviews on these surface structures are available (Knobler, 1990; Ulman, 1991).

Self-Assembled Monolayers

Self-assembled monolayers (SAMs) are surface films that spontaneously form as highly ordered structures

(two-dimensional crystals) on specific substrates (Maoz *et al.*, 1988; Ulman, 1990, 1991; Whitesides *et al.*, 1991; Knoll, 1996). In some ways SAMs resemble LB films, but there are important differences, in particular their ease of formation. Examples of SAM films include *n*-alkyl silanes on hydroxylated surfaces (silica, glass, alumina), alkane thiols [e.g., $CH_3(CH_2)_nSH$] and disulfides on coinage metals (gold, silver, copper), amines and alcohols on platinum, carboxylic acids on aluminum oxide, and silver and phosphates (phosphoric acid or phosphonate groups) on titanium or tantalum surfaces. Silane SAMs and thiols on gold are the most commonly used types. Most molecules that form SAMs have the general characteristics illustrated in Fig. 8. Two processes are particularly important for the formation of SAMs (Ulman, 1991): a moderate to strong adsorption of an anchoring chemical group to the surface (typically 30–100 kcal/mol), and van der Waals interaction of the alkyl chains. The bonding to the substrate (chemisorption) provides a driving force to fill every site on the surface and to displace contaminants from the surface. This process is analogous to the compression to the LB film by the movable barrier in the trough. Once adsorption sites are filled on the surface, the chains will be in sufficiently close proximity so that the weaker van der Waals interactive forces between chains can exert their influence and lead to a crystallization of the alkyl groups. Fewer than nine CH_2 groups do not provide sufficient interactive force to stabilize the 2D quasicrystal and are difficult to assemble. More than 24 CH_2 groups have too many options for defects in the crystal and are also

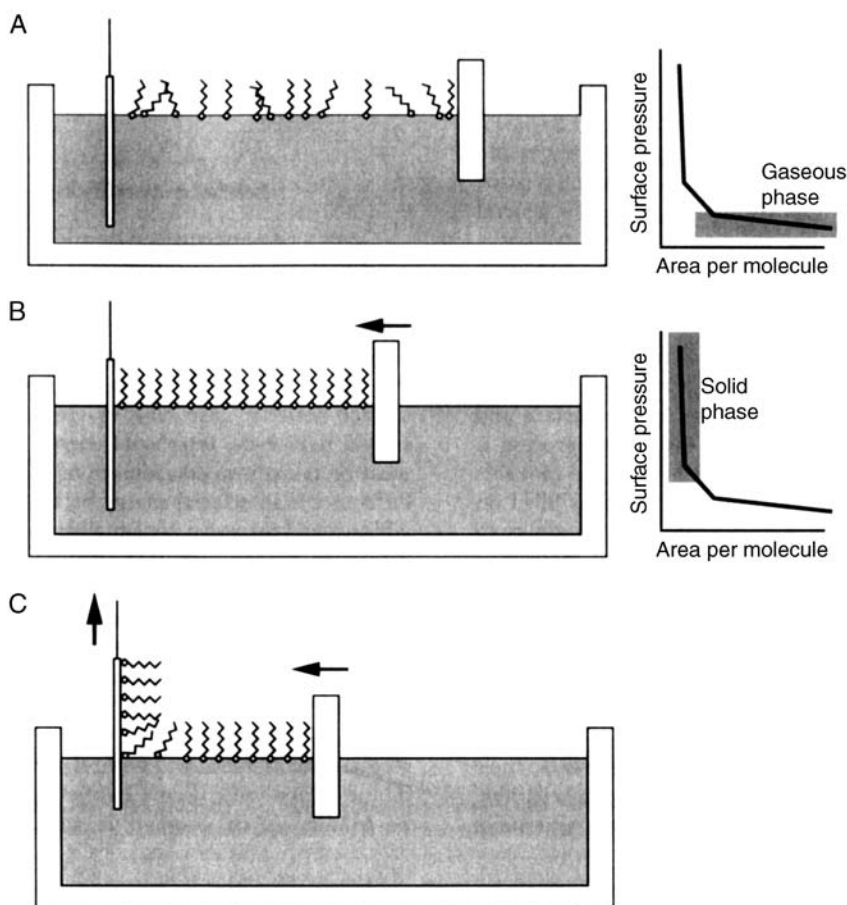

FIG. 6. Deposition of a lipid film onto a glass slide by the Langmuir-Blodgett technique. (A) The lipid film is floated on the water layer. (B) The lipid film is compressed by a moveable barrier. (C) The vertical glass slide is withdrawn while pressure is maintained on the floating lipid film with the moveable barrier.

difficult to assemble. Molecules with lengths between nine and 24 methylene groups will assemble well. Molecular mobility is an important consideration in this surface crystal formation process so that (1) the molecules have sufficient time to maneuver into position for tight packing of the binding end groups at the surface and (2) the chains can enter the quasicrystal.

The advantages of SAMs are their ease of formation, their chemical stability (often considerably higher than that of comparable LB films) and the many options for changing the outermost group that interfaces with the external environment. Many biomaterials applications have already been suggested for SAMs (Lewandowska *et al.*, 1989; Mrksich and Whitesides, 1996; Ferretti *et al.*, 2000). Useful SAMs for creating molecularly-engineered functional surfaces include headgroups of ethylene glycol oligomers, biotin, free radical initiators, *N*-hydroxysuccinimide esters, anhydrides, perfluoro groups, and amines, just to list a small sampling of the many possibilities. Though most SAMs are based on *n*-alkyl chain assembly, SAMs can form from other classes of molecules including proteins (Sara and Sleytr, 1996), porphyrins, nucleotide bases and aromatic ring hydrocarbons.

Multilayer Polyelectrolyte Absorption

A new strategy for the surface modification of biomaterials has been developed within the past few years (Decher, 1996) and has already found application in biomaterials devices. Multilayer polyelectrolyte absorption requires a surface with either a fixed positive or a fixed negative charge. Some surfaces are intrinsically charged (for example, mica) and others can be modified with methods already described in this chapter. If the surface is negatively charged, it is dipped into an aqueous solution of a positively charged polyelectrolyte (e.g., polyethyleneimine). It is then rinsed in water and dipped in an aqueous solution of a negatively charged polyelectrolyte. This process is repeated as many times as desired to build up a polyelectrolyte complex multilayer of the appropriate thickness for a given application. Once a thin layer of a charged component adsorbs, it will repel additional adsorption thus tightly controlling the layer thickness and uniformity. The outermost layer can be the positively charged or negatively charged component. This strategy works well with charged biomolecules, for

FIG. 7. Three examples of molecules that form organized Langmuir-Blodgett films.

FIG. 8. General characteristics of molecules that form self-assembled monolayers.

example hyaluronic acid (-) and chitosan (+). Layers formed are durable and assembly of these multilayer structures is simple. The pH and ionic strength of polyelectrolyte solutions are important process variables. Such overlayer films are now being explored for application in contact lenses.

Surface-Modifying Additives

Specifically designed and synthesized surface-active compositions can be added in low concentrations to a material during fabrication and will spontaneously rise to and dominate the surface (Ward, 1989; Wen *et al.*, 1997). These surface-modifying additives (SMAs) are well known for both organic and inorganic systems. A driving force to minimize the interfacial energy causes the SMA to concentrate at the surface after blending homogeneously with a material. For efficient surface concentration, two factors must be taken into consideration. First, the magnitude of interfacial energy difference between the system without the additive and the same system with the SMA at the surface will determine the magnitude of the driving force leading to a SMA-dominated surface. Second, the molecular mobility of the bulk material and the SMA additive molecules within the bulk will determine the rate at which the SMA reaches the surface, or if it will get there at all. An additional concern is the durability and stability of the SMA at the surface.

A typical SMA designed to alter the surface properties of a polymeric material will be a relatively low molecular weight diblock or triblock copolymer (see Chapter 2.2). The "A" block will be soluble in, or compatible with, the bulk material into which the SMA is being added. The "B" block will be incompatible with the bulk material and have lower surface energy. Thus, the A block will anchor the B block into the material to be modified at the interface. This is suggested schematically in Fig. 9. During initial fabrication, the SMA might be distributed uniformly throughout the bulk. After a period for curing or an annealing step, the SMA will migrate to the surface. Low-molecular-weight end groups on polymer chains can also provide the driving force to bring the end group to the surface.

As an example, an SMA for a polyurethane might have a low-molecular-weight polyurethane A block and a poly(dimethyl siloxane) (PDMS) B block. The PDMS component on the surface may confer improved blood compatibility to the polyurethane. The A block will anchor the SMA in the polyurethane bulk (the polyurethane A block should be reasonably compatible with the bulk polyurethane), while the low-surface-energy, highly flexible silicone B block will be exposed at the air surface to lower the interfacial energy (note that air is "hydrophobic"). The A block anchor should confer stability to this system. However, consider that if the system is placed in an aqueous environment, a low-surface-energy polymer (the B block) is now in contact with water—a high interfacial energy situation. If the system, after fabrication, still exhibits sufficient chain mobility, it might phase-invert to bring the bulk polyurethane or the A block to the surface. Unless the system is specifically engineered to do such a surface phase reversal, this inversion is undesirable. Proper choice of the bulk polymer and the A block can impede surface phase inversion.

An example of a polymer additive that was developed by 3M specifically to take advantage of this surface chemical inversion phenomenon is a stain inhibitor for fabric. Though not a biomaterial, it illustrates design principles for this type of system. The compound has three "arms." A fluoropolymer arm, the lowest energy component, resides at the fabric surface in air. Fluoropolymers and hydrocarbons (typical stains) do not mix,

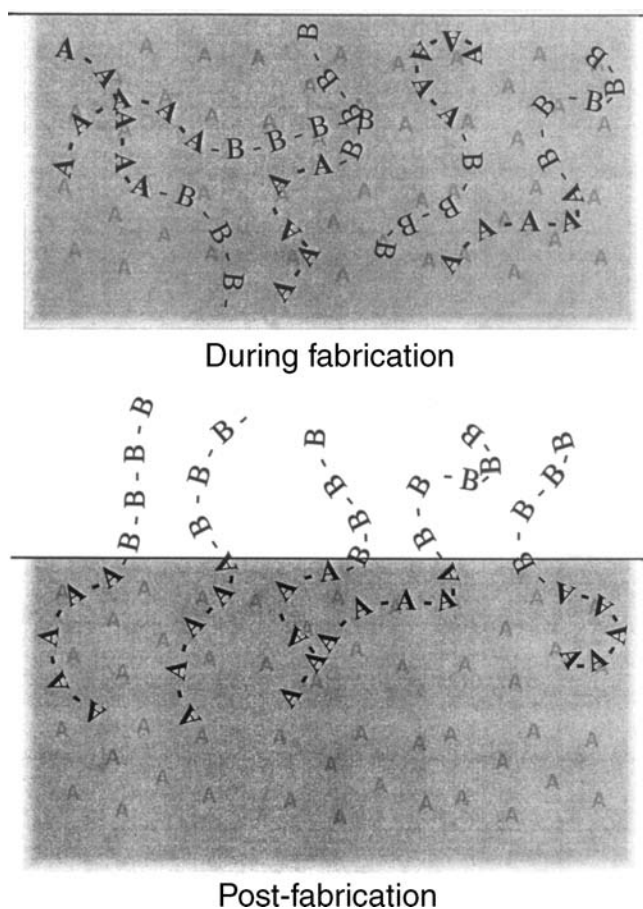

FIG. 9. A block copolymer surface-modifying additive comprising an A block and a B block is blended into a support polymer (the bulk) with a chemistry similar to the A block. During fabrication, the block copolymer is randomly distributed throughout the support polymer. After curing or annealing, the A block anchors the surface-modifying additive into the support, while the low-energy B block migrates to the air-polymer interface.

so hydrocarbons are repelled. A second arm of hydrophilic poly(ethylene oxide) will come to the surface in hot water and assist with the washing out of any material on the surface. Finally, a third arm of hydrocarbon anchors this additive into the fabric.

Many SMAs for inorganic systems are known. For example, very small quantities of nickel will completely alter the structure of a silicon (111) surface (Wilson and Chiang, 1987). Copper will accumulate at the surface of gold alloys (Tanaka *et al.*, 1988). Also, in stainless steels, chromium will concentrate (as the oxide) at the surface, imparting corrosion resistance.

There are a number of additives that spontaneously surface-concentrate, but are not necessarily designed as SMAs. A few examples for polymers include PDMS, some extrusion lubricants (Ratner, 1983), and some UV stabilizers (Tyler *et al.*, 1992). The presence of such additives at the surface of a polymer may be unplanned and they will not necessarily form stable, durable surface layers. However, they can significantly contribute (either positively or negatively) to the bioresponse to the surface.

Conversion Coatings

Conversion coatings modify the surface of a metal into a dense oxide-rich layer that imparts corrosion protection, enhanced adhesivity, altered appearance (e.g., color) and sometimes lubricity to the metal. For example, steel is frequently phosphated (treated with phosphoric acid) or chromated (with chromic acid). Aluminum is electrochemically anodized in chromic, oxalic, or sulfuric acid electrolytes. Electrochemical anodization may also be useful for surface-modifying titanium and Ti-Al alloys (Bardos, 1990; Kasemo and Lausmaa, 1985).

The conversion of metallic surfaces to "oxide-like," electrochemically passive states is a common practice for base-metal alloy systems used as biomaterials. Standard and recommended techniques have been published (e.g., ASTM F4-86) and are relevant for most musculoskeletal load-bearing surgical implant devices. The background literature supporting these types of surface passivation technologies has been summarized (von Recum, 1986).

Base-metal alloy systems, in general, are subject to electrochemical corrosion ($M \rightarrow M^+ + e^-$) within saline environments. The rate of this corrosion process is reduced 10^3 – 10^6 times by the presence of a dense, uniform, minimally conductive, relatively inert oxide surface. For many metallic devices, exposure to a mineral acid (e.g., nitric acid in water) for times up to 30 minutes will provide a passivated surface. Plasma-enhanced surface passivation of metals, laser surface treatments, and mechanical treatments (shot peening) can also impart many of these characteristics to metallic systems.

The reason that many of these surface modifications are called "oxide-like" is that the structure is complex, including OH, H, and subgroups that may, or may not, be crystalline. Since most passive surfaces are thin films (5–500 nm) and are transparent or metallic in color, the surface appears similar before and after passivation. Further details on surfaces of this type can be found in Chapters 1.4, 2.9, and 6.3.

Parylene Coating

Parylene (*para*-xylylene) coatings occupy a unique niche in the surface modification literature because of their wide application and the good quality of the thin film coatings formed (Loeb *et al.*, 1977a; Nichols *et al.*, 1984). The deposition method is also unique and involves the simultaneous evaporation, pyrolysis, deposition, and polymerization of the monomer, di-*para*-xylylene (DPX), according to the following reaction:

The DPX monomer is vaporized at 175°C and 1 torr, pyrolyzed at 700°C and 0.5 torr, and finally deposited on a substrate at 25°C and 0.1 torr. The coating has excellent electrical insulation and moisture barrier properties and has been used for protection of implant electrodes (Loeb *et al.*, 1977b; Nichols *et al.*, 1984) and implanted electronic circuitry (Spivack and Ferrante, 1969). Recently, a parylene coating has been used on stainless steel cardiovascular stents between the metal and a drug-eluting polymer layer (see Chapters 7.3 and 7.14).

Laser Methods

Lasers can rapidly and specifically induce surface changes in organic and inorganic materials (Picraux and Pope, 1984; Dekumbis, 1987; Chrisey *et al.*, 2003). The advantages of using lasers for such modification are the precise control of the frequency of the light, the wide range of frequencies available, the high energy density, the ability to focus and raster the light, the possibilities for using both heat and specific excitation to effect change, and the ability to pulse the source and control reaction time. Lasers commonly used for surface modification include ruby, neodymium: yttrium aluminum garnet (Nd: YAG), argon, and CO₂. Treatments are pulsed (100 nsec to picoseconds pulse times) and continuous wave (CW), with interaction times often less than 1 msec. Laser-induced surface alterations include annealing, etching, deposition, and polymerization. Polymers, metals, ceramics, and even tooth dentin have been effectively surface modified using laser energy. The major considerations in designing a laser surface treatment include the absorption (coupling) between the laser energy and the material, the penetration depth of the laser energy into the material, the interfacial reflection and scattering, and heating induced by the laser.

PATTERNING

Essentially all of the surface modification methods described in this chapter can be applied to biomaterial surfaces as a uniform surface treatment, or as patterns on the surface with length scales of millimeters, microns or even nanometers. There is much interest in deposition of proteins and cells in surface patterns and textures in order to control bioreactions (Chapter 2.16). Furthermore, devices “on a chip” frequently require patterning. Such devices include microfluidic systems (“lab on a chip”), neuronal circuits on a chip, and DNA diagnostic arrays. An overview of surface patterning methods for bioengineering applications has been published (Folch and Toner, 2000).

Photolithographic techniques that were developed for microelectronics have been applied to patterning of biomaterial surfaces when used in conjunction with methods described in this chapter. For example, plasma-deposited films were patterned using a photoresist lift-off method (Goessl *et al.*, 2001).

Microcontact printing is a newer method permitting simple modification. Basically, a rubber stamp is made of the pattern that is desired on the biomaterial surface (Fig. 10). The stamp can be “inked” with thiols (to stamp gold), silanes (to stamp silicon), proteins (to stamp many types of surfaces) or

FIG. 10. Fabrication of a silicone elastomer stamp for microcontact printing. The sequence of steps is a-j.

FIG. 11. (a) Microcontact printed lines of laminin protein (fluorescent labeled) on a cell-resistant background. (b) Cardiomyocyte cells adhering and aligning on the laminin printed lines (see *J. Biomed. Mater. Res.* 60: 472 for details) (used with the permission of P. Stayton, C. Murry, S. Hauschka, J. Angello and T. McDevitt).

polymer solutions (again, to stamp many types of surfaces). Spatial resolution of pattern features in the nanometer range has been demonstrated, though most patterns are applied in the micron range. Methods have been developed to accurately stamp curved surfaces. An example of cells on laminin-stamped lines is shown in Fig. 11. These laminin lines were durable for at least 2 weeks of cell contact. Durability remains a major consideration with patterns on surface generated by this relatively simple method.

There are many other options to pattern biomaterial surfaces. These include ion-beam etching, electron-beam lithography, laser methods, inkjet printers, and stochastic patterns made by phase separation of two components (Takahara *et al.*, 2000).

CONCLUSIONS

Surface modifications are being widely explored to enhance the biocompatibility of biomedical devices and improve other aspects of performance. Since a given medical device may already have appropriate performance characteristics and physical properties and be well understood in the clinic, surface modification provides a means to alter only the biocompatibility of the device without the need for redesign, retooling for manufacture, and retraining of medical personnel.

Acknowledgment

The suggestions and assistance of Professor J. Lemons have enhanced this chapter and are gratefully appreciated.

QUESTIONS

1. You are assigned the task of designing a proteomics array for cancer diagnostics. Six hundred and twenty-five proteins must be attached to the surface of a standard, glass microscope slide in a 25×25 array. Design a scheme to make such a proteomic chip. What are the important surface issues? Which strategies might you apply to address each of the issues? You may find helpful ideas in Chapters 1.4, 2.13, and 2.16.
2. A hydrogel surface must be put on a silicone rubber medical device. A viscous solution of the hydrogel polymer is used to spray-coat the device. When it is placed in aqueous buffer solution the hydrogel layer quickly delaminates from the silicone. How might you permanently attach a hydrogel layer to a silicone device? Briefly describe the method you would use and the general steps needed to produce a reliable coating.
3. List the molecular and design factors that can contribute to increasing the durability of an *n*-alkyl thiol self-assembled monolayer on gold.

2.15 TEXTURED AND POROUS MATERIALS

John A. Jansen and Andreas F. von Recum

INTRODUCTION

Surface irregularities on medical devices, such as grooves/ridges, hills, pores, and pillars, are expected to guide many types of cells (including immunological, epithelial, connective-tissue, neural, and muscle cells) and to aid tissue repair after injury. With the growing interest in tissue engineering, porous scaffold reactions *in vitro* and *in vivo* are assuming increasing importance (see Chapter 8.4). The final response to rough or porous materials is reflected in the organization of the cytoskeleton, the orientation of extracellular matrix (ECM) components, the amount of produced ECM, and angiogenesis. Although significant progress has been made, the exact cellular and molecular events underlying cellular and matrix orientation are not yet completely understood.

This chapter will provide information about how surface roughness is defined, prepared, and measured. In addition, it will cover the biological effects of surface irregularities on cells.

DEFINITION OF SURFACE IRREGULARITIES

Surface irregularities can be considered as deviations from a geometrically ideal (flat) surface. They can be created accidentally by the production process or engineered for specific purposes. Surface irregularities can be classified according to their dimensions and the way they are achieved. In view of this, surface irregularities can be classified into six classes (Sander, 1991). The main distinctive characteristic is their horizontal pattern. Thus, Class 1 irregularities are associated with form errors of the substrate surface such as straightness, flatness, roundness, and cylindricity. Class 2 surface features deal with so-called waviness deviations. Waviness is considered to occur if the wave spacing is larger than the wave depth. Class 3, 4, and 5 irregularities all refer to surface roughness. Roughness is assumed if the space between two hills is about 5 to 100 times larger than the depth. Depending on the manufacturing process used, roughness can be periodic or random. A periodic surface roughness is also referred to as surface texture

and represents a regular surface topography with well-defined dimensions and surface distribution. Further, distinction has to be made among macro, micro, and nano surface roughness. Microroughness deals with surface features sized in cellular and subcellular dimensions. Considering their appearance and morphological structure, class 3 surface roughness has a groove-type appearance; class 4 roughness deals with score marks, flakes, and protuberances, for example created by grit-blasting procedures; and class 5 surface roughness is the result of the crystal structure of a material.

POROSITY

Besides the surface irregularities as mentioned earlier, porosity can also be considered as surface irregularity. Porosity can occur only at the substrate surface or can completely penetrate throughout a bulk material. It consists of individual openings and spacings or interconnecting pores. Porosity can be created intentionally by a specific production process, such as sintering of beads, leaching of salt, sugar, or starch crystals, or knitting and weaving of fibers. On the other hand, porosity can also arise as a manufacturing artifact, for example, in casting procedures.

For many biomedical applications, there is a need for porous implant materials. They can be used for artificial blood vessels, artificial skin, drug delivery, bone and cartilage reconstruction, periodontal repair, and tissue engineering (Lanza *et al.*, 1997). For each application, the porous materials have to fulfil a number of specific requirements. For example, for bone ingrowth the optimum pore size is in the range of 75–250 μm (Pilliar, 1987). On the other hand, for ingrowth of fibrocartilagenous tissue the recommended pore size ranges from 200 to 300 μm (Elema *et al.*, 1990). Besides pore size, other parameters play a role, such as compressibility, pore interconnectivity, pore interconnection throat size, and possibly degradability of the porous material (de Groot *et al.*, 1990).

Although porosity can also be discerned as a different class of surface irregularity, the following sections will consider porosity as microtexture, much like other surface features. This choice is based on the many reports that emphasize the importance of this type of surface morphology for cell and tissue response.

PREPARATION OF SURFACE MICROTTEXTURE

For the production of microtextured implant surfaces, numerous techniques are available ranging from simple manual scratching to more controlled fabrication methods. For example, from semiconductor technology, photolithographic techniques used in conjunction with reactive plasma and ion-etching, LIGA and electroforming, have become available. Deep reactive ion etching (DRIE) enhances the depth of surface etched features and gives parallel sidewalls—it is especially well suited for microelectromechanical systems (MEMS) fabrication. Microcontact printing (μCP) allows patterns to be transferred to biomaterial surfaces by a rubber stamp.

Because these techniques are relatively fast and cheap, and also allow the texturing of surfaces of reasonable size, they appear to be promising for biomedical research and applications. Other methods that offer the ability to texture and pattern surfaces include UV laser machining, electron-beam etching, and ion-beam etching.

Reactive Plasma and Ion Etching

For this method the material, usually silicon, is first cleaned and dried with filtered air (den Braber *et al.*, 1998a; Hoch *et al.*, 1996; Jansen *et al.*, 1996). Then it is coated with a primer and photoresist (PR) material. Photolithography is used to create a micropattern in the photoresist layer. Masks with predetermined dimensions are exposed with either UV light or electron beams depending on the size of the required surface configuration. Subsequently, the exposed resist is developed and rinsed off. Finally, this lithographically defined photoresist pattern is transferred into the underlying material by etching. This etching can be performed under wet or dry conditions. In the first situation, materials are placed in chemicals. Etch direction is along the crystal planes of the material. In the second situation, dry etching is performed using directed ions from a plasma or ion beam as etchants. This technique of physical etching allows a higher resolution than the wet technique. It is also applicable in noncrystalline materials because of the etch directionality without using crystal orientation. Finally, after the etching process, the remaining resist is removed. If a substrate is formed with microgrooves, the dimensions of the texture are usually described in pitch (or spacing), ridge width, and groove width (von Recum *et al.*, 1995).

Plasma and ion etching techniques can be used to create micropatterns in a wide variety of biopolymers. The micropatterns can be prepared directly in the polymer surface or transferred into the polymer surface via solvent-casting or injection-molding methods, whereby a micropatterned silicon wafer is used as a template (Fig. 1).

FIG. 1. Scanning electron micrograph of a micropatterned silicon wafer, which can be used as a template in a solvent-casting replication process.

LIGA

Another technology suitable for creating surface microtextures is the so-called LIGA process (Rogner *et al.*, 1992). LIGA refers to the German “Lithographie, Galvanoformung, Abformung” (lithography, electroplating, molding). The LIGA technique differs completely from that described in the preceding section, since it is not based on etching. In the LIGA process a thick X-ray-resistant layer is exposed to synchrotron radiation using a special X-ray mask membrane. Subsequently, the exposed layer is developed, which results in the desired resist structure. Then, metal is deposited onto the remaining resist structure by galvanization. After removal of the remaining resist either a metal structure or mold for subsequent cost-effective replication processes is achieved.

Microcontact Printing

The microcontact printing (μ CP) method, developed in the laboratory of George Whitesides, provides a simple method to create patterns over large surface areas at the micro and even nanoscale (Kumar *et al.*, 1994). A master silicon template or mold is formed by conventional photolithographic and etching methods generating the micron-scale pattern of interest. Onto that template, a curable silicone elastomer is poured. When the silicone polymer cures, it is peeled off and then serves as a rubber stamp. The stamp can be “inked” in thiols, silanes, proteins or other polymers (see Chapter 2.14). Flat and curved surfaces can be patterned with these μ CP stamps.

PARAMETERS FOR THE ASSESSMENT OF SURFACE MICROTTEXTURE

Since the final biological performance of a microtextured surface is determined by the size and dimensions of the surface features, specific surface parameters have to be provided to describe and define the surface structure.

The definition of surface parameters is mostly based on a two-dimensional profile section. Occasionally, three-dimensional profiles are created (see the next two sections).

In general, for the quantitative description of surface microtexture, three parameters can be used:

1. Amplitude parameters, to obtain information about height variations
2. Spacing parameters, to describe the spacing between features
3. Hybrid parameters, a combination of height and spacing parameters

These parameters are presented as R_a , R_q , R_t , R_z , R_{sk} , R_{ku} (amplitude parameters), Sc_x , Sc_y , St_i (spacing parameters), and Δq and λq (hybrid parameters). The R-parameters are denominations for a two-dimensional description. The S-parameters stand for a three-dimensional evaluation. These S-denominations are generally accepted since the work of

TABLE 1 Definition of Surface Parameters

Parameter	Definition
lm	Evaluation length = the horizontal limitation for the assessment of surface parameters
lv	Pre-travel length = the distance traversed by the tracing system over the sample before the tracing (lt) starts
ln	Over-travel length = the distance traversed or area scanned by the tracing system over the sample after the tracing (lt)
lt	Tracing length = the distance traversed by the tracing system when taking a measurement. It comprises the pre- and overtravel, and the evaluation length
le	Sampling length = a standardized number of evaluation lengths/areas as required to obtain a proper surface characterization
Ra/Sa	Arithmetical mean roughness = the arithmetical average value of all vertical departures of the profile or surface from the mean line throughout the sampling length/area
Rq/Sq	Root-mean square roughness = the root-mean square value of the profile or surface departures within the sampling length/area
Rt/St	Maximum roughness depth = the distance between the highest and lowest points of the profile or surface within the evaluation length/area
Rz/Sz	Mean peak-to-valley height = the average of the single peak-to valley heights of five adjoining sampling lengths/areas
Rsk/Ssk	Skewness = measure of the symmetry of the amplitude density function (ADF)
ADF	Amplitude density function = the graphical representation of the material distribution within the evaluation length/area
Rku/Sku	Kurtosis = fourth central moment of the profile or surface amplitude density with the evaluation length/area. Kurtosis is the measure of the sharpness of the profile or surface
Rcx/Rcy Scx/Scy	= mean spacing between surface peaks of the surface/area profile along the X or Y direction
Sti	= surface texture index, i.e. $\min. (Rq/Sq \text{ divided by max. } Rq/Sq + \min. Rsk/Ssk \text{ divided by max } Rsk/Ssk + \min. (q \text{ divided by max.})q + \min (Rc/Sc \text{ divided max. } Rc/Sc) \text{ divided by } 4$
Δq	= the root mean square slope of the rough profile throughout the evaluation length/area
λq	= the root mean square of the spacings between local peaks and valleys, taking into account their relative amplitudes and individual spatial frequencies

Stout *et al.* (1993). For a detailed description of available surface parameters, reference can be made to Sander (1991) and Wennerberg *et al.* (1992). A brief summary is given in Table 1.

Further, it has to be emphasized that for a correct assessment of surface parameters various requirements have to be met. A first condition is the provision of a reference line to which measurements can be related. Also, surface parameters have to be determined with a clear separation between roughness and waviness components. This separation has to be achieved by an electronic filtering procedure. In view of this, perhaps the most important measurement requirements are the parameters measuring length over the substrate surface and cutoff wavelength of the filter used. Measuring or tracing length has to be described in terms of real evaluation length (lm) and pre- and overtravel (lv resp. ln). The function of the electronic filter is to eliminate waviness and roughness frequencies out of the surface profile. As surface features differ in both their wavelength and surface profile depths, various filters are available. The filter type to be selected for a specific surface profile is defined in DIN standards. Use of the wrong filter will result in incorrect measurements (Sander, 1991).

CHARACTERIZATION OF SURFACE TOPOGRAPHY

Various methods are available to describe surface features. Scanning electron microscopy can be used to obtain a qualitative image of the surface geometry. Contact and noncontact profilometry are methods to quantify the surface roughness.

Contact Profilometry

The principle of contact profilometry is that a finely pointed stylus moves over the detected area. The vertical movements of the stylus are switched into numerical information. This method results in a two-dimensional description of the surface. The advantage of contact profilometry is that the method is inexpensive, direct, and reproducible. Contact profilometry can be applied on a wide variety of materials. The major disadvantage is that the diameter of the pointed stylus limits its use to surface features larger than the stylus point diameter. Another problem is that, because of the physical contact between the stylus and substrate surface, distortion of the surface profile can occur.

FIG. 2. Results of a confocal laser scanning microscope (CLSM) surface analysis of a microgrooved substratum. CLSM has to be considered as a noncontact technique. A three- and two-dimensional surface representation is obtained, composed from 256 optical Z sections. To the right of the 3D surface profile, the size of the scanned area ($30 \mu\text{m}^2$) and the difference in X versus Z enlargement can be found (Scale 1 : 1.64).

Noncontact Profilometry

In this method, the pointed stylus is replaced by a light or laser spot. This spot never touches the substrate surface. The light or laser beam is focused on the surface and the light is reflected and finally converted to an electrical signal. In this way both two- and three-dimensional surface profiles can be created (Fig. 2). Occasionally, techniques are used in which the reflected light is not directly translated to an electrical signal. In these so-called interferometers a surface profile is created by combining light reflecting off the surface with light reflecting off a reference substrate. When those two light bundles combine, the light waves interfere to produce a pattern of fringes, which are used to determine surface height differences.

The resolution of noncontact methods can be in the nanometer range. The limiting factor is the spot size. Several scans have to be taken to obtain a representative surface area. Occasionally, this is impossible or too laborious. In light beam interferometry, an additional disadvantage is that the substrate surface has to provide at least some reflectivity.

Atomic Force Microscopy

Atomic force microscopy (AFM) is a direct method for determining high-resolution surface patterns (Binnig *et al.*, 1986; van der Werf *et al.*, 1993) (also see Chapters 1.4 and 5.6). In AFM the substrate surface is brought close to a tip on a

FIG. 3. Three-dimensional representation of an AFM measurement of a silicon wafer provided with $10\text{-}\mu\text{m}$ -wide and $0.5\text{-}\mu\text{m}$ -deep microgrooves. The raised wall of the edge shows a small inclination. This is a distortion due to the size and movement of the tip over the silicon surface.

small cantilever which is attached to a piezo tube. The deflection of the cantilever, generated by interaction forces between tip and substrate surface, is detected and used as an input signal for a measuring system. AFM is frequently used as a contact method. However, noncontact and transient contact modes of analysis are also available. The advantage of AFM above other contact techniques is that AFM is generally not as destructive. Considering resolution, a limiting factor in AFM is again the size of the used tip (Fig. 3). Still, a significantly smaller tip diameter is used compared with conventional contact methods such as profilometry.

BIOLOGICAL EFFECTS OF SURFACE MICROTTEXTURE

The role of standardized surface texture in inducing a specific cellular response is a field of active research. For example, various reports have suggested that a regular surface microtexture can benefit the clinical success of skin penetrating devices by preventing epithelial downgrowth (Brunette *et al.*, 1983; Chehroudi *et al.*, 1988) and reduce the inflammatory response (Campbell *et al.*, 1989) and fibrous encapsulation (Chehroudi *et al.*, 1991) of subcutaneous implants. Closely related to these studies, certain porosities have led to an increase of the vascularity of the healing response and a reduction of collagenous capsule density (Brauker *et al.*, 1995; Sharkawy *et al.*, 1998). The literature on the effect of surface texture on the healing of silicone breast implants is extensive (for example, see Pollock, 1992). Therefore, much current research has been focused on the effect of standardized surface roughness on the soft tissue reaction. Excellent reviews on the effect of surface microtexturing on cellular growth, migration, and attachment have been written by Singhvi *et al.* (1994), von Recum and van Kooten (1995), Brunette (1996), Curtis and Wilkinson (1997), and Folch and Toner (2000).

Hypotheses on Contact Guidance

Contact guidance is the phenomenon that cells adapt and orient to the substrate surface microtopography (Harrison, 1912). Early studies on contact guidance describe the alignment of cells and focal adhesions to microgrooves with dimensions 1.65–8.96 μm in width and 0.69 μm in depth. This cellular behavior was suggested to be due to the mechanical properties of the cytoskeleton (Dunn, 1982; Dunn and Brown, 1986). The relative inflexibility of cytoskeletal components was considered to prevent bending of cell protrusions over surface configurations with too large an angle.

Later studies and hypotheses focused on the relationships among cell contact site, deposited extracellular matrix, surface microtexture, and cell response. For example, a microtextured surface was supposed to possess local differences in surface free energy resulting in a specific deposition pattern of the substratum bound attachment proteins (Brunette, 1996; Maroudas, 1972; von Recum and van Kooten, 1995). The spatial arrangement of the adsorbed proteins and their conformational state were hypothesized to be affected. In addition to wettability properties, the specific geometric dimensions of the cell adhesion sites were suggested to induce a cell orientational effect (Dunn, 1982; Dunn and Brown, 1986; Ohara *et al.*, 1979). A recent hypothesis suggests that contact guidance on microtextured surfaces is a part of the cellular efforts to achieve a biomechanical equilibrium condition with a resulting minimal net sum of forces. The significance of this theory has been described extensively by Ingber (1993, 1994) in his tensegrity models. According to this model, the anisotropic geometry of substratum surface features establishes stress- and shear-free planes that influence the direction of cytoskeletal elements in order to create a force economic situation (Oakley and Brunette, 1993, 1995; O'Neill *et al.*, 1990).

The *in Vitro* Effect of Surface Microtexturing

A considerable number of *in vitro* studies have been performed to determine which of the hypotheses mentioned in the preceding section can be experimentally supported. Up to this point, we have to emphasize that comparison of the obtained data is difficult because most of the studies had differences in the surface textures of the materials explored. In addition, different bulk materials were also applied. Modern surface feature fabrication methods have allowed more precise surfaces to be fabricated so studies from different groups might be compared.

In the experiments performed by Curtis *et al.* (Clark *et al.*, 1987, 1990, 1991; Curtis and Wilkinson, 1997) with fibroblasts and macrophages cultured on microgrooved glass substrates, groove depth was observed to be more important than groove width in the establishment of contact guidance. Therefore, these experiments believe that cytoskeletal flexibility and the possibility of making cellular protrusions are the determining cellular characteristics for contact guidance. As a consequence of these studies, other researchers further explored the involvement of cytoskeletal elements in cell orientation processes. Also, the possibility of a relationship between cytoskeletal organization and cell–substrate contact sites was investigated (den Braber *et al.*, 1995, 1996, 1998b; Meyle *et al.*,

1991, 1993; Oakley *et al.*, and Brunette, 1993, 1995; Oakley 1997; Walboomers *et al.*, 1998a, 1999). Although these studies varied in cell type used, substrate surface feature dimensions and substrate bulk chemical composition, the results clearly confirmed that very fine microgrooves ($\leq 2 \mu\text{m}$) have an orientational effect on both cell body and cytoskeletal elements. Transmission electron microscopy observations showed that cells were only able to penetrate into very shallow ($\leq 1 \mu\text{m}$) or wide ($\geq 5 \mu\text{m}$) microgrooves. Cells were also observed to possess cell adhesion structures that were wrapped around the edge of a ridge or attached to the wall of the ridge. On the basis of these findings, these investigators suggested that the mechanical properties of cellular structures can never be the only determining factor in contact guidance.

Further, a mechanical model to explain contact guidance suggests that the “surface feature stimulus” is transduced to the cytoskeleton via cell contact sites and cell surface receptors. In this model, the cytoskeleton is considered as a static structure. This is incorrect. The cytoskeleton is a highly dynamic system (Lackie, 1986), which is constantly broken down and elongated in living cells. Consequently, if the mechanical theory is still true, the fundamentals should be derived from other processes than just the remodeling of the cytoskeleton (Walboomers *et al.*, 1998a). Studies on cell nuclear connections to the cytoskeleton may offer insights into the relationships between surface features and cell behavior (Maniotis *et al.*, 1997).

Apart from changes in cell size, shape, and orientation, surface microtopography has been reported to influence other cell processes. For example, several studies described changes in cellular differentiation, DNA/RNA transcription, cellular metabolism, and cellular protein production of cells cultured on microtextured surfaces (Chou *et al.*, 1995; Hong and Brunette 1987; Matsuzaka *et al.*, 1999; von Recum and van Kooten, 1995; Singhvi *et al.*, 1997; Wójciak-Stothard *et al.*, 1995). A study using μCP surfaces with square cell adhesive and nonadhesive domains has shown that where surface adhesive domains are small ($< 75 \mu\text{m}$), apoptosis levels in endothelial cells is high (particularly so for $5 \mu\text{m} \times 5 \mu\text{m}$ domains) and when cells are placed on larger domains, cell spreading and growth occurs (Chen *et al.*, 1997). Whether these additional effects have to be considered as independent phenomena is still a topic of discussion. According to Hong and Brunette (1987), the good news was that surface microtopography can enhance the production of specific, perhaps favorable proteins. On the other hand, the production or secretion of less favorable metabolic products can also be enhanced. If this occurs, this might have a deleterious effect on the overall cell response. For example, a rise in the production or release of proteinases may not be beneficial for connective tissue cell response. This example shows that, at least at the molecular level, the regulation of cell function by substrate surface microtexture may be a complex affair.

The *in Vivo* Effect of Surface Microtexturing

Based upon interesting results from *in vitro* experiments, *in vivo* studies with microtextured implants have been performed. Unfortunately, the results from the various studies

are not consistent. For example, in some animal experiments it was demonstrated that silicone-coated filters and bulk silicone rubber implants provided with surface features of 1–3 μm showed a minimal inflammatory response with direct fibroblast attachment and a very reduced connective capsule (Campbell and von Recum, 1989; Schmidt and von Recum, 1991, 1992). In contrast, other animal studies suggested that implant surface microgrooves were unable to influence the wound healing process at all (den Braber *et al.*, 1997; Walboomers *et al.*, 1998b). These differing results may hint at multiple surface-texture-related factors that are not yet identified and controlled.

Besides the effect on wound healing, microtextured implants have also been used to inhibit epidermal downgrowth along skin penetrating devices (Chehroudi *et al.*, 1989, 1990, 1992). This downgrowth is considered as a major failure mode for this type of implant. Indeed, the experiments suggested that epidermal downgrowth can be prevented or delayed by percutaneous devices provided with surface microgrooves.

DIRECTIONS FOR FURTHER DEVELOPMENTS

Considering the *in vitro* experiments, none of the earlier mentioned hypotheses to explain contact guidance has been fully supported. Therefore, based on various findings we suggest a new theory that is a refinement of the “mechanical” theory discussed earlier. The breakdown and formation of fibrous cellular components, especially in the filopodium, is influenced by the microgrooves. These microgrooves create a pattern of mechanical stress, which affects cell spreading and causes the alignment of cells. On the other hand, we must also notice that the ECM possesses mechanical properties. The ECM is not a rigid structure, but a dynamic mass of molecules. Many *in vitro* studies have already indicated that cell-generated forces of tension and traction can reorganize the ECM into structures that direct the behavior of single cells (Erickson, 1994; Choquet *et al.*, 1997; Janmey and Chaponnier, 1995; Janmey, 1998). As cells cannot penetrate very shallow or small grooves, we suppose that on those surfaces the forces as exerted by the cells will result in an enhanced reorganization of the deposited ECM proteins. Consequently, contact guidance and other cell behaviors are induced. No doubt, cell surface receptors and inside–outside cell signaling phenomena play an important role in this process. As far as *in vivo* applications of surface microtexturing, more research has to be done to learn and understand the full impact of surface microtexturing for medical devices. A first step is the development of techniques that enable the production of standardized microstructures on nonplanar surfaces. Evidently, this development will benefit not only biomaterial research, but also the production of microelectronic, mechanical, and optical devices and subsystems. As a second step, the relationship between the surface topographical design of an implant and histocompatibility has to be further documented. These studies must focus not only on the soft tissue response; they must also involve bone tissue behavior.

2.16 SURFACE-IMMOBILIZED BIOMOLECULES

Allan S. Hoffman and Jeffrey A. Hubbell

Biomolecules such as enzymes, antibodies, affinity proteins, cell receptor ligands, and drugs of all kinds have been chemically or physically immobilized on and within biomaterial supports for a wide range of therapeutic, diagnostic, separation, and bioprocess applications. Immobilization of heparin on polymer surfaces is one of the earliest examples of a biologically functional biomaterial. Living cells may also be combined with biomaterials, and the fields of cell culture, artificial organs, and tissue engineering are additional, important examples. These “hybrid” combinations of natural and synthetic materials confer “biological functionality” to the synthetic biomaterial. Since many sections and chapters in this text cover many aspects of this topic, including adsorption of proteins and adhesion of cells and bacteria on biomaterial surfaces, nonfouling surfaces, cell culture, tissue engineering, artificial organs, drug delivery, and others, this chapter will focus on the methodology involving physical adsorption and chemical immobilization of biomolecules on biomaterial surfaces, especially for applications requiring bioactivity of the immobilized biomolecule.

Among the different classes of biomaterials that could be biologically modified, polymers are especially interesting because their surfaces may contain reactive groups *de novo*, or they may be readily derivatized with reactive groups that can be used to covalently link biomolecules. Another advantage of polymers as supports for biomolecules is that the polymers may be fabricated in many forms, including films, membranes, tubes, fibers, fabrics, particles, capsules, and porous structures. Furthermore, polymer compositions vary widely, and molecular structures include homopolymers, and random, alternating, block, and graft copolymers. Living anionic polymerization

techniques, along with newer methods of living free radical polymerizations, now provide fine control of molecular weights with narrow distributions. The molecular forms of solid polymers include un-cross-linked chains that are insoluble at physiologic conditions, cross-linked networks, physical blends, and interpenetrating networks (IPNs) (e.g., Piskin and Hoffman, 1986; see also Chapter 2.2). When surfaces of metals or inorganic glasses or ceramics are involved, biological functionality can sometimes be added via a chemically immobilized or physisorbed polymeric or surfactant adlayer, or by use of techniques such as plasma gas discharge to deposit polymer compositions having functional groups (see also Chapter 2.14).

Patterned Surfaces

Biomaterial surfaces may be functionalized uniformly or in geometric patterns (Bernard *et al.*, 1998; Blawas and Reichert, 1998; James *et al.*, 1998; Kane *et al.*, 1999; Ito, 1999; Folch and Toner, 2000). Sometimes the patterned surfaces will have regions that repel proteins (“nonfouling” compositions) while others may contain covalently-linked cell receptor ligands (Neff *et al.*, 1999; Alsberg *et al.*, 2002; Csucs *et al.*, 2003; VandeVondele *et al.*, 2003), or may have physically adsorbed cell adhesion proteins (McDevitt *et al.*, 2002; Ostuni *et al.*, 2003). There has also evolved a huge industry based on “biochips” that contain microarrays of immobilized, single-stranded DNA (for genomic assays) or peptides or proteins (for proteomic assays) (Housman and Mrksich, 2002; Lee and Mrksich, 2002). The majority of these microarrays utilize inorganic silica chips rather than polymer substrates directly, but it is possible to incorporate functionality through chemical modification with silane chemistries (Puleo, 1997) or adsorption of a polymeric adlayer (Scotchford *et al.*, 2003; Winkelmann *et al.*, 2003). A variety of methods have been used for the production of these patterned biochips, including photocontrolled synthesis (Ellman and Gallop, 1998; Folch and Toner, 2000), microfluidic fluid exposure (Ismagilov *et al.*, 2001), and protection with adhesive organic protecting layers that are lifted off after exposure to the biomolecular treatment (Jackman *et al.*, 1999).

Immobilized Biomolecules and Their Uses

Many different biologically functional molecules can be chemically or physically immobilized on polymeric supports (Table 1) (Laskin, 1985; Tomlinson and Davis, 1986). When some of these solids are water-swollen they become hydrogels, and biomolecules may be immobilized on the outer gel surface as well as within the swollen polymer gel network. Examples of applications of these immobilized biological species are listed in Table 2. It can be seen that there are many diverse uses of such bifunctional systems in both the medical and biotechnology fields. For example, a number of immobilized enzyme supports and reactor systems (Table 3) have been developed for therapeutic uses in the clinic (Table 4) (De Myttenaere *et al.*, 1967; Kolff, 1979; Sparks *et al.*, 1969; Chang, 1972; Nose *et al.*, 1983, 1984; Schmer *et al.*, 1981; Callegaro and Denti, 1983; Lavin *et al.*, 1985; Sung *et al.*, 1986).

TABLE 1 Examples of Biologically Active Molecules that May Be Immobilized on or within Polymeric Biomaterials

Proteins/peptides	Drugs
Enzymes	Antithrombogenic agents
Antibodies	Anticancer agents
Antigens	Antibiotics
Cell adhesion molecules	Contraceptives
“Blocking” proteins	Drug antagonists
Saccharides	Peptide, protein drugs
Sugars	Ligands
Oligosaccharides	Hormone receptors
Polysaccharides	Cell surface receptors (peptides, saccharides)
Lipids	Avidin, biotin
Fatty acids	Nucleic acids, nucleotides
Phospholipids	Single or double-stranded
Glycolipids	DNA, RNA (e.g., antisense oligonucleotides)
Other	
Conjugates or mixtures of the above	

TABLE 2 Application of Immobilized Biomolecules and Cells

Enzymes	Bioreactors (industrial, biomedical) Bioseparations Biosensors Diagnostic assays Biocompatible surfaces
Antibodies, peptides, and other affinity molecules	Biosensors Diagnostic assays Affinity separations Targeted drug delivery Cell culture
Drugs	Thrombo-resistant surfaces Drug delivery systems
Lipids	Thrombo-resistant surfaces Albuminated surfaces
Nucleic acid derivatives and nucleotides	DNA probes Gene therapy
Cells	Bioreactors (industrial) Bioartificial organs Biosensors

TABLE 3 Bioreactors Supports and Designs

“Artificial cell” suspensions (microcapsules, RBC ghosts, liposomes, reverse micelles [w/o] microspheres)
Biologic supports (membranes and tubes of collagen, fibrin ± glycosaminoglycans)
Synthetic supports (porous or asymmetric hollow fibres, particulates, parallel plate devices)

TABLE 4 Examples of Immobilized Enzymes in Therapeutic Bioreactors

Medical application	Substrate	Substrate action
Cancer treatment		
L-Asparaginase	Asparagine	Cancer cell nutrient
L-Glutaminase	Glutamine	Cancer cell nutrient
L-Arginase	Arginine	Cancer cell nutrient
L-Phenylalanine lyase	Phenylalanine	Toxin
Indole-3-alkane α hydroxylase	Tryptophan	Cancer cell nutrient
Cytosine deaminase	5-Fluorocytosine	Toxin
Liver failure (detoxification)		
Bilirubin oxidase	Bilirubin	Toxin
UDP-Glucuronyl transferase	Phenolics	Toxin
Other		
Heparinase	Heparin	Anticoagulant
Urease	Urea	Toxin

Immobilized Cell Ligands

Cell interactions with foreign materials are usually mediated by a biological intermediate, such as adsorbed proteins, as described in Chapter 3.2. An approach using biologically functional materials can be much more direct, by adsorbing or covalently grafting ligands for cell-surface adhesion receptors to the material surface. This has been accomplished with peptides grafted randomly over a substrate (Massia and Hubbell, 1991) as well as with peptides presented in a pre-clustered manner (Irvine *et al.*, 2001). The latter has important advantages: Cells normally cluster their adhesion receptors into assemblies referred to as focal contacts, and preassembly confers benefits in terms of both adhesion strength (Ward and Hammer, 1993) and cell signaling (Maheshwari *et al.*, 2000). In addition to peptides, saccharides have also been grafted to polymer surfaces to confer biological functionality (Griffith and Lopina, 1998; Chang and Hammer, 2000).

Specific biomolecules can be immobilized in order to control cellular interactions; one important example is the polypeptide growth factor. Such molecules can be immobilized and retain their ability to provide biological cues that signal specific cellular behavior, such as support of liver-specific function in hepatocytes (Kuhl and Griffith-Cima, 1996), induction of neurite extension in neurons (Sakiyama-Elbert *et al.*, 2001), induction of angiogenesis (Zisch *et al.*, 2001), or the differentiation of mesenchymal stem cells into bone-forming osteoblasts (Lutolf *et al.*, 2003b). Other molecules may be immobilized that can partake in enzymatic reactions at the surface. McClung *et al.* (2001, 2003) have immobilized lysines, whose ϵ -amino groups may interact with pre-adsorbed tissue plasminogen activator (tPA) during coagulation, to enhance fibrin clot dissolution at that surface.

TABLE 5 Some Advantages and Disadvantages of Immobilized Enzymes

Advantages
Enhanced stability
Can modify enzyme microenvironment
Can separate and reuse enzyme
Enzyme-free product
Lower cost, higher purity product
No immunogenic response (therapeutics)
Disadvantages
Difficult to sterilize
Fouling by other biomolecules
Mass transfer resistances (substrate in and product out)
Adverse biological responses of enzyme support surfaces (<i>in vivo</i> or <i>ex vivo</i>)
Greater potential for product inhibition

Some of the advantages and disadvantages of immobilized biomolecules are listed in Table 5, using enzymes as an example.

IMMOBILIZATION METHODS

There are three major methods for immobilizing biomolecules (Table 6) (Stark, 1971; Zaborsky, 1973; Dunlap, 1974). It can be seen that two of them are physically based, while the third is based on covalent or “chemical” attachment to the support molecules. Thus, it is important to note that the term “immobilization” can refer either to a transient or to a long-term localization of the biomolecule on or within a support. In the case of a drug delivery system, the immobilized drug is supposed to be released from the support, while an immobilized enzyme or adhesion-promoting peptide in an artificial organ is designed to remain attached to or entrapped within the support over the duration of use. Either physical or chemical immobilization can lead to “permanent” or long-term retention on or within a solid support, the former being due to the large size of the biomolecule. If the polymer support is biodegradable, then

TABLE 6 Biomolecule Immobilization Methods

Physical adsorption
van der Waals

Solid surfaces
Hydrogels

the chemically immobilized biomolecule may be released as the matrix erodes or degrades away. The immobilized biomolecule may also be susceptible to enzymatic degradation *in vivo*, and this remains an interesting aspect that has received relatively little attention.

A large and diverse group of methods have been developed for covalent binding of biomolecules to soluble or solid polymeric supports (Weetall, 1975; Carr and Bowers, 1980; Dean *et al.*, 1985; Shoemaker *et al.*, 1987; Yang *et al.*, 1990; Park and Hoffman, 1990; Gombotz and Hoffman, 1986; Schense *et al.*, 1999; Lutolf *et al.*, 2003a). Many of these methods are schematically illustrated in Fig 1. The same biomolecule may be immobilized by many different methods; specific examples of the most common chemical reactions utilized are shown in Fig. 2.

For covalent binding to an inert solid polymer surface, the surface must first be chemically modified to provide reactive groups (e.g., $-\text{OH}$, $-\text{NH}_2$, $-\text{COOH}$, $-\text{SH}$, or $-\text{CH}=\text{CH}_2$) for the subsequent immobilization step. If the polymer support does not contain such groups, then it is necessary to modify it in order to permit covalent immobilization of biomolecules to the surface. A wide number of solid surface modification techniques have been used, including ionizing radiation graft copolymerization, plasma gas discharge, photochemical grafting, chemical modification (e.g., ozone grafting), and chemical derivatization (Hoffman *et al.*, 1972, 1986; Hoffman, 1987, 1988; Gombotz and Hoffman, 1986, 1987). (See also Chapter 2.14.)

A chemically immobilized biomolecule may also be attached via a spacer group, sometimes called an “arm” or a “tether” (Cuatrecasas and Anfinsen, 1971; Hoffman *et al.*, 1972; Hoffman, 1987). One of the most popular tethers is PEG that has been derivatized with different reactive end groups (Kim and Feijen, 1985), and some companies offer a variety of chemistries of heterobifunctional linkers having activated coupling end groups such as *N*-hydroxysuccinimide (NHS), maleimide, pyridyl disulfide, and vinyl sulfone. Such spacer groups can provide greater steric freedom and thus greater specific activity for the immobilized biomolecule, especially in the case of smaller biomolecules. The spacer arm may also be either hydrolytically or enzymatically degradable, and therefore will release the immobilized biomolecule as it degrades (Kopecek, 1977; Hern and Hubbell, 1998).

Inert surfaces, whether polymeric, metal, or ceramic, can also be functionalized through modification of an polymeric adlayer. Such physisorbed or chemisorbed polymers can be bound to the surface via electrostatic interactions (VandeVondele *et al.*, 2003), hydrophobic interactions (Neff *et al.*, 1999), or specific chemical interactions, such as that between gold and sulfur atoms (Harder *et al.*, 1998; Bearinger *et al.*, 2003). Metal or ceramic surfaces may also be derivatized with functional groups using silane chemistry, such as with functionalized triethoxysilanes (Massia and Hubbell, 1991; Puleo, 1997). Plasma gas discharge has been used to deposit polymeric amino groups for conjugation of hyaluronic acid to a metal surface (Verheye *et al.*, 2000).

As noted earlier, hydrophobic interactions have been used to functionalize surfaces, utilizing ligands attached to hydrophobic sequences (e.g., Ista *et al.*, 1999; Nath and Chilkoti, 2003).

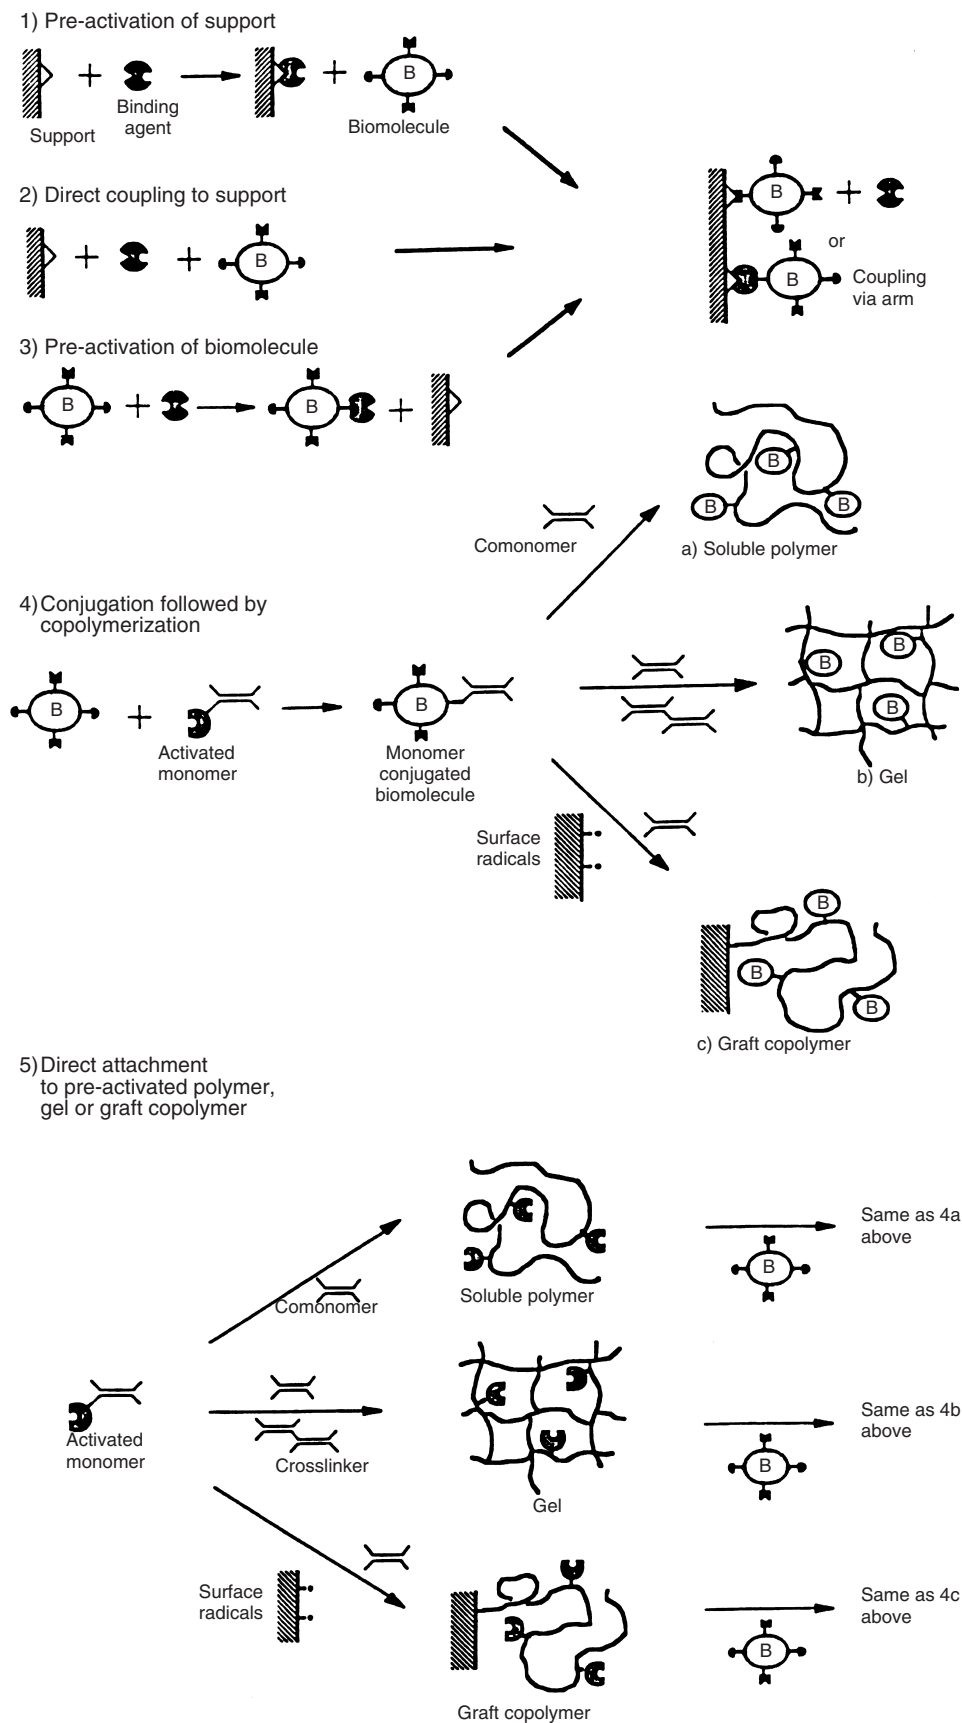

FIG. 1. Schematic cartoons showing various methods for covalent biomolecule immobilization.

Support function	Coupling agent	Active intermediate	Activation conditions	Coupling conditions	Major reacting groups on proteins
	CNBr		pH 11–12.5 2M carbonate	pH 9–10. 24 hr at 4°C	—NH ₂
	 R = Cl, NH ₂ , OCH ₂ COOH, or NHCH ₂ COOH		Benzene 2 hr at 50°C	pH 8. 12 hr at 4°C 0.1M phosphate	—NH ₂
			10% thiophosgene CHCl ₃ , reflux reaction	pH 9–10. 0.05M HCO ₃ ⁻ 2 hr at 25°C	
			Same as isothiocyanate	Same as isothiocyanate	
			2.5% Glutaraldehyde in pH 7.0, 0.1M PO ₄	pH 5–7, 0.05 M phosphate, 3 hr at R.T.	
			1% Succinic anhydride, pH 6	See carboxyl derivatives	
	HNO ₂		2N HCl: 0.2g NaNO ₂ at 4°C for 30 min (reaction conditions for aryl amine function)	pH 8, 0.05M bicarbonate. 1–2 hr at 0°C	
				pH 8, 0.05M bicarbonate. 1–2 hr at 0°C	
			50mg 1-cyclohexyl-3- (2-morpholinoethyl)- carbodiimide metho- p-toluene sulfate/10ml, pH 4–5 2–3 hr at R.T.	pH 4, 2–3 hr at R.T.	
		(Intermediate formed from carboxyl group are either protein or matrix)			
	SOCl ₂		10% Thionyl chloride/CHCl ₃ , reflux for 4 hr	pH 8–9, 1 hr at R.T.	—NH ₂
			0.2% N-hydroxysuccinimide, 0.4% N,N-dicyclohexyl- carbodiimide/dioxane	pH 5–9, 0.1M phosphate, 2–4 hr at 0°C	—NH ₂

FIG. 2. Examples of various chemical methods used to bond biomolecules directly to reactive supports (Carr and Bowers, 1980).

TABLE 7 Biomolecule Immobilization Methods

Method:	Physical and electrostatic adsorption	Cross-linking (after physical adsorption)	Entrapment	Covalent binding
Ease:	High	Moderate	Moderate to low	Low
Loading level possible:	Low (unless high S/V)	Low (unless high S/V)	High	(depends on S/V and site density)
Leakage (loss):	Relatively high (sens. to Δ pH salts)	Relatively low	Low to none ^a	Low to none
Cost:	Low	Low to moderate	Moderate	High

^aExcept for drug delivery systems.

Surfaces with hydrophobic gradients have also been prepared for this purpose (Detrait *et al.*, 1999). An interesting surface active product was developed several years ago that was designed to convert a hydrophobic surface to a cell adhesion surface by hydrophobic adsorption; it had an RGD cell adhesion peptide coupled at one end to a hydrophobic peptide sequence.

Sometimes more than one biomolecule may be immobilized to the same support. For example, a soluble polymer designed to “target” a drug molecule may have separately conjugated to it a targeting moiety such as an antibody, along with the drug molecule, which may be attached to the polymer backbone via a biodegradable spacer group (Ringsdorf, 1975; Kopecek, 1977; Goldberg, 1983). In another example, the wells in an immunodiagnostic microtiter plate usually will be coated first with an antibody and then with albumin or casein, each physically adsorbed to it, the latter acting to reduce nonspecific adsorption during the assay. In the case of affinity chromatography supports, the affinity ligand may be covalently coupled to the solid packing, and in some cases a “blocking” protein such as albumin or casein is then added to block nonspecific adsorption to the support.

It is evident that there are many different ways in which the same biomolecule can be immobilized to a polymeric support. Heparin and albumin are two common biomolecules that have been immobilized by a number of widely differing methods. These are illustrated schematically in Figs. 3 and 4.

Some of the major features of the different immobilization techniques are compared and contrasted in Table 7. The important molecular criteria for successful immobilization of a biomolecule are that a large fraction of the available biomolecules should be immobilized, and a large fraction of those immobilized biomolecules should retain an acceptable level of bioactivity over an economically and/or clinically appropriate time period.

CONCLUSIONS

It can be seen that there is a wide and diverse range of materials and methods available for immobilization of biomolecules and cells on or within biomaterial supports. Combined with the great variety of possible biomedical and biotechnological

applications, this represents a very exciting and fertile field for applied research in biomaterials.

BUDDY D. RATNER, FREDERICK J. SCHOEN, AND ANDREW YEE

3.1 BACKGROUND CONCEPTS

Buddy D. Ratner

Much of the richness of biomaterials science lies in its interdisciplinary nature. The two pillars of fundamental knowledge that support the structure that is biomaterials science are *materials science*, introduced in Part I, and the *biological-medical sciences*, introduced here. Complete introductory texts and a large body of specialized knowledge dealing with each of the chapters in this section, are available. However, these four chapters present sufficient background material so that a reader might reasonably follow the arguments presented later in this volume on biological interactions, biocompatibility, material performance and clinical performance.

In as short a time as can be measured after implantation in a living system (< 1 second), proteins are already observed on biomaterial surfaces. In seconds to minutes, a monolayer of protein adsorbs to most surfaces. The protein adsorption event occurs well before cells arrive at the surface. Therefore, cells see primarily a protein layer, rather than the actual surface of the biomaterial. Since cells respond specifically to proteins, this interfacial protein film may be the event that controls subsequent bioreaction to implants. Protein adsorption is also of concern for biosensors, immunoassays, array diagnostics, marine fouling and a host of other phenomena. Protein adsorption concepts are introduced in Chapter 3.2.

After proteins adsorb, cells arrive at an implant surface propelled by diffusive, convective or active (locomotion) mechanisms. The cells can adhere, release active compounds, recruit other cells, grow in size, replicate and die. These processes often occur in response to the proteins on the surface. Cell processes lead to responses (some desirable and some undesirable) that physicians and patients observe with implants. Cell processes at artificial surfaces are also integral to the unwanted buildup of marine organisms on ships, bacterial biofilms on implants and the useful growth of cells in bioreactors used to manufacture biochemicals. Cells at surfaces are discussed in Chapter 3.3.

After cells arrive and interact at implant surfaces, they may differentiate, multiply, communicate with other cell types and organize themselves into tissues comprised of one or more

cell types. Cells secrete extracellular matrix (ECM) molecules that fill the spaces between cells and serve as attachment structures for proteins and cells. The processes of angiogenesis (small blood vessel formation) and vasculogenesis (formation of larger blood vessels) are critical to provide this new tissue with nutrition and remove wastes. Finally, these tissues have distinctive reactions to irritation and injury. The development, organization and response to injury of tissues must be understood to appreciate the interplay between synthetic materials and tissues. Tissue structure and organization is reviewed in Chapter 3.4.

Finally, cells and tissues respond to mechanical forces. Two samples made of the same material, one a triangle shape and the other a disk, implanted in soft tissue, will show different healing reactions with considerably more fibrous reaction at the asperities of the triangle than along the circumference of the circle. Blood cells and the endothelial lining of the blood stream show distinctly different behaviors depending upon whether they are exposed to high or low shear forces. In recent years, much has been learned about the way external mechanical forces are transduced at cell surfaces into chemical signals that, in turn, direct cytoskeleton formation (or dissolution) and influence the nucleus of the cell to up- and down-regulate genes and messenger RNAs. Chapter 3.5 overviews mechanical effects on blood cells.

3.2 THE ROLE OF ADSORBED PROTEINS IN TISSUE RESPONSE TO BIOMATERIALS

Thomas A. Horbett

INTRODUCTION

The replacement of injured or diseased tissues with devices made from materials that are not of biologic origin is the central approach in current biomaterials science and clinical practice. The prevalence of this approach is due largely to the fact that these materials are not attacked by the immune system, unlike donor tissues or organs. This fundamental difference arises

FIG. 1. Cell interactions with foreign surfaces are mediated by integrin receptors with adsorbed adhesion proteins that sometimes change their biological activity when they adsorb. The cell is shown as a circular space with a bilayer membrane in which the adhesion receptor protein molecules (the slingshot-shaped objects) are partly embedded. The proteins in the extracellular fluid are represented by circles, squares, and triangles. The receptor proteins recognize and cause the cell to adhere only to the surface-bound form of one protein, the one represented by a solid circle. The bulk phase of this same adhesion protein is represented by a triangle, indicating that the solution and solid phase forms of this same protein have a different biological activity. The figure is schematic and not to scale. (From Horbett, 1996.)

from the presence of immunologically recognizable biologic motifs on donor tissue and their absence on synthetic materials.

Nonetheless, there are other types of biological responses to implanted biomaterials that often impair their usefulness, including the clotting of blood and the foreign body reaction. Clearly, the body does recognize and respond to biomaterials. The basis for these reactions is the adsorption of adhesion proteins to the surface of the biomaterials that are recognized by the integrin receptors present on most cells. The adsorption of adhesion proteins to the biomaterial converts it into a biologically recognizable material, as illustrated in Fig. 1.

The interaction of adhesion receptors with adhesion proteins thus constitutes a major cellular recognition system for biomaterials. Therefore, the role of adsorbed adhesion proteins in mediating cellular interactions with biomaterials will be the primary focus of this chapter. Examples illustrating the ability of adsorbed adhesion proteins to influence cellular interactions with foreign materials are presented first. Then, some of the major physicochemical characteristics of

protein adsorption are illustrated and discussed, including rapid kinetics, monolayer adsorption, and competitive adsorption. Molecular spreading events related to the conformational stability of the protein are presented at some length as background for a section on how the biological activity of adsorbed adhesion proteins is affected by the substrate. The final section summarizes the principles underlying the role of adsorbed proteins in mediating platelet response to biomaterials as an illustrative case study representative of many other types of cellular responses.

This chapter includes material that is discussed in greater detail in several previous review articles by the author (Horbett, 1993, 1994, 1999; Horbett and Brash, 1995). Those articles also give citations to all the work discussed here.

EXAMPLES OF THE EFFECTS OF ADHESION PROTEINS ON CELLULAR INTERACTIONS WITH MATERIALS

Protein adsorption to materials can be performed with a single protein, typically in a buffer solution, or from complex, multiprotein solutions such as blood plasma that can contain hundreds of proteins. Single proteins in buffer can be used to model fundamental aspects of protein adsorption or to study biological reactions to one protein. Adsorption from complex media approximates the reaction observed for implanted biomaterials. Examples of both types of adsorption are presented.

The Effects of PreadSORption with Purified Adhesion Proteins

PreadSORption of certain kinds of proteins onto a solid substrate such as tissue culture polystyrene greatly increases its adhesiveness to many kinds of cells, and such proteins are called adhesion proteins. The increased adhesiveness is because many cells have receptors on their cell membrane that bind specifically to these specialized proteins. The adhesion receptors are called integrins. For example, fibronectin preadsorption greatly increases adhesion of fibroblasts, whereas albumin preadsorption prevents it. Experiments of this type have been done with a wide variety of cells and adhesion proteins, with basically similar results. Adhesion proteins also promote the flattening out or spreading of the cell onto the surface. A specific example is provided by measuring the percentage of attached cells that spread on surfaces pretreated with increasing concentrations of fibronectin. Spreading is only about 5% in the absence of fibronectin, but increases to nearly 100% as the fibronectin concentrations in the preadsorption solution are increased from 0.03 to 3 $\mu\text{g/ml}$.

Another example of the effect of fibronectin is shown in Fig. 2, which also contrasts it with the effects of the non-adhesive protein immunoglobulin G. As shown in the figure, the adhesion of the fibroblast-like 3T3 cells to a series of polymers and copolymers of 2-hydroxyethyl methacrylate (HEMA) and ethyl methacrylate (EMA) varies, being much less on the hydrophilic polyHEMA-rich surfaces than on the hydrophobic polyEMA-rich surfaces. The preadsorption of the surfaces

FIG. 2. 3T3 cell adhesion to HEMA-EMA copolymers: effect of preadsorption with fibronectin (designated CIG in the figure) or immunoglobulin G. Unpublished data from the author's laboratory.

with immunoglobulin G greatly reduces the adhesion of the cells to all the surfaces. In contrast, surfaces preadsorbed with fibronectin (designated CIG in the figure) are all fairly adhesive, much more so than the IgG preadsorbed surfaces or to the HEMA-rich surfaces not preadsorbed with fibronectin.

Preadsorption of adhesion proteins also affects cell interactions with surfaces studied under *in vivo* conditions. For example, platelet deposition onto polymeric arteriovenous shunts in dogs is greatly increased when fibrinogen or fibronectin are preadsorbed to the surfaces.

Depletion Studies

Although adsorption of purified adhesion proteins to a surface is one way to see their effect on cell adhesion, as presented in the preceding section, it does not mimic very well what occurs with implanted biomaterials. This is because implants are exposed to complex mixtures of proteins such as plasma or serum, so the adhesion protein must compete with many others for adsorption to the biomaterial. In that condition, despite its presence in the bulk phase, a given adhesion protein may really play little or no role. It is possible that very little of the adhesion protein may adsorb to the surface, as it is outcompeted by other proteins for the limited surface sites. Thus, a more biologically relevant way to understand the role of an adhesion protein in reactions to implants is to study the effect of their selective depletion from the complex mixture. The observations presented in this section and the articles they are based on are presented in greater detail in a review by the author (Horbett, 1999).

Selective depletion means that only one of the proteins is removed from the mixture at a time, by immunoadsorption chromatography, by use of plasma from mutant individuals lacking the adhesion protein of interest, or by selective enzymatic degradation. Thus, the more important role of adsorbed vitronectin as opposed to fibronectin in mediating attachment and spreading of cells on many surfaces has emerged from

FIG. 3. Platelet adhesion to Immulon preadsorbed with normal and afibrinogenemic plasma. Platelet adhesion to Immulon I preadsorbed with normal (triangles) or afibrinogenemic plasma (squares). The solid line represents the platelet adhesion to Immulon I preadsorbed with a series of dilutions of normal plasma, whereas the dotted line represents the platelet adhesion to Immulon I preadsorbed with a series of dilutions of afibrinogenemic plasma. The arrow at lower right corner indicates platelet adhesion to Immulon I preadsorbed with 2% BSA only. Source: Fig. 4 in Tsai and Horbett (1999).

immunoabsorption studies. Several studies illustrate the important role that adsorbed fibrinogen plays in the adhesion of platelets, neutrophils, and macrophages.

The effects of removal of fibronectin or vitronectin or both proteins from serum on the adhesion of endothelial cells depends on surface chemistry. On tissue culture polystyrene (TCPS), fibronectin removal has little effect, whereas vitronectin removal greatly reduces adhesion. The results clearly show the primary role of adsorbed vitronectin in supporting endothelial cell adhesion to TCPS. In contrast, adhesion to a surface modified by ammonia in a glow discharge requires fibronectin, since removal of that protein greatly reduces adhesion to this surface, while vitronectin removal has little effect. However, the results for TCPS are more typical, i.e., on most surfaces studied by this method it appears that vitronectin, not fibronectin, is the primary agent responsible for cell adhesion.

Platelet adhesion to surfaces preadsorbed with plasma deficient in fibrinogen is much less than to the same surface preadsorbed with normal plasma, as illustrated in Fig. 3. Most of the adhesion supporting activity can be restored to fibrinogen deficient plasma by addition of normal levels of exogenous fibrinogen. In contrast, removal of fibronectin or vitronectin or von Willebrand's factor from plasma has little effect on platelet adhesion (not shown), even though these other plasma proteins act as adhesion proteins when adsorbed as single proteins to surfaces. It appears that too little of these other proteins adsorbs from plasma to make much difference, i.e., competition from fibrinogen and other proteins keeps their surface concentration too low and so their removal has no effect.

When mice are depleted of fibrinogen by treatment with an enzyme that degrades it, the adhesion of neutrophils and macrophages to a polymer implanted in their peritoneal cavity

is greatly reduced. The fibrinogen depleted animals exhibited near normal neutrophil and macrophage adhesion to the implants if the implants are preadsorbed with fibrinogen. These studies illustrate the power of the depletion method very well. Previously, it had been thought that either complement or IgG would be the main adhesion proteins for neutrophils and monocytes because of the presence of receptors on these cells that bind these proteins. Instead, it appears that an integrin receptor for fibrinogen (CD11b/CD18, also known as Mac-1) plays a major role, at least during the initial or acute phase of the foreign body response in the mouse peritoneal cavity.

Inhibition of Receptor Activity with Antibodies

Another way to show the role of adhesion proteins in cell interactions with biomaterials is to add specific inhibitors of their function. Adhesion proteins cause cell adhesion by binding to integrin receptors that specifically recognize the adhesion protein. One way to inhibit this reaction is to add an antibody that binds to the receptor, blocking access to the adhesion protein. Examples of this approach are now presented.

Platelet-receptor-mediated interactions appear to be the primary mechanism of platelet interaction *in vivo* with certain vascular grafts because platelet deposition is largely inhibited by antibodies to the glycoprotein III/IIIa receptor. *In vitro* platelet adhesion to surfaces preadsorbed with blood plasma is also inhibited by anti-glycoprotein IIb/IIIa in a dose-dependent manner, as illustrated in Fig. 4. In this study, samples of the polyurethane Biomer were preadsorbed with plasma and then exposed to platelets in an albumin containing buffered saline suspension that had increasing amounts of the antibody. As shown in the figure, adhesion declined to very low values when high concentrations of the anti-integrin antibody were present.

FIG. 4. Effect of anti-IIb/IIIa antibody on platelet adhesion to Biomer preadsorbed with plasma. Adhesion of platelets incubated in monoclonal antibody LJ-cp8 (monovalent Fab' fragment) directed against the glycoprotein (GP) IIb/IIIa complex to Biomer. Substrates were contacted with 1.0% plasma for 2 hr, then with washed, antibody-treated platelets for 2 hr. From Chinn, Horbett, and Ratner (1991).

FIG. 5. The conversion of nonwetttable polystyrene surface (top panel) into one completely wetttable by water (bottom panel) is due to the adsorption of proteins.

THE ADSORPTION BEHAVIOR OF PROTEINS AT SOLID/LIQUID INTERFACES

Adsorption Transforms the Interface

Figure 5 illustrates an experiment that is performed by the author to demonstrate the adsorption of proteins to surfaces. As illustrated in part A, a water droplet placed on the surface of an unused polystyrene cell culture dish is easily visible because it beads up, i.e., the contact angle between the droplet and the polystyrene surface is very high because of the water-repellant, hydrophobic nature of polystyrene. If a cell were placed on a polystyrene dish instead of the water droplet, it also would encounter a very nonwetttable surface. Part B of the figure illustrates the results of placing a water droplet on the surface of a polystyrene dish that had first been exposed to a protein solution for a short time and then rinsed extensively with water. As illustrated, no water droplet can be seen on this surface, reflecting the fact that in this case the added drop of water completely spread out over the surface of the preadsorbed dish. This happens because the water in part B was not able to interact with the polystyrene surface, because the surface had become coated with a layer of the hydrophilic protein adsorbate. Similarly, cells that come into contact with surfaces adsorbed with proteins do not directly "see" the substrate, but instead they interact with the intervening protein adsorbate.

Rapid Adsorption Kinetics and Irreversibility

The kinetics of adsorption of proteins to solid surfaces typically consists of a very rapid initial phase, followed by a slower phase upon approach to the steady-state value. Initially, proteins adsorb as quickly as they arrive at the largely empty surface. In this phase, adsorption is linear when plotted against time^{1/2}, characteristic of a diffusion-controlled process. In the later, slower phase, it is more difficult for the arriving proteins to find and fit into an empty spot on the surface.

FIG. 6. The adsorption kinetics of lysozyme to a silica surface as studied with ellipsometry. The adsorbed amount versus time for adsorption of lysozyme to silica followed by buffer rinsing after 1800 sec, addition of surfactant (SDS) after 3600 sec, and a final rinse with buffer after 5400 sec (open circles). Adsorption from a mixture of the protein and surfactant for 1800 sec followed by rinsing is also included (closed circles). The experiments were carried out at 25°C in 0.01 M phosphate buffer, 0.15 M NaCl, pH 7. From Arnebrandt and Wahlgen (1995).

Figure 6 shows the time course of adsorption of lysozyme on silica measured with a high-speed, automated ellipsometer

capable of very rapid measurements. At the earliest measurement time, less than a second into the study, the adsorption has reached almost half of the steady-state value. At 2000 sec, the protein solution was replaced with a buffer, resulting in some removal of loosely bound protein, but the adsorption stabilizes and would have remained at this value for much longer than shown, due to the tight, irreversible binding. At 3600 sec, a solution of the detergent sodium dodecyl sulfate (SDS) was infused, leading to complete removal of the protein. Thus, this experiment illustrates the rapid adsorption of proteins. It also illustrates that most of the adsorbed protein is irreversibly bound, as indicated by the fact that washing the surface with buffer does not remove the protein. The adsorbed protein is only removed when a strong surfactant (SDS in this example) is used. All these features are characteristic of protein adsorption to solid surfaces.

The Monolayer Model

The existence of a close packed monolayer of adsorbed protein is suggested by studies with single protein solutions in which a saturation effect can often be observed in the adsorption isotherm (Fig. 7). Adsorption to surfaces exposed to different concentrations of protein until steady state adsorption is achieved (2 hours or more) increases steeply at low bulk-phase concentrations but typically reaches a plateau or saturation value at higher bulk concentrations. Usually, the plateau value falls within the range expected for a close-packed monolayer of protein (about 0.1 to 0.5 $\mu\text{g}/\text{cm}^2$, depending on the diameter and orientation assumed for the protein).

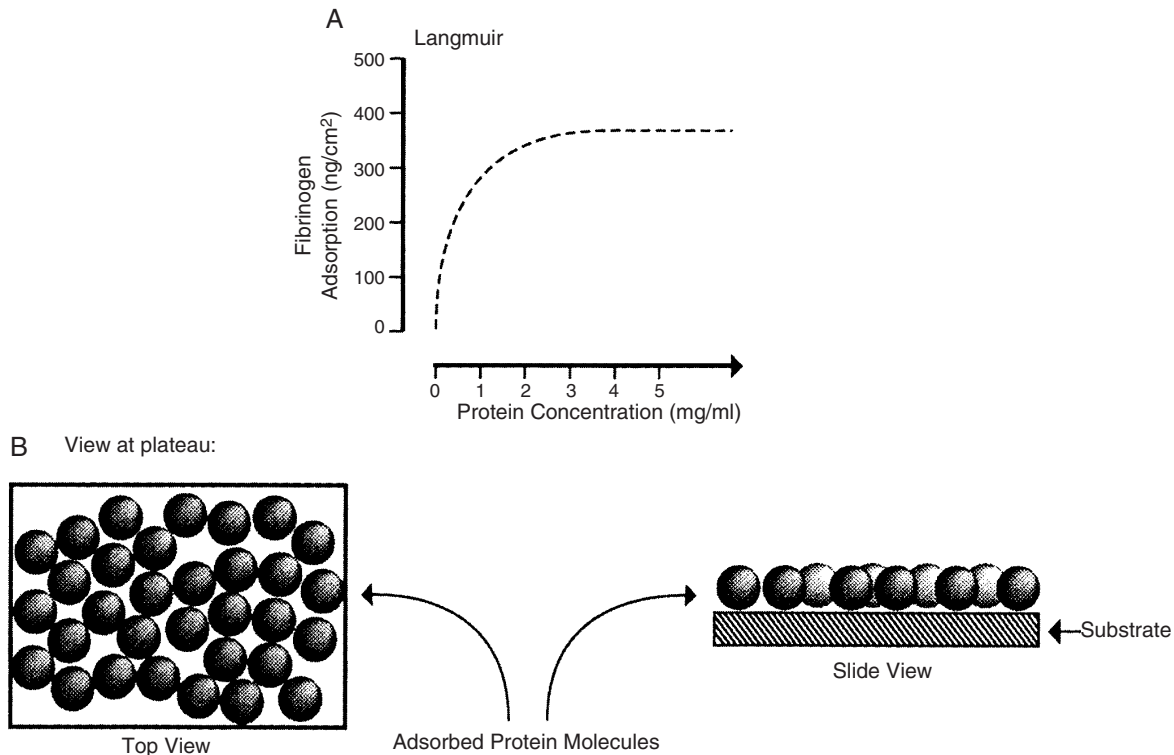

FIG. 7. Adsorption isotherms and the monolayer concept. From Horbett (1996).

The adsorption values from complex protein mixtures also typically are in the monolayer range. For example, the sum total of the amount of adsorption of the three major proteins in plasma (albumin, IgG, and fibrinogen) on the HEMA-EMA series of surfaces is also in the range of 0.1 to 0.5 $\mu\text{g}/\text{cm}^2$. In addition, the fact that competition exists between proteins for adsorption to a surface (see next section) also indicates the existence of limited sites. Thus, when a monolayer is the limit, there must be some selection for which proteins are present in the adsorbed film. It should be noted that well-defined plateaus are not always observed, but instead adsorption rises much more slowly at higher bulk-phase concentrations than at low concentrations, i.e., Freundlich isotherms do occur.

Competitive Adsorption of Proteins to Surfaces from Protein Mixtures

Adsorption from mixtures of proteins is selective, leading to enrichment of the surface phase in certain proteins. In this context, enrichment means that the fraction of the total mass of the adsorbed protein layer corresponding to a given protein is often much higher than the fraction of this protein in the bulk phase mixture from which it adsorbed. Since the solid can accommodate only a small fraction of the total protein present in the bulk phase, and proteins vary greatly in their affinity for surfaces, some adsorbed proteins are present in greater amounts than others. Studies of surfaces exposed to plasma have shown that many different proteins are present in the adsorbed film.

The competitive phenomena underlying differential enrichment from multi protein mixtures are most clearly illustrated in binary mixtures of proteins. Figure 8 has three separate curves in it, which overlap at the high and low ends. These curves represent the typical outcome of binary-mixture studies, but for three different conditions. For example, when a radio-labeled protein such as fibrinogen ("A" in the figure) is mixed with various amounts of an unlabeled protein such as albumin ("B" in the figure), the adsorption of fibrinogen ("A") always declines when sufficiently high amounts of albumin ("B") are present. However, the amount of competing protein needed to inhibit the adsorption of the labeled protein is different in each curve. This is meant to illustrate that, for a given pair of competing proteins, the competition curves will be different if

FIG. 8. Competitive adsorption of two proteins from a mixture. From Horbett (1993).

the surfaces they are competing for are different. In addition, if the surfaces are kept the same, but the competition of different pairs of proteins are studied, the curves will differ because the ability of proteins to compete for surface sites is quite different for different proteins.

For example, inhibition of fibrinogen adsorption to polyethylene requires a roughly 10-fold excess by weight of lower-affinity competing proteins such as albumin, but is effectively inhibited by the higher-affinity protein hemoglobin even when hemoglobin is present at only 10% of the mass of fibrinogen. However, the amounts needed for this inhibition will vary with the surfaces. Affinity variation is thus a major principle determining the outcome of competitive adsorption processes.

Examples of surface enrichment from complex protein mixtures are readily available. Although fibrinogen is only the third most concentrated protein in plasma, after IgG and albumin, biomaterials exposed to plasma are enriched in fibrinogen in the adsorbed phase. Hemoglobin is present in very low concentrations in plasma (0.01 mg/ml or less), but it is still adsorbed in amounts similar to the more predominant proteins because of its high surface affinity. Albumin, a lower-affinity protein, presents a counterexample. Albumin concentration in plasma is much higher than fibrinogen, yet the surface concentration of albumin adsorbed from plasma is typically about the same as fibrinogen. The high concentration of albumin in the plasma drives it onto the surface according to the law of mass action. Similarly, fibrinogen adsorption is higher from plasmas that contain higher concentrations of fibrinogen. Thus, mass concentration in the bulk phase is the second major factor determining competitive adsorption behavior.

The adsorption of fibrinogen from plasma exhibits some unusual behavior. On some surfaces, fibrinogen adsorption is maximal at intermediate dilutions of plasma (see example in Fig. 9A). In addition, fibrinogen adsorption from full-strength or moderately diluted plasma is higher at very early adsorption times than at later times (example shown in Fig. 9B). These are examples of the Vroman effect for fibrinogen. This phenomenon is a clear example of the unique effects of competitive adsorption on both the steady-state and the transient composition of the adsorbed layer that forms from plasma. The Vroman effect appears to involve displacement of initially adsorbed fibrinogen by later-arriving, more surface-active plasma proteins, especially high-molecular-weight kininogen, and transitions in the adsorbed fibrinogen that make it less displaceable with adsorption time (reviewed in Slack and Horbett, 1995).

MOLECULAR SPREADING EVENTS: CONFORMATIONAL AND BIOLOGICAL CHANGES IN ADSORBED PROTEINS

Proteins that adsorb to solid surfaces can undergo conformational changes because of the relatively low structural stability of proteins and the tendency to unfold to allow further bond formation with the surface. Conformational changes can be detected with many types of physicochemical methods and also by measuring changes in the biological activity of the adsorbed proteins.

FIG. 9. The Vroman effect. (A) Fibrinogen adsorption to biomer and glass from various concentrations of blood plasma. (B) Time course of fibrinogen adsorption to glass and poly(ethyl methacrylate) (PEMA) from undiluted blood plasma. Source: Fig. 1 in Slack and Horbett, (1995).

Physicochemical Studies of Conformational Changes

“Soft” proteins are found to adsorb more readily and more tenaciously than “hard” proteins. In this context, a “soft” protein is one with a low thermodynamic stability, whereas a “hard” protein is more stable to unfolding in solution in response to denaturing conditions such as elevated temperature. This concept and the articles supporting the following discussion are presented in detail elsewhere (Horbett and Brash, 1995).

Comparison of the adsorptive behavior of different proteins to their molecular properties indicates that less stable proteins are more adsorptive. The important role of structural stability in adsorption is also supported by recent studies with engineered mutant proteins with single amino acid substitutions that vary in stability. Lysozyme adsorption at the solid/liquid interface and tryptophan synthase occupation of the air/water interface are greater for less stable mutants.

Several studies with differential scanning calorimetry (DSC) methods seemed to indicate that adsorbed proteins may lose much of their structure, depending on how “soft” they are. Heat is taken up at a certain temperature for proteins in

solution due to unfolding of the native protein at the transition temperature. An absence or reduction of this effect for an adsorbed protein suggests that the adsorbed protein has already undergone the transition, i.e., that it has already unfolded upon adsorption. The transition enthalpy of lysozyme adsorbed to negatively charged polystyrene was much less than for the protein in solution (0–170 kJ/mol for the adsorbed protein versus about 600 kJ/mol for the native protein, depending on the pH). However, for lysozyme adsorbed on hematite, the unfolding enthalpy is only about 20% less than for the native protein, indicating that changes in the enthalpy of unfolding depend on the adsorbing surface. Furthermore, for lactalbumin the heat released is nearly zero when adsorbed on either the polystyrene or the hematite surface, suggesting complete unfolding of lactalbumin on both surfaces. These observations are consistent with the lower stability of lactalbumin in comparison to lysozyme. Several proteins adsorbed to pyrolytic carbon do not show any release of heat at the expected transition temperature, suggesting that pyrolytic carbon induces complete unfolding, a result that is consistent with the tenacious binding of proteins to this surface. It has also been shown that albumin and lysozyme adsorbed to polystyrene

exhibit no unfolding enthalpy, whereas lysozyme adsorbed to a hydrophilic contact lens still exhibits about 50% of the heat released by the native protein. Streptavidin adsorbed to polystyrene displays an unfolding enthalpy that is very similar to that for the native protein in solution, probably because of the greater stability of streptavidin in comparison to lysozyme or albumin.

However, more recent studies of adsorbed proteins by the DSC method in conjunction with other, more direct conformational measurements such as circular dichroism (CD) show that at least some adsorbed proteins that appear to be completely denatured as judged by DSC still have considerable amounts of their native structure as measured by CD. It thus appears that some proteins become somewhat more stable after adsorption, and thus do not show heat release at the normal melting temperature.

The concept of molecular spreading of the adsorbed protein suggested by these observations has been used to explain differences in the amount of IgG adsorbed during stepwise adsorption. When the final concentration of bulk protein is achieved in a series of smaller concentration steps, as opposed to bringing the bulk concentration to its final value in one step, adsorption is smaller. Conformational changes upon adsorption of fibronectin to polystyrene beads and Cytodex microcarrier beads have been detected using electron spin resonance spectroscopy. Many other physicochemical studies are consistent with partial unfolding of the adsorbed proteins (Andrade, 1985; Horbett and Brash, 1995; Lundstrom, 1985).

Biological Changes in Adsorbed Proteins

Although physicochemical studies sometimes suggest complete denaturation of adsorbed proteins, most probes for biological activity suggest the changes are more limited (reviewed with citations in Horbett, 1993). Thus, enzymes retain at least some of their activity in the adsorbed state, especially when the surface are more fully loaded with enzyme. Measurements of enzyme activity or retention times during passage over hydrophobic chromatography matrices have shown that the degree of denaturation is highly dependent on the protein, the length of time the protein has spent on the matrix, the solvent, and other conditions, and is not necessarily complete.

Changes in the binding of a monoclonal antibody to fragment D of fibrinogen upon fibrinogen adsorption to polystyrene have been attributed to changes in the conformation of fibrinogen after adsorption. Thus, solution-phase fibrinogen does not bind the antibody raised to fragment D, but the surface-adsorbed fibrinogen does, and furthermore, bulk fibrinogen does not compete for the binding of the antibody to the surface-adsorbed fibrinogen. The RIBS (receptor-induced binding site) antibodies are similar: They bind to fibrinogen only after the fibrinogen has bound to either a solid surface or to the platelet IIb/IIIa receptor. The binding of the RIBS antibodies and others that bind to the platelet-binding regions of fibrinogen varies with the length of time after adsorption of the fibrinogen. Platelet adhesion to polymethacrylates has been correlated with the amount of antifibrinogen binding,

FIG. 10. Transitions in adsorbed fibrinogen. The effect of three-day residence in buffer or buffered albumin solution upon anti-fibrinogen binding to fibrinogen adsorbed from dilute plasma to biomer is shown. From Fig. 3A in Chinn *et al.* (1992).

suggesting that the adsorbed fibrinogen is in different conformations on the various polymethacrylates.

Fibrinogen undergoes a time-dependent transition after its adsorption to a surface that results in reduced platelet and antibody binding to the adsorbed fibrinogen as well as reduction in the sodium dodecyl sulfate and plasma displaceability, and changes in amide II frequency of the adsorbed fibrinogen. The losses in platelet binding, antibody binding, and SDS elutability are prevented if albumin is included in the storage buffer. An example showing time-dependent losses in antibody binding to fibrinogen and its prevention by albumin is shown in Fig. 10 (from Chinn *et al.*, 1992). Vitronectin also appears to undergo conformational changes upon adsorption that affect its ability to bind heparin and its infrared spectra.

Modulation of the biologic activity of fibronectin has been shown in several studies in which the ability of fibronectin adsorbed to various surfaces to support cell attachment or spreading was found to differ. For example, fibronectin adsorbed to tissue-culture-grade polystyrene was able to support cell attachment and spreading, whereas fibronectin adsorbed to ordinary polystyrene does not support spreading very well unless some albumin is added to the fibronectin solution. Fibronectin adsorbed to self-assembled monolayer films (SAMs) with various functional end groups also varies. On hydrophobic SAMs there is poor cell spreading unless albumin is coadsorbed (albumin "rescuing"). The albumin "rescuing" phenomenon observed for SAMs is similar to the albumin effect on fibronectin's ability to promote cell spreading on polystyrene, and to the effect of albumin addition in preventing losses in platelet adhesion to fibrinogen adsorbed surfaces discussed above. The ability of fibronectin adsorbed to a series of polymers to support the outgrowth of corneal epithelial cells has also been found to vary a great deal, despite the presence of similar amounts of fibronectin on the surfaces.

The effect of albumin addition in enhancing the adhesivity of fibronectin-coated surfaces is opposite of what one

TABLE 1 Principles Underlying the Influence of Adsorbed Plasma Proteins on Platelet Interactions with Biomaterials

1. Synthetic foreign materials acquire bioreactivity only after first interacting with dissolved proteins. The principal means by which the transformation from an inert, nonthrombogenic polymer to a biologically active surface takes place is the interaction of the proteins with the surface that then mediates cell adhesion.
2. Platelets are a major example of why and how adsorbed proteins are influential in cell-biomaterials interactions.
3. Sensitivity of platelets to adsorbed proteins is due to:
 - a. Some proteins in plasma are strongly adhesive for platelets: fibrinogen, fibronectin, vitronectin, and von Willebrand factor.
 - b. Concentrating, localizing, immobilizing effects of adsorbing the proteins at the interface accentuates the receptor-adhesion protein interaction.
 - c. Platelets have receptors (IIb/IIIa and Ib/IX) that bind specifically to a few of the plasma proteins, mediating adhesion.
4. Principles of protein adsorption to biomaterials
 - a. Monolayer adsorption and consequent competition for available adsorption sites means that not all proteins in the plasma phase can be equally represented on the surface.
 - b. Driving forces for adsorption are the intrinsic surface activity and bulk phase concentration of the proteins.
 - c. Surfaces vary in selectivity of adsorption.
 - d. Biological activity of the adsorbed protein varies on different surfaces.

might expect, because the added albumin should reduce the amount of adsorbed fibronectin, as albumin competes for sites on the surfaces. The explanation for the albumin effect is thought to be that by adsorbing along with the fibronectin to the surface, the albumin molecules occupy surface sites near the fibronectin molecules. The adsorbed albumin molecules thus keep the adsorbed fibronectin molecules from undergoing structural changes that they would otherwise do in trying to spread into formerly empty surface sites but cannot do so if albumin molecules fill those sites.

The studies with platelets, fibroblasts, and epithelial cells show that substrate properties somehow modulate the ability of adsorbed proteins to interact with cells. These differences may arise at least in part from differences in the availability of epitopes on adhesive proteins for the cell surface receptor. That is, both the amount of the adsorbed adhesive protein and its "bioreactivity" are actively influenced by the properties of the surface to which it is adsorbed.

THE IMPORTANCE OF ADSORBED PROTEINS IN BIOMATERIALS

Table 1 summarizes the principles underlying the influence of adsorbed proteins in biomaterials used in contact with the blood. All of the principles listed also apply in other environments such as the extravascular spaces, albeit with other proteins and other cell types (e.g., macrophages in the peritoneum adhere via other receptors and other adhesion proteins). The platelets therefore provide a "case study," and we close this chapter by considering this case.

The sensitivity of platelet/surface interactions to adsorbed proteins is fundamentally due to the presence of adhesion receptors in the platelet membrane that bind to certain plasma proteins. There are only a few types of proteins in plasma that are bound by the adhesion receptors. The selective adsorption of these proteins to synthetic surfaces, in competition with

the many nonadhesive proteins that also tend to adsorb, is thought to mediate platelet adhesion to these surfaces. However, since the dissolved, plasma-phase adhesion proteins do not bind to adhesion receptors unless the platelets are appropriately stimulated, whereas unstimulated platelets can adhere to adsorbed adhesion proteins, it appears that adsorption of proteins to surfaces accentuates and modulates the adhesion receptor/adhesion protein interaction. The type of surface to which the adhesion protein is adsorbed affects the ability of the protein to support platelet adhesion (Horbett, 1993). The principles that determine protein adsorption to biomaterials include monolayer adsorption, the intrinsic surface activity and bulk concentration of the protein, and the effect of different surfaces on the selectivity of adsorption and biologic activity of the adsorbed protein.

More generally, all proteins are known to have an inherent tendency to deposit very rapidly on surfaces as a tightly bound adsorbate that strongly influences subsequent interactions of many different types of cells with the surfaces. It is therefore thought that the particular properties of surfaces, as well as the specific properties of individual proteins, together determine the organization of the adsorbed protein layer, and that the nature of this layer in turn determines the cellular response to the adsorbed surfaces.

3.3 CELLS AND CELL INJURY

Richard N. Mitchell and Frederick J. Schoen

Composed of nucleic acids, proteins, and other large and small molecules, cells constitute the basic structural building blocks of all living matter. They are held together by cell-to-cell junctions to form tissues comprising four general types: epithelium, connective tissue, muscle, and nerve. Organs are assembled from these basic tissues, “glued” together by a largely proteinaceous extracellular matrix (ECM) synthesized by the individual cells. The organs, in turn, perform the various functions required by the intact living organism, including circulation, respiration, digestion, excretion, movement, and reproduction.

A major goal in this and the following chapter is to describe how biological structure is adapted to perform physiologic function. This general and overarching concept extends from cells (and their subcellular constituents) to the organization of tissues and of organs. Beginning with the smallest subunits of cellular organization we will build to progressively more complex systems. In the following chapter, we will extend the concepts of structure–function correlation beyond cells to include extracellular matrix and complex tissues, and will also describe the technologies by which histologists and pathologists examine normal and abnormal tissues. In these chapters, we also provide an introduction to the physiologic responses to environmental stimuli, the mechanisms of cell injury, cell–materials interactions, and the methodologies by which these are all studied.

In this chapter on cells and cell injury and in the following chapter on tissues and the extracellular matrix, we will highlight the following fundamental concepts:

Cells and cell injury:

- General characteristics and functions of cells
- Compartmentalization of regionally specialized function by membranes
- Cellular specialization to facilitate unique functions
- Regulation and coordination of cell function
- The response of cells to injury, including mechanisms of cell death

Tissues and the extracellular matrix:

- The structure and function of the extracellular matrix
- Grouping of cells into tissues
- Integration of tissues into organs
- Remodeling of the extracellular matrix
- The interaction of cells, tissues, and foreign materials
- Basic methods used to study cells and tissues

NORMAL CELL HOUSEKEEPING

In very broad strokes, we will first outline the general organization of a prototypical cell, using it to identify the functional considerations required for maintaining a living cell. We will then revisit each of these structural features to illustrate important concepts in cellular maintenance and response to environment.

Conceptually, cells may be viewed as independent collections of self-replicating enzymes and structural proteins that carry out certain general functions. The most essential cell attributes are:

- Self-replication
- Protection from the environment
- Acquisition of nutrients
- Movement
- Communication
- Catabolism of extrinsic molecules
- Degradation and renewal of senescent intrinsic molecules
- Energy generation

Intracellular constituents exist in a microcosm of water, ions, sugars, and small-molecular-weight molecules called the cytosol or cytoplasm. Within the cytosol is also a source of energy, typically adenosine triphosphate (ATP). Although long conceptualized as a randomly diffusing bag of soluble molecules, the cell is, in fact, a structurally highly ordered and functionally integrated assembly of organelles, cytoskeletal elements, and enzymes.

The cytosol is delimited and protected from the environment by a phospholipid bilayer, the plasma membrane, which permits the cell to maintain cytosolic constituents at concentrations different from those in the surrounding environment. Because of its hydrophobic inner core, the plasma membrane is impermeant to charged and/or large polar molecules; however, it is rendered selectively permeable (i.e., permits

FIG. 1. General schematic of a typical mammalian cell, demonstrating the general organization and major organelles. Note that each compartment has distinct functions made possible by selectively permeable membranes. (Reproduced by permission from Bergman, A. R., Afifi, A. K., and Heidger, P. M., eds., 1996. *Histology*. Saunders, Philadelphia.)

specific passage) to incoming or outgoing material (ions, amino acids, etc.) by channel or transport proteins inserted through it. Most nutrient acquisition is thereby accomplished by the movement of desired substrates either through pores or by energy-driven transport. Cells also have the capacity to internalize material from the outside environment by capturing bits of the extracellular environment in invaginated folds of the plasma membrane called vesicles. Depending on the volume and size of the ingested material, the process may be called phagocytosis (“cell eating”) or pinocytosis (“cell drinking”). Transcytosis is the movement of vesicles from one side of a cell to another, and it may play an important role in mediating the increased vascular permeability (“leaky vessels”) that occurs around tumors or at sites of inflammation. The plasma membrane may also express a variety of specific surface molecules that facilitate interactions with other cells, soluble ligands (e.g., insulin), and/or with the extracellular matrix (communication).

Many of a cell’s normal “housekeeping” functions are compartmentalized within membrane-bounded intracellular organelles (Fig. 1) thus permitting adjacent regions of the cell

to have vastly different chemistries. By isolating certain cellular functions within distinct compartments, potentially injurious degradative enzymes or toxic metabolites can be kept at usefully high concentrations locally without causing damage to more delicate intracellular constituents. Moreover, compartmentalization also allows the creation of unique intracellular environments (e.g., low pH, high calcium, or high concentration of a potent enzyme) that permit more efficient functioning of certain chemical processes, enzymes, or metabolic pathways.

The enzymes and structural proteins of the cell are constantly being renewed by ongoing synthesis tightly balanced with intracellular degradation. Oversight for the new synthesis of macromolecules, including deoxyribonucleic acid (DNA) and ribonucleic acid (RNA), is provided by the nucleus. New proteins destined for the plasma membrane or for secretion into the extracellular environment are synthesized and packaged in the rough endoplasmic reticulum (RER) and Golgi apparatus; proteins intended for remaining in the cytosol are synthesized on free ribosomes. Smooth endoplasmic reticulum (SER) may be abundant in certain cell types where it is used for

steroid hormone and lipoprotein synthesis, as well as for the modification of hydrophobic compounds into water-soluble molecules for export. Degradation of internalized molecules or senescent self-molecules into their constituent amino acids, sugars, and lipids (catabolism) is the primary responsibility of the lysosomes and proteasomes. Peroxisomes play a specialized role in the breakdown of fatty acids, generating hydrogen peroxide in the process. Intracellular vesicles busily shuttle internalized material to appropriate intracellular site(s) for catabolism, or direct newly synthesized materials to the plasma membrane or relevant target organelle. The architecture of the cell is maintained by a scaffolding of intracellular proteins collectively called the cytoskeleton, analogous in some ways to the support provided by bones of our bodies.

Cell movement, including both movement of organelles and proteins within the cell, as well as movement of the cell in its environment, is accomplished through rearrangement of the cytoskeleton. These structural proteins also provide basic cellular shape and intracellular organization, which are necessary for the maintenance of cell polarity (differences in cell structure and function at the top of a cell versus its side or base). For example, in many cell types, and particularly in epithelial tissues, it is critical for cells to distinguish—and keep separated—the top (apical) versus the bottom and side (basolateral) surfaces. The major energy source for macromolecular synthesis, metabolite degradation, and intracellular transport is the mitochondrion, using oxidative phosphorylation to generate ATP. Finally, all of these organelles must be replicated (organelle biogenesis) and correctly apportioned in daughter cells following mitosis.

The specific function(s) of a given cell are reflected by the relative amount and types of organelles it contains. The relative predominance of specific types of organelles can be inferred by examination of tissue sections prepared by standard histologic techniques and can be confirmed by transmission electron microscopy. For example, cells with high energy requirements can be expected to have a significantly greater capacity to generate that energy. Thus, kidney tubular epithelial cells (which reabsorb sodium and chloride against concentration gradients), and cardiac myocytes (which rhythmically contract 50–100 times per minute) have a generous complement of mitochondria. Conversely, cells specifically adapted to synthesize and export selected proteins (e.g., insulin in a pancreatic islet cell, or antibody produced by a plasma cell) have a well-developed rough endoplasmic reticulum.

THE PLASMA MEMBRANE: PROTECTION, NUTRIENT ACQUISITION, AND COMMUNICATION

Plasma membranes, as well as all other organellar membranes, are dynamic, fluid, and inhomogeneous lipid bilayers containing a variety of embedded proteins. Biologic membranes are composed of phospholipids that are amphipathic; that is, they have a polar head group that prefers to interact with water (hydrophilic), and nonpolar fatty acid chains that resist interacting with water (hydrophobic). These phospholipids will spontaneously assemble to form two-dimensional

FIG. 2. Model of a prototypical cell membrane. Note the lipid bilayer with outer, hydrophilic (exposed to an aqueous environment) and inner, hydrophobic (maintains a barrier to solute movement) domains. Inserted through the membrane or in either inner or outer planes are various proteins that permit transport, cell–cell and signal–molecule interactions, and linkage of the membrane to the intracellular cytoskeleton. (Reproduced by permission from Bergman, A. R., Afifi, A. K., and Heidger, P. M., eds., 1996. *Histology*. Saunders, Philadelphia.)

sheets with their hydrophilic head groups facing toward the aqueous cytoplasm or extracellular fluid, and their hydrophobic lipid tails interacting to form a central core that largely excludes water. Since the lipid core of plasma membrane is intrinsically resistant to the movement of large or polar molecules, continued cell function requires that specific protein channels or transport mechanisms be in place to facilitate uptake of ions and metabolites. In addition, the plasma membrane is also the interface between the extracellular environment and the inner cellular domains; interactions of proteins at the cell surface with extracellular molecules or even other cells can trigger a cascade of intracellular signaling events (Fig. 2).

The lipid confers structural integrity and barrier function to the membrane and the inserted proteins provide specialized membrane functions (see later discussion). In addition, the specific composition of the lipid bilayer, e.g., relative amounts of various phospholipids, cholesterol, and glycolipids, will alter the physicochemical properties of the membrane, as well as the functioning of associated proteins. Although the various lipid and protein constituents can move about easily in the plane of the membrane, certain components have a predilection for each other, and different domains with distinct lipid compositions are thereby created. Since inserted membrane proteins have different solubilities in these various lipid domains, the membrane lipid inhomogeneities result in functionally distinct islands and patches of protein molecules. This has significance in terms of cell–cell and cell–matrix interactions, as well as in intracellular signaling. The lipid component of the plasma membrane is also asymmetric, that is, there are different general compositions of the inner and outer leaflets. The asymmetry has functional significance in that gangliosides, conferring a net negative charge, and glycolipids—both of which are on the outer face of the bilayer—are important for cell–cell and cell–matrix interactions, local electrostatic effects, and creation of

barriers to infection. Inositol phospholipids, on the inner face, are important for intracellular signaling.

How proteins associate with membranes reflects their function. Most proteins inserted into membranes are integral or transmembrane proteins, having one or more relatively hydrophobic segments that traverse the lipid bilayer and securely anchor the protein. Occasionally, proteins are attached to the membrane via weaker lipid–protein or protein–protein interactions. This has functional significance in that nonintegral proteins can potentially interact with a variety of membrane molecules and can be used to transduce transient signals. Proteins involved in forming pores or transporting other molecules will typically be transmembrane, whereas those involved in signaling or cytoskeletal interactions will not.

Plasma membrane proteins frequently function together as large complexes. These complexes may be primarily assembled as the proteins are synthesized in the RER, or may arise by lateral diffusion in the plasma membrane. Such *de novo* complex formation, followed by signal cascade inside the cell, is a typical paradigm employed to translate ligand–surface receptor binding into an intracellular response. Large complexes also form the basis for intercellular connections such as tight junctions (see later discussion), and interactions between the same proteins on adjacent cells (homotypic interactions) create a zone that separates the apical and basolateral aspects of cells in epithelial layers, thereby establishing cell polarity.

The hydrophobic lipid core of plasma membranes is an effective barrier to the passage of most polar molecules. Small, nonpolar molecules such as O_2 and CO_2 readily dissolve in lipid bilayers, and therefore rapidly diffuse across them. Large hydrophobic molecules such as steroid hormones (testosterone and estrogen, for example) also readily cross lipid bilayers. Even polar molecules, if sufficiently small (e.g., water, ethanol, and urea at molecular weights of 18, 46, and 60 daltons, respectively) rapidly cross membranes. In contrast, glucose, at a molecular weight of only 180 daltons, is effectively excluded, and lipid bilayers are completely impermeant to ions, regardless of size, because of their charge and high degree of hydration. Therefore, to facilitate the entrance or disposal of various molecules, specific transport proteins are required. For small-molecular-weight molecules (ions, glucose, nucleotides, and amino acids up to approximately 1000 daltons) there are two main categories, carrier proteins and channel proteins. For larger molecules or even particles, uptake is mediated by specific receptors, internalized via endocytosis. Large molecules destined for export are packaged in secretory vacuoles that fuse with the plasma membrane and expel their contents in a process called exocytosis.

Each type of transported molecule (ion, sugar, nucleotide, etc.) requires a unique membrane transport protein to facilitate passage. These transporters typically exhibit strong specificity. Thus, a particular transporter will move glucose but not galactose; another transporter will move potassium but not sodium. Carrier proteins bind their specific ligand and undergo a series of conformational changes to transfer it across the membrane; their transport is relatively slow. In comparison, channel proteins create hydrophilic pores; when open, these permit rapid movement of selected solutes. In most cases, a concentration and/or electrical gradient between the

inside and outside of the cell drives solute movement by passive transport (virtually all plasma membranes have an electrical potential difference across them, with the inside of a cell negative relative to the outside). In some cases, active transport against a concentration gradient is accomplished by carrier molecules (never channels) and requires energy expenditure (provided by the breakdown of ATP). Transporters also include the multidrug resistance (MDR) protein, which pumps polar compounds (for example, chemotherapeutic drugs) out of cells and may render cancer cells more resistant to treatment. Similar transport mechanisms also regulate intracellular and intraorganellar pH; human beings and most of their cytosolic enzymes prefer to work at pH 7.2, whereas lysosomes function best at pH 5 or less.

Because the plasma membrane is freely permeable to water, water will move into or out of cells along its concentration gradient (by osmosis). Extracellular salt in excess of that seen in the cytoplasm (hypertonicity) will cause a net movement of water out of cells; conversely, hypotonicity will cause a net movement of water into cells. Since the intracellular environment is rich in charged molecules that attract a large number of charged counterions (tending to increase osmolarity), cells need to constantly actively regulate their intracellular osmolarity by pumping out small inorganic ions (typically sodium and chloride). Loss of the ability to generate energy (e.g., in a cell injured by toxins or lacking oxygen) therefore results in an osmotically swollen, and eventually ruptured, cell.

Uptake and metabolism of large extracellular molecules requires vesicle targeting and membrane recycling. Proteins, large carbohydrates, and other macromolecules cannot enter cells by either channels or carriers. Instead, they are internalized by endocytosis (see Fig. 3). Endocytosis begins at a specialized region of the plasma membrane called the clathrin-coated pit, which rapidly invaginates and pinches off to form a clathrin-coated vesicle (about 2500 per minute in a typical fibroblast). Clathrin is a hexamer of proteins that spontaneously assemble into a basket-like lattice to drive the budding process of endocytosis. Trapped within the vesicle will be a minute gulp of the extracellular milieu, as well as any molecules specifically bound to receptors on the internalized bit of plasma membrane (receptor-mediated endocytosis). This is the pathway, for example, by which cells internalize iron from the circulation: ionized iron, bound to a protein called transferrin, interacts with cell surface transferrin receptors, which are then internalized via receptor-mediated endocytosis.

The vesicles rapidly lose their clathrin coat and then fuse with an acidic intracellular structure called the endosome, where they discharge their contents for digestion and further passage to the lysosome (Fig. 4 and later discussion). After release of bound ligand, receptors can either return to the plasma membrane for another cycle (e.g., the transferrin receptor) or may be degraded [e.g., the low-density lipoprotein (LDL) receptor]. Degradation of a receptor after internalization (receptor down-regulation) provides an important control for receptor expression and receptor-mediated signaling. Endocytosis can also deliver material completely across a cell, i.e., from the apical surface to the basolateral face (transcytosis), forming the basis for transport of nutrients from the gastrointestinal tract to the blood stream. Endocytosis is an

FIG. 3. Schematic of receptor-mediated endocytosis, enabling large molecules (e.g., transferrin with bound iron) to enter the cell. After binding to specific receptors, proteins will be internalized on clathrin-coated pits, which pinch off to form clathrin-coated vesicles. The clathrin coat is then removed and the vesicle fuses with endosomes delivering its bound contents. After fusion, vesicles may pinch off from the endosome and recycle to the plasma membrane (exocytosis, not shown). (Reproduced by permission from Bergman, A. R., Afifi, A. K., and Heidger, P. M., eds., 1996. *Histology*. Saunders, Philadelphia.)

FIG. 4. Schematic demonstrating the pathways by which internalized material is degraded. There is convergence of endocytic, phagocytic, and autophagic vesicles as they fuse with newly synthesized hydrolase-containing vesicles or with preexisting lysosomes. The contents are nearly completely degraded to constituent amino acids, sugars, and lipids; nondegradable material will accumulate in residual bodies. (Reproduced by permission from Bergman, A. R., Afifi, A. K., and Heidger, P. M., eds., 1996. *Histology*. Saunders, Philadelphia.)

ongoing process, with constant recycling of vesicles back to the plasma membrane (exocytosis). Endocytosis and exocytosis must be tightly coupled since a cell will internalize 10–20% of its own cell volume each hour, or about 1–2% of its plasma membrane each minute.

Cell communication is critical in multicellular organisms. At the most basic level, extracellular signals may determine whether a cell lives or dies, whether it remains quiescent, proliferates, migrates, or otherwise becomes active to perform its specific function(s). Intercellular signaling is critical in the developing embryo in order that that cells appear in the correct quantity and location, and in maintaining tissue organization. Intercellular signaling is also important in the intact organism, ensuring that all tissues act in appropriate concert in response to stimuli as divergent as food or threat to life. Loss of communication may be reflected in a congenital structural defect in the first instance, or in unregulated cell growth (cancer) or an ineffective response to an extrinsic stress in the second.

Cells communicate over short or long distances. Adjacent cells may communicate via gap junctions, which are narrow, hydrophilic channels that effectively connect the two cells' cytoplasm. The channels permit movement of small ions, various metabolites, and potential second messenger molecules, but not larger macromolecules. Extracellular signaling via soluble mediators occurs in three different forms:

1. Paracrine, meaning that it affects cells only in the immediate vicinity. To accomplish this, there can be only minimal diffusion, with the signal rapidly degraded, taken up by other cells, or trapped in the ECM.
2. Synaptic, where activated neural tissue secretes neurotransmitters at a specialized cell junction (synapse) onto target cells.
3. Endocrine, where a regulatory substance, such as a hormone, is released into the blood stream and acts on target cells at a distance.

Since most signaling molecules are present at extremely low concentrations ($\leq 10^{-8}$ M), binding to the appropriate target cell receptor is typically a high-affinity and exquisitely specific interaction. Receptor proteins may be on the cell surface or they may be intracellular; in the latter case, ligands must

be sufficiently hydrophobic to enter the cell (e.g., vitamin D, or steroid and thyroid hormones). For intracellular receptors, ligand binding leads to formation of a receptor–ligand complex that directly associates with nuclear DNA and subsequently either activates or turns off gene transcription. For cell-surface receptors, the binding of ligand can (1) open ion channels (e.g., at the synapse between electrically excitable cells), (2) activate an associated GTP-binding regulatory protein (G protein), or (3) activate an associated enzyme. Secondary intracellular downstream events frequently involve phosphorylation or dephosphorylation of target molecules, with subsequent changes in enzymatic activity.

An individual cell is exposed to a remarkable cacophony of signals, which it must sort through and integrate into a rational response. One ligand may induce a given cell type to differentiate, another may signal proliferation, and yet another may direct the cell to perform a specialized function. Multiple ligands at once, in a certain ratio, may signal yet another unique response. Many cells require certain signals just to continue living; in the absence of appropriate exogenous ligand, they may undergo a form of cellular suicide called apoptosis, or programmed cell death.

THE CYTOSKELETON: CELLULAR INTEGRITY AND MOVEMENT

The ability of cells to adopt a particular shape, maintain cell polarity, organize the relationship of intracellular organelles, and move depends on the intracellular scaffolding of proteins called the cytoskeleton. In eukaryotic cells there are three major classes of cytoskeletal proteins: 6- to 8-nm-diameter actin microfilaments, 10-nm-diameter intermediate filaments, and 25-nm-diameter microtubules. Although these proteins impart some structure (especially the intermediate filaments), it should also be emphasized that they are all dynamic. In particular, actin and microtubules are also used by cells to achieve movement or cellular contraction.

The globular protein actin (G-actin, 43,000 daltons) is the major subunit of microfilaments and is the most abundant cytosolic protein in cells. The monomers polymerize into long double-stranded helical filaments (F-actin), with a defined polarity (one end is stable, the other end grows or shrinks). In muscle cells, the filamentous protein myosin binds to actin and moves along it, driven by ATP hydrolysis forming the basis of muscle contraction. In nonmuscle cells, F-actin and an assortment of actin-binding proteins form well-organized bundles and networks that control cell shape and surface movements.

Intermediate filaments comprise a large and heterogeneous family of closely related structural proteins. Although they generally perform similar functions, each member of the family has a relatively restricted expression in specific cell types. These ropelike fibers are found predominantly in a stable polymerized form within cells; they are not usually actively reorganizing like actin and microtubules. Intermediate filaments impart strength and carry mechanical stress, e.g., in epithelia where they connect spot desmosomes (see below). They also form the major structural proteins of skin and hair (i.e., keratin).

Microtubules consist of polymerized dimers of α - and β -tubulin arrayed in constantly elongating or shrinking

hollow tubes. These have a defined polarity with ends designated “+” or “–.” In most cells, the “–” end is embedded in a microtubule organizing center (MTOC or centrosome) that lies near the nucleus; the “+” end elongates or recedes in response to various stimuli by the addition or subtraction of tubulin dimers. Within cells, microtubules may serve as mooring lines for protein “molecular motors” that hydrolyze ATP to move vesicles, organelles, or other molecules around cells; the polarity of the microtubules allows cells to direct whether attached structures are “coming” or “going” relative to the nucleus. In neurons, microtubules are critical for the delivery of molecules synthesized in the nuclear area to the far-flung reaches of the cytosol of the axon, which may be as far away as 10,000 times the width of the cell body (indeed, the nuclei of some motor neurons in the spinal cord have axons extending to the muscles of the big toe over 3 feet away!). Microtubules are also used to move chromosomes apart during mitosis, and thus play a basic role in cellular proliferation. Finally, in certain cells, microtubules and their associated molecular motors have been harnessed to facilitate cellular motility—they form cilia to move mucus and dust out of the airways and flagella to propel sperm.

Maintaining cellular and tissue integrity requires cell–cell and cell–ECM interactions, mediated through the plasma membrane and translated into the cytoskeleton. The organization of tissues requires attaching cells together and to the underlying ECM scaffolding. These surface attachments are connected via transmembrane proteins to the cytoskeletal elements. Thus, extracellular perturbations in a tissue may be translated into intracellular events.

As discussed earlier, the external face of a cell membrane is diffusely studded with carbohydrate-modified (glycosylated) proteins and lipids. This cell coat (or glycocalyx) functions primarily as a chemical and mechanical barrier, but also serves an important role in cell–cell and cell–matrix interactions, including sperm–egg attachment, blood clotting, lymphocyte recirculation, and inflammatory responses. For example, neutrophils (cells involved in acute inflammation) are recruited to sites of infection by local vascular wall cell expression of lectin-like molecules (selectins) that bind specific sugars expressed on the circulating cells.

Cell–cell connections include occluding junctions (tight junctions) and anchoring junctions (desmosomes) (Fig. 5) [gap junctions (described earlier) function primarily in cell-to-cell communication and do not materially contribute to cellular adhesiveness]. Tight junctions seal cells together in a continuous sheet, preventing even small molecules (but not water) from leaking from one side to the other. These junctions are the basis of the high electrical resistance of many epithelia, as well as the ability to segregate apical and basolateral spaces. It is important to remember, however, that these junctions (as well as the desmosomes) are also dynamic structures that intermittently dissociate and reform. This permits processes as diverse as healing of an epithelial wound, or allowing passage of inflammatory cells across vascular endothelium to sites of infection. Intracellular actin microfilaments are connected to these tight junctions and span from side to side across the cell. This creates a circumferential band (adhesion belt) of cytoskeleton that provides structural integrity and shear strength to the sheets of interconnected cells.

FIG. 5. Diagram of two prototypical epithelial cells (imagine these as part of a larger planar sheet) demonstrating attachments to the underlying basal lamina (hemidesmosomes) and to each other (tight junction, adhesion belt, and spot desmosomes). Note the cytoskeletal elements underlying each attachment point giving structural integrity to the individual cells as well as to the larger epithelial structure. Gap junctions do not confer intercellular adhesion, but are responsible for intracellular signaling. (Reproduced by permission from Bergman, A. R., Afifi, A. K., and Heidger, P. M., eds., 1996. *Histology*. Saunders, Philadelphia.)

Desmosomes mechanically attach cells (and their cytoskeletons) to other cells or the ECM. When they occur in broad belts or bands between cells, they are referred to as belt desmosomes; when they are small and rivet-like, they are denoted as spot desmosomes. Desmosomes are formed by a homotypic association (two proteins of the same type) of transmembrane glycoproteins called cadherins. The cytosolic ends of cadherins are associated with cytoskeletal actin microfilaments and intermediate filaments. Focal adhesion complexes or hemidesmosomes (literally, half a desmosome) are “spot welds” that connect cells to the extracellular matrix; in the case of epithelial tissues, the connections are to a dense ECM meshwork called the basal lamina or basement membrane (see Chapter 3.4). The plasma membrane proteins forming the basis of these interactions are called integrins; like cadherins, they attach to intracellular intermediate filaments. These focal adhesion complexes, connecting cells to the ECM, also act to generate intracellular signals when cells are subjected to increased shear stress (such as endothelium in a turbulent area of the blood stream).

THE NUCLEUS: CENTRAL CONTROL

With the exception of the terminally differentiated hematopoietic cells (erythrocytes and platelets), every human cell has a central regulatory nucleus containing nucleic acids (DNA and RNA) and proteins that determine the sequence and rate of macromolecular synthesis. The full complement of DNA in a cell is called its genome.

The nucleus is not a uniform static repository of molecules. At any given time, and depending on the functional state of

the cell, there will be active replication (duplication of DNA) or transcription (conversion of DNA into messenger RNA) of selected subsets of the genome. Clearly, proliferating cells will be busily generating an entire copy of all nuclear material so that daughter cells can be each afforded a complete set of genetic material. It is also intuitive that cells actively synthesizing and exporting specific proteins will have frenzied activity surrounding those relevant genes. However, even apparently quiescent cells have a constant turnover of proteins and organelles, requiring a tightly orchestrated on-and-off switching of the correct genes in the correct sequence.

Nuclear proteins and nucleic acids are organized into clumps and clusters called chromatin. Two basic forms of chromatin are recognizable by light microscopy and routine staining correlating with the activity of the gene. When genes are transcriptionally inactive, they are tightly coiled in compact aggregates wrapped around protein histones and are not accessible to transcription machinery. This results in a cytochemically dense appearance called heterochromatin. In actively transcribing genes, the nuclear material uncoils into a more extended linear form, which is cytochemically disperse and called euchromatin. The degree of cellular activation or gene transcription may thus be inferred from the general staining characteristics of nuclei (Fig. 6). The nucleolus is a subcompartment of the nucleus dedicated to ribosomal RNA

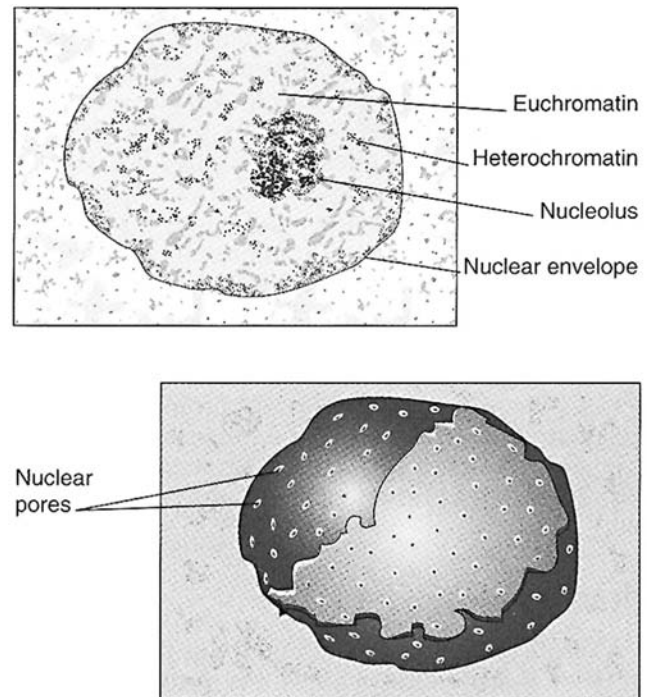

FIG. 6. Diagram of the nucleus and nuclear pore system. (Top). Illustration of heterochromatin (clumped nontranscribing nuclear material), euchromatin (dispersed, transcribing nuclear material), and nucleolus (site of ribosome synthesis). (Bottom) Schematic representation of nuclear pores; note that they are not passive openings in the nuclear envelope, but rather are selective transporters. (Reproduced by permission from Bergman, A. R., Afifi, A. K., and Heidger, P. M., eds., 1996. *Histology*. Saunders, Philadelphia.)

synthesis and ribosome assembly. Its size may also reflect the translational activity of the cell; the greater the protein synthesis, the larger the nucleolus.

Movement of molecules into and out of the nucleus is restricted and tightly regulated. The nucleus is surrounded by a nuclear envelope formed by two concentric membranes supported by networks of intermediate filaments. The outer membrane is continuous with the endoplasmic reticulum and is joined to the inner membrane at numerous nuclear pores that punctuate the envelope. The pores are elaborate, gated structures that permit the active transport of molecules to and from the cytosol. Since the pores are freely permeable only to globular proteins $\leq 50,000$ daltons, the process of moving large molecules and complexes (e.g., ribosomes out of the nucleus, or histones and polymerase complexes into the nucleus) is accomplished by specific receptor proteins. Macromolecules destined for the nucleus are identified by specific nuclear localization signals (typically certain amino acid sequences) that permit binding to the pore receptor proteins. Of note, these localization signals may be cryptic, as in some inactive steroid receptor proteins. Subsequent binding of the steroid ligand causes a conformational change that uncovers the localization signal; the receptor can then be translocated to the nucleus.

ROUGH AND SMOOTH ENDOPLASMIC RETICULUM, AND GOLGI APPARATUS: BIOSYNTHETIC MACHINERY

The endoplasmic reticulum (ER) is the site for the synthesis of all the transmembrane proteins and lipids for most of a cell's organelles, including the ER itself. It is also the initial site for the synthesis of the majority of molecules destined for residence in the inside of ER, Golgi, and lysosomes, or for export out of the cell. The ER is organized into a mesh-like maze of interconnecting branching tubes and flattened vesicles (see Fig. 1) forming a continuous sheet around a single highly convoluted space topologically equivalent to the extracellular environment. The ER is composed of contiguous but distinct domains, distinguished by the presence (rough ER or RER) or absence (smooth ER or SER) of ribosomes.

Membrane-bound ribosomes on the cytosolic face of RER are actively translating mRNA into proteins, which are folded and edited in the lumen of the ER (Fig. 7). This process, called translation, is directed by amino acid signal peptides generally present on the N-termini of nascent proteins; if a new protein with a signal peptide is produced on a free ribosome, the signal peptide directs the entire complex to attach to the ER membrane. Proteins synthesized in this way are directly inserted into the ER as they are being made. Within the ER lumen, the proteins fold and form multisubunit complexes under the scrutiny of ER chaperone molecules. These chaperones interact with a variety of proteins within the ER ensuring that they are completely assembled and functional. Failure to appropriately fold results in retention and eventually degradation within the ER; thus the ER has an editing function for safeguarding the fidelity of the transcriptional apparatus.

For proteins lacking a signal sequence, the translation apparatus remains on free ribosomes in the cytosol, frequently

FIG. 7. Schematic demonstrating the general steps in the synthesis of proteins on rough endoplasmic reticulum (RER). (A) Peptide synthesis from mRNA begins on free ribosomes in the cytosol. (B) Signal peptide sequences on the nascent proteins direct the entire complex to attach to the ER membrane with insertion of the synthesizing protein into the RER lumen. (C) The signal sequence is cleaved and the protein is completely synthesized, eventually detaching from the ribosome. (D) The protein is folded and assembled (if necessary) into multi-subunit complexes; the ribosome detaches from the ER surface and returns to the cytoplasm. (Reproduced by permission from Bergman, A. R., Afifi, A. K., and Heidger, P. M., eds., 1996. *Histology*. Saunders, Philadelphia.)

forming polyribosomes as multiple translation units attach to the mRNA; the resulting protein remains within the cytoplasm and is not exported from the cell.

After leaving the RER, proteins and lipids are modified in the Golgi apparatus and sorted for intracellular delivery (Fig. 8). In the Golgi proteins are glycosylated—modified by

FIG. 8. Functional, schematic diagram of the relationship among the rough endoplasmic reticulum (RER), smooth endoplasmic reticulum (SER), and the Golgi apparatus. Proteins destined for export or for other intracellular organelles pass from the RER to the SER where they form vesicles for transport to the Golgi; there they are progressively modified and sorted, eventually leaving in transport vesicles to their appropriate final destination. (Reproduced by permission from Bergman, A. R., Afifi, A. K., and Heidger, P. M., eds., 1996. *Histology*. Saunders, Philadelphia.)

a stepwise addition of various sugars. These modifications are important in subsequent sorting of molecules to various intracellular sites, and also because glycosylation is critical for surface molecules involved in cell–cell or cell–matrix interactions. In addition to the stepwise glycosylation of lipids and proteins, the trans Golgi network sorts molecules for dispatch to other organelles (including the plasma membrane) or secretory vacuoles destined for extracellular release. The Golgi complex is especially prominent in cells specialized for secretion, including goblet cells of the intestine or bronchial epithelium (making large amounts of polysaccharide-rich mucus), and plasma cells (secreting antibodies).

The SER has a role in steroid hormone synthesis, modification of certain metabolites, and intracellular calcium regulation. The SER in most cells is relatively sparse. However, in cells that synthesize steroid hormones (e.g., the adrenal cortex or gonads) or that catabolize lipid-soluble molecules (e.g., liver cells make certain drugs more water-soluble so that they may be excreted), the SER may be particularly conspicuous. The SER is also responsible for sequestering intracellular Ca^{2+} ; release of Ca^{2+} from the SER is a mechanism by which cells can rapidly respond to extracellular signals. Finally, in muscle cells, specialized SER called sarcoplasmic reticulum regulates the successive cycles of myofiber contraction (Ca^{2+} released into the cytosol) and relaxation (Ca^{2+} pumped back into the SER).

LYSOSOMES AND PROTEASOMES: WASTE DISPOSAL

To digest internalized macromolecules or senescent organelles, cells primarily rely upon lysosomes. Lysosomes are membrane-bounded organelles containing a large assortment (>40) of acid hydrolase enzymes including proteases, nucleases, lipases, glycosidases, phosphatases, and sulfatases. Each has an optimal activity at pH 5, which is a protective feature since these enzymes will do less damage should they leak into the pH 7.2 cytosol. Materials destined for catabolism arrive in the lysosomes by one of three pathways:

1. Internalized by fluid-phase or receptor-mediated endocytosis. Material passes from plasma membrane to early endosome to late endosome, and ultimately into the lysosome (see Fig. 4).
2. Obsolete organelles within cells (the average mitochondrion, for example, only lives 10 days) are shuttled into lysosomes by a process called autophagy. The resultant autophagosome then fuses with lysosomes and the organelle is catabolized.
3. Phagocytosis of microorganisms or large fragments of matrix or debris occurs primarily in professional phagocytes (macrophages or neutrophils). The material is engulfed to form a phagosome that subsequently fuses with a lysosome.

Proteasomes degrade cytosolic molecules that are senescent or require constant turnover to regulate their activity. The cytosol also needs to have a mechanism to degrade misfolded proteins (like the ER chaperone function) and to regulate the longevity of certain other proteins that turn over at

discrete rates. To do this, many proteins destined for destruction are marked by covalently binding one or more 76-amino-acid proteins called ubiquitin; ubiquitin-tagged molecules are then fed into a large polymeric protein complex called the proteasome. Each proteasome is a cylinder composed of several different proteases, each with its active site pointed at the hollow core; proteins are degraded into small (6–12 amino acids) fragments. This degradative mechanism is thought to be a holdover from prokaryotes (i.e., primitive cellular organisms) that lack lysosomes.

MITOCHONDRIA: ENERGY GENERATION

Energy to run intracellular processes is extracted from adenosine triphosphate generated by mitochondria. Mitochondria accomplish ATP production by utilizing by-products of carbohydrate oxidation (such as glucose) to CO_2 and water through the glycolytic pathway that breaks down glucose to pyruvate or lactate (in the cell cytosol), the metabolism of pyruvate to carbon dioxide and water through the Krebs cycle, and oxidative phosphorylation. (The latter two occur in the mitochondria.) These reactions, and particularly oxidative phosphorylation (the process of generating ATP from substrate oxidation), are critically dependent on the availability of oxygen. When oxygen is present, 38 ATP are generated from metabolism of one glucose molecule; in the absence of oxygen, only two molecules of ATP are generated. ATP hydrolysis, the chemical reaction that removes a terminal phosphate from ATP, is accompanied by the release of a large amount of energy. Breakdown of fats and proteins also contributes to ATP production. The energy derived from the hydrolysis of ATP is used for cell needs such as active transport of ions and molecules across membranes, synthesis of molecules for cell housekeeping and for export, and specialized cell functions such as contraction of muscle.

Each mitochondrion has two separate and specialized membranes. There is a core matrix space (containing most of the enzymes for breaking down glucose and its primary metabolites) surrounded by an inner membrane (containing the enzymes to transfer electrons to oxygen) folded into cristae; these constitute the major working parts of the organelle. The inner membrane is enclosed by the intermembrane space (site of ADP to ATP phosphorylation), which is in turn surrounded by the outer membrane; the latter is studded with a transport protein called porin, which forms aqueous channels permeable to low-molecular-weight substrates (Fig. 9). Mitochondria are also central to the pathways leading to apoptosis (see later discussion).

Mitochondria probably evolved from ancestral prokaryotes engulfed by primitive eukaryotes about 1–2 billion years ago. That explains why mitochondria contain their own DNA (circularized, about 1% of the total cellular DNA) encoding for approximately one-fifth of the proteins involved in oxidative phosphorylation. Although the mitochondrial DNA codes for only a very small number of proteins, mitochondria have the machinery necessary to carry out all the steps of DNA replication, transcription, and translation. Consistent with its evolutionary origin, mitochondrial translational machinery is

FIG. 9. Schematic diagram of the mitochondrion demonstrating the functional segregation of the enzymatic machinery required to generate ATP. (Reproduced by permission from Bergman, A. R., Afifi, A. K., and Heidger, P. M., eds., 1996. *Histology*. Saunders, Philadelphia.)

similar to present-day bacteria. For example, protein synthesis is initiated with the same modified amino acid as bacteria (*N*-formylmethionine) and is sensitive to the same antibiotics. It is noteworthy that new mitochondria can only derive from preexisting mitochondria. Thus, since the ovum contributes the vast majority of cytoplasmic organelles in the fertilized zygote, mitochondrial DNA is maternally inherited.

CELL SPECIALIZATION AND DIFFERENTIATION

As discussed earlier, basic functional attributes of cells include nutrient absorption and assimilation, respiration, synthesis of macromolecules, growth, and reproduction. Without these basic activities, cells cannot live. However, most cells also exhibit specialization, that is, they have additional capabilities, such as irritability, conductivity, absorption, or secretion of molecules (for use by other cells). Multicellular organisms are thus composed of individual cells with marked specialization of structure and function. These differentiated cells allow a division of labor in the performance and coordination of complex functions carried out in architecturally distinct and organized tissues.

Differentiated cells have developed well-defined structural and/or functional characteristics associated with increasing specialization. For example, striated muscle cells have well-organized actin and myosin filaments that slide over one another, facilitating cellular contraction. Gastric (stomach) epithelial cells have large numbers of mitochondria to generate the ATP necessary to pump hydrogen ions out of the cell against a concentration gradient and acidify the stomach contents. Skin keratinocytes function as a protective barrier by losing their organelles and becoming scale-like structures filled with durable, nonliving keratin (an intermediate filament). Specialized phagocytic cells of the immune system must detect infectious microorganisms (e.g., bacteria,

parasites, and viruses), actively migrate to them, and then ingest and destroy them. Polymorphonuclear leukocytes (also called PMNs or neutrophils) are particularly active against bacteria, and macrophages react to other types of organisms and foreign material. B lymphocytes are not phagocytic but contribute to immunity by producing antibodies that can bind and neutralize infectious agents.

The structural and functional changes that occur during cellular differentiation are usually irreversible. Moreover, increasing specialization results in a loss of cell potentiality, as well as a loss in the capacity for cell division. For example, the newly fertilized ovum is absolutely undifferentiated and has the capacity to divide extensively, ultimately giving rise to progeny that make up all the cells of the body. These initially undifferentiated cells are said to be totipotent or pluripotent. As cells differentiate into particular tissue pathways, they lose the ability to interconvert and develop into all cell types; with further differentiation, cells may lose the ability to replicate at all. Thus, cells capable of dividing to produce several (but not all) types of cells are multipotent. Cells capable of both dividing and yielding differentiated cells of one or more types are called stem cells. Conversely, nerve cells and heart muscle cells are considered to be examples of highly specialized cells that, according to traditional teaching, can neither differentiate into other tissue types nor reproduce. Obviously, this has clinical significance when these terminally differentiated cells are injured (e.g., by stroke or heart attack). Nevertheless, recent evidence suggests that cells of end-stage, specialized and highly differentiated tissues can, under certain conditions such as following injury, dedifferentiate into multipotent forms or serve as stem cells capable of generating more specialized cells (Lee *et al.*, 2003; Nadal-Ginard *et al.*, 2003; Zheng *et al.*, 2003).

Cellular differentiation involves an alteration in gene expression. Every cell in the body has the same complement of genes (called the genotype). With progressive differentiation, selected subsets of genes are preferentially expressed, yielding a distinct biological profile (called the phenotype). As cells progressively specialize, more and more of the “unnecessary” genes in the differentiating cell are irreversibly turned off. Some genes are active at all times (constitutively expressed); others may be selectively activated or modulated depending on external influences (e.g., injury).

CELL INJURY AND REGENERATION

Cells constantly adjust their structure and function to accommodate alterations in their environment, particularly responding to chemical and mechanical stressors (Fig. 10). Cells attempt to maintain their intracellular milieu within relatively narrow physiologic parameters—i.e., they maintain normal homeostasis. Consequently, as they encounter physiologic stresses or pathologic stimuli, cells and tissues can adapt, achieving a new steady state and preserving viability. The principal adaptive responses are:

- Hypertrophy: an increase in size of individual cells
- Hyperplasia: an increase in cell number

FIG. 10. The sequential cellular structural changes seen in necrosis (left) versus apoptosis (right). In necrosis, there is chromatin clumping, organelle swelling, and eventually membrane damage; dead cells typically must be degraded and digested by an influx of inflammatory cells. In apoptosis, the initial changes consist of nuclear chromatin condensation and fragmentation, followed by cytoplasmic budding of apoptotic bodies, and eventual phagocytosis by adjacent cells of the extruded cell fragments. (Reproduced by permission from Cotran, R. S., Kumar, V., and Collins, T., 1999. *Robbins Pathologic Basis of Disease*, 6th ed. Saunders, Philadelphia.)

Atrophy: a decrease in size, without appreciable change in cell number

Metaplasia: transformation from one mature cell type to another

There may also be more subtle changes in the expression of selected genes that are functionally beneficial but are not necessarily reflected in alterations of morphology.

Usually, if the extracellular stressors recede, the cells and tissues will revert to their prestressed state. However, if the stressors persist and a cell's adaptive capability is exceeded, cell injury develops. Up to a point, cell injury itself is reversible, and with normalization of the stimulus, the cell returns to its baseline state, usually no worse for wear. However, with severe or persistent stress, the cell suffers irreversible injury and dies.

For example, when heart muscle cells are subjected to persistent increased load (e.g., high blood pressure), the cells adapt by undergoing hypertrophy (enlargement of the individual myocytes, and eventually the entire heart) to compensate for the higher pressures they must pump against. Conversely, in periods of prolonged starvation (as can happen in prolonged illness or with malignant tumors), all myocytes (and thus the heart) will undergo atrophy. The same myocytes, subjected to an imbalance between blood supply and energy demand due to an occluded coronary artery (ischemia), may be reversibly injured if the occlusion is incomplete or sufficiently brief; alternatively, they may undergo irreversible injury (i.e., cell death,

as in myocardial infarction) following complete or prolonged occlusion.

Moreover, certain genetic abnormalities and/or environmental stimuli may trigger abnormal tissue growth that is uncoordinated relative to normal tissues, has lost its responsiveness to normal growth controls, and persists after cessation of the stimuli that initiated it. This condition is called "neoplasia"; in its malignant form, this is more commonly called cancer (see Chapter 4.7).

CAUSES OF CELL INJURY

Hypoxia and ischemia. Hypoxia is decreased O_2 supply relative to the needs of a particular tissue. Anoxia is the complete absence of oxygen. Hypoxia due to diminished blood flow is called ischemia; irreversible tissue injury (necrosis) due to ischemia is called infarction. Note that although diminished blood flow will invariably lead to hypoxia, oxygen deficiency can occur in the setting of adequate tissue perfusion.

Chemical injury. Chemical agents include components of food, naturally occurring toxins, hormones, neurotransmitters, synthetic drugs, environmental pollutants, poisons, ethanol, tobacco, even toxic biomaterials. Chemicals induce cell injury by one of two general mechanisms:

- By combining directly with a critical molecular component or cellular organelle and thereby inhibiting its normal activity. Chemotherapeutic drugs generally fall into this category.
- Chemicals that are not intrinsically biologically active may be converted to toxic metabolites during normal physiologic breakdown. Such modification is usually accomplished by the P-450 mixed function oxidases in the smooth endoplasmic reticulum (SER) of the liver, and the most important mechanism of cell injury is by formation of free radicals (see below). Acetaminophen belongs to this category of compounds.

Biologic agents. Infectious agents run the gamut from virus and bacteria to fungi, protozoans, and helminths. There is generally a preferred cell or tissue of invasion (called a tropism), and therefore each agent tends to have a defined spectrum of potential injury. Viruses multiply intracellularly, appropriating host biosynthetic machinery in the process; cell lysis may occur directly, or as a result of the immune system's recognition and destruction of infected cells. More insidiously, viruses may compromise the ability of a cell or tissue to perform its normal functions; worse still, viruses may play a role in transformation to malignant neoplasms. Bacteria have toxic cell wall constituents (e.g., endotoxin) and can release a variety of exotoxins. Moreover, the very process of eradicating infections can also cause injury.

Physical injury. Injury can result by direct mechanical force (trauma, pressure), temperature extremes (burn, frostbite), electric shock, or ionizing radiation.

Genetic defects. Mutations in a variety of cellular proteins can lead to cellular dysfunction and eventually irreparable cellular injury. Congenital defects generally manifest as progressive disorders; examples include lysosomal storage diseases where progressive accumulation of certain nondegradable metabolites eventually causes cell rupture, disorders of muscle (myopathies) due to defective energy synthesis by mitochondria, and sickle-cell anemia caused by a mutated hemoglobin that results in stiff, nondeformable red blood cells.

PATHOGENESIS OF CELL INJURY

There are two basic mechanisms of cell injury due to any cause:

Oxygen and oxygen-derived free radicals. Lack of oxygen obviously underlies the pathogenesis of cell injury in ischemia, but in addition partially reduced, activated oxygen species are important mediators of cell death. Free radicals are chemical species with a single unpaired electron in an outer orbital; they are extremely unstable and readily react with inorganic or organic chemicals. The most important ones in biological systems are oxygen-derived and include hydroxyl (OH^\bullet) radicals (from the hydrolysis of water, e.g., by ionizing radiation), superoxide radicals ($\text{O}_2^{\bullet-}$), and nitric oxide radicals (NO^\bullet). Free radicals initiate autocatalytic reactions; molecules that react with free radicals are in turn converted into free radicals, further propagating the chain of damage. When generated in cells, they cause single-strand breaks in DNA, fragment lipids in membranes via lipid peroxidation, and fragment or cross-link proteins leading to accelerated degradation or loss of enzymatic activity. Free-radical damage is a pathogenic mechanism in such varied processes as chemical and radiation injury, oxygen and other gaseous toxicity, cellular aging, microbial killing by phagocytic cells, inflammatory damage, and tumor destruction by macrophages, among others.

It is important to note that besides being a consequence of chemical and radiation injury, free-radical generation is also a normal part of respiration and other routine cellular activities, including microbial defense. It therefore makes sense that cells and tissues have developed mechanisms to degrade free radicals and thereby minimize any injury. Fortunately, free radicals are inherently unstable and generally decay spontaneously; superoxide, for example, rapidly breaks down in the presence of water into oxygen and hydrogen peroxide. The rate of such decay is significantly increased by the action of superoxide dismutases (SODs) found in many cell types. Other enzymes, e.g., glutathione (GSH) peroxidase, also protect against injury by catalyzing free radical breakdown, and catalase directs the degradation of hydrogen peroxide. In addition, endogenous or exogenous antioxidants, e.g., vitamin E, may either block free radical formation or scavenge them once they have formed.

Failure of intracellular ion homeostatic mechanisms is also important. Cytosolic free calcium is normally maintained by ATP-dependent calcium transporters at extremely low concentrations (less than $0.1 \mu\text{M}$); this is in the face of sequestered mitochondrial and endoplasmic reticulum calcium stores, and an extracellular calcium typically at 1.3 mM (or about a 10^4 -fold gradient). Ischemic or toxin-induced injuries allow a net influx of extracellular calcium across the plasma membrane, followed by release of calcium from the intracellular stores. Increased cytosolic calcium in turn activates a variety of phospholipases (promoting membrane damage), proteases (catabolizing structural and membrane proteins), ATPases (accelerating ATP depletion), and endonucleases (fragmenting genetic material).

RESPONSES TO CELL INJURY

Whether a specific form of stress induces adaptation or causes reversible or irreversible injury depends not only on the nature and severity of the stress, but also on several other cell-specific variables including vulnerability, differentiation, blood supply, nutrition, and previous state of the cell.

- Cellular response to injurious stimuli depends on the type of injury, its duration, and its severity. Thus, low doses of toxins or a brief period of low blood flow (ischemia) may lead only to reversible cell injury, whereas larger toxin doses or longer ischemic intervals may result in irreversible injury and cell death.
- Consequences of an injurious stimulus are also dependent on the type of cell being injured, its current status (nutritional, hormonal, etc.), and its adaptability. For example, striated skeletal muscle in the leg can tolerate complete ischemia for 2–3 hours without suffering irreversible injury, whereas cardiac muscle will die after only 20–30 minutes, and CNS neurons are dead after 2–3 minutes. Similarly, a well-nourished liver can withstand an ischemic or anaerobic challenge far better than a liver without any energy reserve.
- Four intracellular systems are particularly vulnerable to injury:
 - (i) Aerobic respiration, important in generating the adenosine triphosphate (ATP) energy stores that maintain the intracellular ion gradients (by active pumping) and synthetic pathways
 - (ii) Cell membrane integrity, critical to cellular ionic and osmotic homeostasis
 - (iii) Protein synthesis
 - (iv) Integrity of the genetic apparatus

Most injury alters (in one form or another) the ability of cells to generate energy (make ATP) to run the various intracellular housekeeping chores. Hypoxia and ischemia are the most common ways that energy production is abated in the human body. The first effect of hypoxia is on the cell's aerobic respiration, i.e., oxidative phosphorylation by mitochondria;

as a consequence of reduced oxygen tension, the intracellular generation of ATP is markedly reduced. In quick succession:

1. The activity of the plasma-membrane ATP-driven sodium pump (Na^+/K^+ -ATPase) declines with accumulation of intracellular sodium and diffusion of potassium out of the cell. The net gain of sodium solute is accompanied by an isosmotic gain of water, producing acute cellular swelling.
2. This is further exacerbated by the increased osmotic load from the accumulation of other metabolites, including inorganic phosphates, lactic acid, and purine nucleosides, as the cell struggles to generate ATP via anaerobic pathways. The cytoplasm also becomes acidic.
3. Ribosomes begin to detach from the rough endoplasmic reticulum and polysomes dissociate into monosomes, with consequent reduction in protein synthesis.
4. Worsening mitochondrial function and increasing membrane permeability cause further morphologic deterioration with dispersion of the cytoskeleton and formation of cell surface “blebs.” Organelles, and indeed whole cells, appear swollen because of loss of osmotic regulation. Precipitation of intracellular proteins and organelles in conjunction with the cellular edema leads to the microscopic appearance of “cloudy swelling.”

NECROSIS

If the injurious stimulus is removed, all the above disturbances are potentially reversible; if it persists, cell death may follow. For example, in ischemic injury, if oxygen is restored, all of the above disturbances are potentially reversible. However, if ischemia persists, irreversible injury follows; the cells and tissue become necrotic (undergo necrosis). Two phenomena consistently characterize irreversibility. The first is the inability to reverse mitochondrial dysfunction (lack of oxidative phosphorylation and ATP generation) even upon restoration of oxygen; the second is the development of profound disturbances in membrane function. Massive calcium influx into the cell occurs, particularly if ischemic tissue is reperfused after the point of irreversible injury, with broad activation of calcium-dependent catabolic enzymes. Precipitation of calcium salts in cells (calcification) is discussed in detail in Chapter 6.4. Proteins, essential coenzymes, and ribonucleic acids seep out through the newly permeable membranes, and the cells also lose metabolites vital for the reconstitution of ATP. Injury to the lysosomal membranes results in leakage of their enzymes into the cytoplasm; the acid hydrolases are activated in the reduced intracellular pH of the ischemic cell and will further degrade cytoplasmic and nuclear components.

APOPTOSIS

Apoptosis (from root words meaning “a falling away from”) has in the past decade been appreciated as a relatively distinctive and important mode of cell death that should be differentiated from standard-variety necrosis (Fig. 10). Apoptosis

is responsible for the programmed cell death (or cellular “suicide”) in several important physiologic (as well as pathologic) processes:

- The programmed destruction of cells during embryogenesis, including implantation, organogenesis, and developmental involution
- Hormone-dependent physiologic involution, such as the endometrium during the menstrual cycle, or the lactating breast after weaning; or pathologic atrophy, as in the prostate after castration
- Cell deletion in proliferating populations such as intestinal crypt epithelium, or cell death in tumors
- Deletion of autoreactive T cells in the thymus, cell death of cytokine-starved lymphocytes, or cell death induced by cytotoxic T cells

Indeed, failure of cells to undergo physiologic apoptosis may result in unimpeded tumor proliferation, autoimmune diseases, or aberrant development.

Apoptosis usually involves single cells or clusters of cells with condensed nuclear chromatin or chromatin fragments. The cells rapidly shrink, form cytoplasmic buds, and fragment into apoptotic bodies composed of membrane-bound vesicles of cytosol and organelles (see Fig. 10). These fragments are quickly extruded, phagocytosed, or degraded by neighboring cells and do not elicit an inflammatory response. The nuclear changes are due to fragmentation of DNA into histone-sized pieces, presumably through the activation of endonucleases.

The mechanisms underlying apoptosis are the subject of extensive and evolving investigation (Fig. 11). The process may be triggered by granzymes, degradative enzymes released by cytotoxic T cells, by activation of intrinsic pathways, e.g., in embryogenesis or direct radiation injury, or by interaction of a number of related plasma membrane receptors [e.g., Fas, or the tumor necrosis factor (TNF) receptor]. The plasma membrane receptors share an intracellular “death domain” protein sequence that, when multimerized, leads to a cascade of enzyme activation culminating in cell death.

Current data suggest that the various activators of the apoptosis pathway are ultimately funneled through the synthesis and/or activation of a number of cytosolic proteases. These proteases are termed caspases because they have an active-site cysteine and cleave after aspartic acid residues. In experimental systems, overexpression of any of the caspases will result in cellular apoptosis, suggesting that under normal circumstances, they must be tightly controlled. Increased cytosolic calcium can directly activate some intracellular proteases; in addition, increased intracellular calcium induces a “permeability transition” in mitochondria, resulting in caspase-3 activation. Initial activation of one or more such enzymes with broad specificity putatively leads to a cascade of activation of other proteases, inexorably culminating in cell suicide. For example, downstream endonuclease activation results in the characteristic DNA fragmentation, whereas cell volume and shape changes are caused by breakdown of the cytoskeleton.

The general framework of cell injury is summarized in Fig. 12. In the following chapter, we will extend the concepts

FIG. 11. Schematic of events occurring in apoptosis. Items labeled (1) are various stimuli for apoptosis; some involve direct activation of caspases (cytotoxic T cells) while others act via adaptor proteins (e.g., surface receptors such as FAS), or via mitochondrial release of cytochrome c. Items labeled (2) are an expanding set of inhibitors or promoters that fine-tune the death pathways leading to activation of the caspase mediators. Execution caspases (3) activate endonucleases that degrade nuclear chromatin, and intracellular proteases which degrade the cytoskeleton. The end result (4) is extruded apoptotic bodies containing various organelles and cytosolic components and that express a new surface molecule that induces their uptake by adjacent phagocytic cells. 3.4 TISSUES, THE EXTRACELLULAR MATRIX, AND CELL–BIOMATERIAL INTERACTIONS

Frederick J. Schoen and Richard N. Mitchell

This chapter will extend the concepts discussed previously in Cells and Cell Injury to describe how cells are organized to form specialized tissues and organs. Particularly important

will be understanding the role of cell interactions with extracellular matrix, the material that surrounds cells and support tissues. The chapter will also show how environmental stimuli and injury affect tissue structure and function, and how tissues respond to various insults, including those related to the insertion of biomaterials. Four general areas will be covered:

1. Key principles governing the structure and function of normal tissues and organs
2. Basic processes leading to and resulting from abnormal (injured or diseased) tissues and organs
3. Key concepts in cell–biomaterials interactions
4. Approaches to studying the structure and function of tissues

Germane to this discussion are two basic definitions: Histology is the microscopic study of tissue structure; pathology is the study of the molecular, biochemical, and structural alterations and their consequences in diseased tissues and organs, and the underlying mechanisms that cause these changes. Some excellent general references are available (Fawcett, 1986; Cormack, 1987; Cotran *et al.*, 1999; Lodish *et al.*, 1999; Alberts *et al.*, 2002).

STRUCTURE AND FUNCTION OF NORMAL TISSUES

Biologic tissue is composed of three basic components: cells, intercellular (interstitial) substances, especially extracellular matrix, and various body fluids. Cells, the living component of the body, were discussed in detail in the previous chapter. They are surrounded by and obtain their nutrients and oxygen, including the body fluids blood, tissue fluid (known as extracellular fluid), and lymph. Blood consists of blood cells suspended in a slightly viscous fluid called plasma. Capillaries exude a clear watery liquid called tissue fluid that permeates the amorphous intercellular substances lying between capillaries and cells. More tissue fluid is produced than can be absorbed back into the capillaries; the excess is carried away as lymph by a series of vessels called lymphatics, which ultimately empty the lymph into the bloodstream.

In all tissues, cells are assembled during embryonic development into coherent groupings by virtue of specific cell–cell and cell–matrix interactions. Each type of tissue has a distinctive pattern of structural organization adapted to its particular function, which is strongly influenced by metabolic (Carmeliet, 2000) and/or mechanical factors (Ingber, 2002; Carter *et al.*, 1996).

The Need for Tissue Perfusion

Since all mammalian cells require perfusion (i.e., blood flow bringing oxygen and nutrients and carrying away wastes) for their survival, most tissues have a rich vascular network and the circulatory system is a key feature of tissue and organ structure and function (Fig. 1). Perfusion is provided by the cardiovascular system, composed of a pump (the heart), a series of distributing and collecting tubes (arteries and veins),

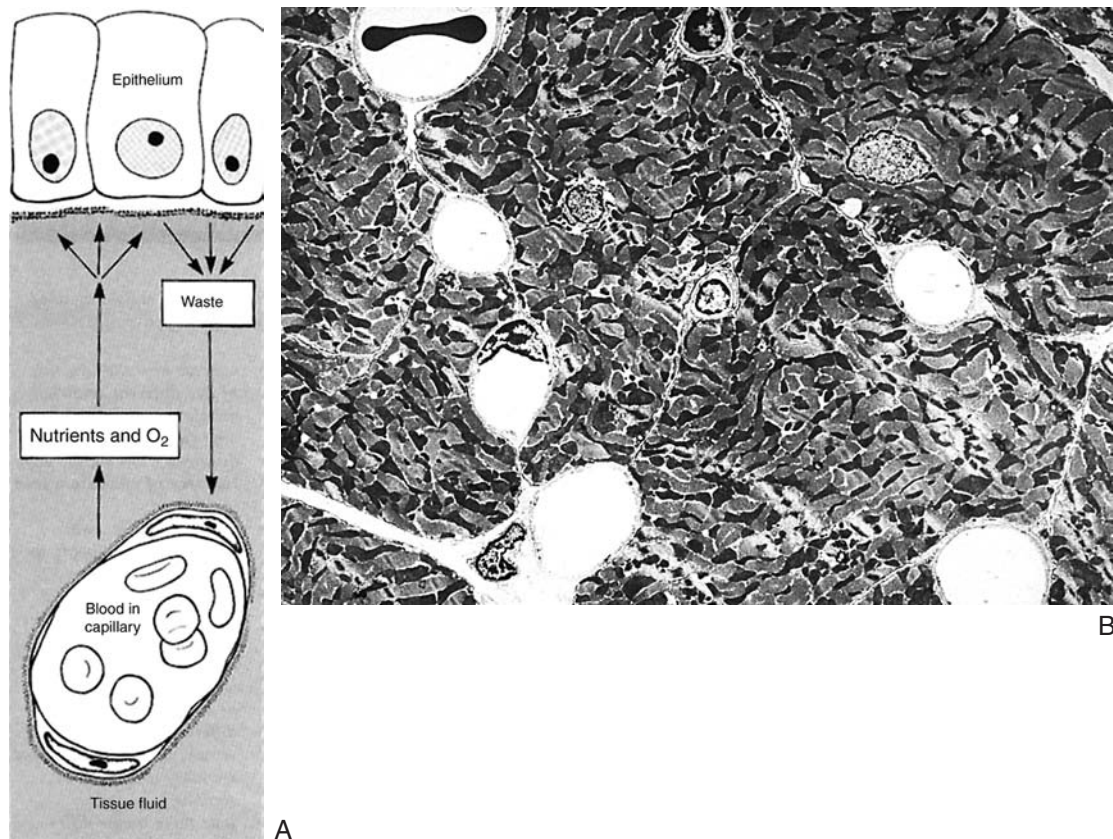

FIG. 1. Role of the vasculature in tissue function. (A) Schematic diagram of the route by which the cells in a tissue obtain their nutrients and oxygen from underlying capillaries. Metabolic waste products pass in the reverse direction and are carried away in the blood stream. In each case, diffusion occurs through the tissue fluid that permeates the amorphous intercellular substances lying between the capillaries and the tissue cells. (B) Myocardium, a highly metabolic tissue, has a rich vascular/capillary network as demonstrated by transmission electron microscopy. Capillaries are visualized as six open spaces. A red blood cell is noted in the capillary at upper left. This photo contains nearly four complete myocyte profiles and parts of two others at the lower left and right corners. (A) Reproduced by permission from Cormack, D. H., 1987. *Ham's Histology*, 9th ed. Lippincott, Philadelphia.)

and an extensive system of thin-walled vessels (capillaries) that permit exchange of substances between the blood and the tissues. Circulation of blood transports and distributes essential substances to the tissues and removes by-products of metabolism. Implicit in these functions are the intrinsic capabilities of the cardiovascular system to buffer pulsatile flow in order to ensure steady flow in the capillaries, regulate blood pressure and volume at all levels of the vasculature, maintain circulatory continuity while permitting free exchange between capillaries/venules and the extravascular compartments, and control hemostasis (managing hemorrhage by a coordinated response of vasoconstriction and plugging of vascular defects by coagulation and platelet clumps). Other functions of the circulation include such homeostatic (control) mechanisms as regulation of body temperature, and distribution of various regulating substances (e.g., hormones, inflammatory mediators, growth factors). Moreover, the circulatory system distributes immune and inflammatory cells to their sites of action and the endothelium itself has important immunological and inflammatory functions (Schoen and Cotran, 1999).

Although the cardiac output is intermittent owing to the cyclical nature of the pumping of the heart, continuous flow to the periphery occurs by virtue of distention of the aorta and its branches during ventricular contraction (systole), and elastic recoil of the walls of the large arteries with forward propulsion of the blood during ventricular relaxation (diastole). Blood moves rapidly through the aorta and its arterial branches, which become narrower and whose walls become thinner and change histologically toward the peripheral tissues. By adjusting the degree of contraction of their circular muscle coats, the distal arteries (arterioles) control the distribution of tissue blood flow among the various capillary beds and permit regulation of blood pressure. Blood returns to the heart from the capillaries, the smallest and thinnest-walled vessels, by passing through venules and then through veins of increasing size.

Blood entering the right ventricle of the heart via the right atrium is pumped through the pulmonary arterial system at mean pressures about one-sixth of those developed in the systemic arteries. The blood then passes through the lung capillaries in the alveolar walls, where carbon dioxide is released to

and oxygen taken up from the alveoli. The oxygen-rich blood returns through the pulmonary veins to the left atrium and ventricle to complete the cycle.

Large-diameter blood vessels are effective in delivering blood. Small vessels are most effective in diffusional transport to and from the surrounding tissues. Thus, owing to the very thin walls and slow velocity of blood in the capillaries, which falls to approximately 0.1 cm/sec from 50 cm/sec in the aorta, most exchange of oxygen, nutrients, and cellular wastes takes place through capillaries. Owing to the diffusion limit of oxygen of 100 to 200 μm in most highly metabolic tissues, cells are generally located no more than that distance from capillaries (recall Fig. 1). Thus, three-dimensional tissue formation and growth requires the formation of new blood vessels, a process called angiogenesis (Carmeliet, 2003). It also follows that tissues that require less nutrition and those that are relatively thin (e.g., heart valve leaflets) may either require a sparse vascular network or none at all.

In the following sections we will cover the general functional principles of tissue organization and response to various types of injury, highlighted by specific examples where illustrative.

Extracellular Matrix

Extracellular matrix (ECM) comprises the biological material produced by, residing in between, and supporting cells. ECM, cells, and capillaries are physically integrated in functional tissues (Fig. 2; see also Fig. 5). The ECM holds cells together by providing physical support and a matrix to which cells can adhere, signal each other, and interact. During normal development and as a component of the response of tissues to injury, adhesive interactions coordinate interactions with cell-surface receptors and subsequently, the cytoskeleton and the nucleus (Bokel and Brown, 2002). The resultant intracellular signaling affects a variety of events including gene expression and cell proliferation, mobility, and differentiation.

ECM consists of large molecules synthesized by cells, exported to the intercellular space and linked together into a structurally supportive composite. ECM is composed of (1) fibers (collagen and elastin) and (2) a largely amorphous interfibrillary matrix (mainly proteoglycans, noncollagenous cell-binding adhesive glycoproteins, solutes, and water). The principal functions of the ECM are:

- Mechanical support for cell anchorage
- Determination of cell orientation
- Control of cell growth
- Maintenance of cell differentiation
- Scaffolding for orderly tissue renewal
- Establishment of tissue microenvironment
- Sequestration, storage, and presentation of soluble regulatory molecules

Some extracellular matrices are specialized for a particular function, such as strength (tendon), filtration (the basement membranes in the kidney glomerulus), or adhesion (basement membranes supporting most epithelia). To produce additional mechanical strength in bones and teeth, the ECM is calcified.

Even in a tissue as “simple” as a heart valve leaflet, the coordinated interplay of several ECM components is critical to function (Schoen, 1997).

ECM components are synthesized, secreted, and remodeled by cells in response to appropriate stimuli. Virtually all cells secrete and degrade ECM to some extent. Certain cell types (e.g., fibroblasts and smooth muscle cells), are particularly active in production of interstitial ECM (i.e., the ECM between cells). Epithelial cells also synthesize the ECM of their basement membranes (see Fig. 5D).

Matrix components and the mechanical forces that cells experience markedly influence the maintenance of cellular phenotypes and affect cell shape, polarity, and differentiated function through receptors for specific ECM molecules on cell surfaces (such as integrins). The resultant changes in cytoskeletal organization and in production of second messengers can modify gene expression. ECM plays a critical role in cytodifferentiation and organogenesis, and as a scaffold allowing orderly repair following injury. The reciprocal instructions between cells and ECM are termed dynamic reciprocity.

In most tissues, the ECM is constantly turning over and being remodeled. Although matrix turnover is generally quite low in normal mature tissues, rapid and extensive proteolytic destruction characterizes various adaptive and pathologic states and accommodates changes in tissue form during embryogenesis. Regulated remodeling of ECM occurs during wound repair, tumor cell invasion, and metastasis, and at specific sites of embryonic tissue morphogenesis. The processes of directed cell motility and invasion require highly localized proteolytic reactions to carve through dense, structural areas of tissue. Two main classes of enzyme that have been implicated in the degradation of the protein components of the ECM are the plasminogen activator/plasmin family and the metalloproteinase family (Mutsaers *et al.*, 1997; Shapiro, 1998).

ECM consists of large molecules interlinked to form a reticulum that schematically resembles a fiber-reinforced composite; in reality, ECM forms an expansile glycoprotein–water gel held in dynamic equilibrium by fibrillar proteins. Present to some degree in all tissues and particularly abundant as an intercellular substance in connective tissues, ECM has both fibrous and amorphous components. The key constituents of ECM include fibrillar proteins such as collagen and elastin, amorphous matrix components exemplified by glycosaminoglycans (GAGs) and proteoglycans, and adhesive proteins such as fibronectin and laminin (Fig. 3).

Collagens and Elastin

Collagen comprises a family of closely related but genetically, biochemically, and functionally distinct molecules, which are responsible for tissue tensile strength. The most common protein in the animal world, collagen provides the extracellular framework for all multicellular organisms. The collagens are composed of a triple helix of three polypeptide α chains; about 30 different α chains form at nearly 20 distinct collagen types. Types I, II, and III are the interstitial or fibrillar collagens and are the most abundant. Types IV, V, and VI are nonfibrillar

FIG. 2. Organization of tissue demonstrated at low and high power. (A) The components of the integumentary system (skin) demonstrating relationships among the major components. The entire diagram represents approximately 1 mm. (B) Diagrammatic representation of the cells and fibers of loose connective tissue. These microscopically identifiable components lie embedded in amorphous ground substance and are continuously bathed with tissue fluid produced by capillaries. The entire diagram represents approximately 100 μm . (A, Reproduced by permission from Martini, F. H., 2001. *Fundamentals of Anatomy and Physiology*. Prentice Hall, Upper Saddle River, NJ. B, Reproduced by permission from Cormack, D. H., 1987. *Ham's Histology*, 9th ed. Lippincott, Philadelphia.)

(or amorphous) and are present in interstitial tissue and basement membranes.

Since some individual structural components of the ECM such as collagen are substantially larger than the cells that produce them, they must be synthesized in discrete protein subunits

that are secreted into the extracellular environment and are self-assembled there. For example, collagens are synthesized as soluble procollagen precursors, which are secreted and proteolytically processed to mature insoluble collagen molecules in the extracellular space. The main steps in collagen synthesis are

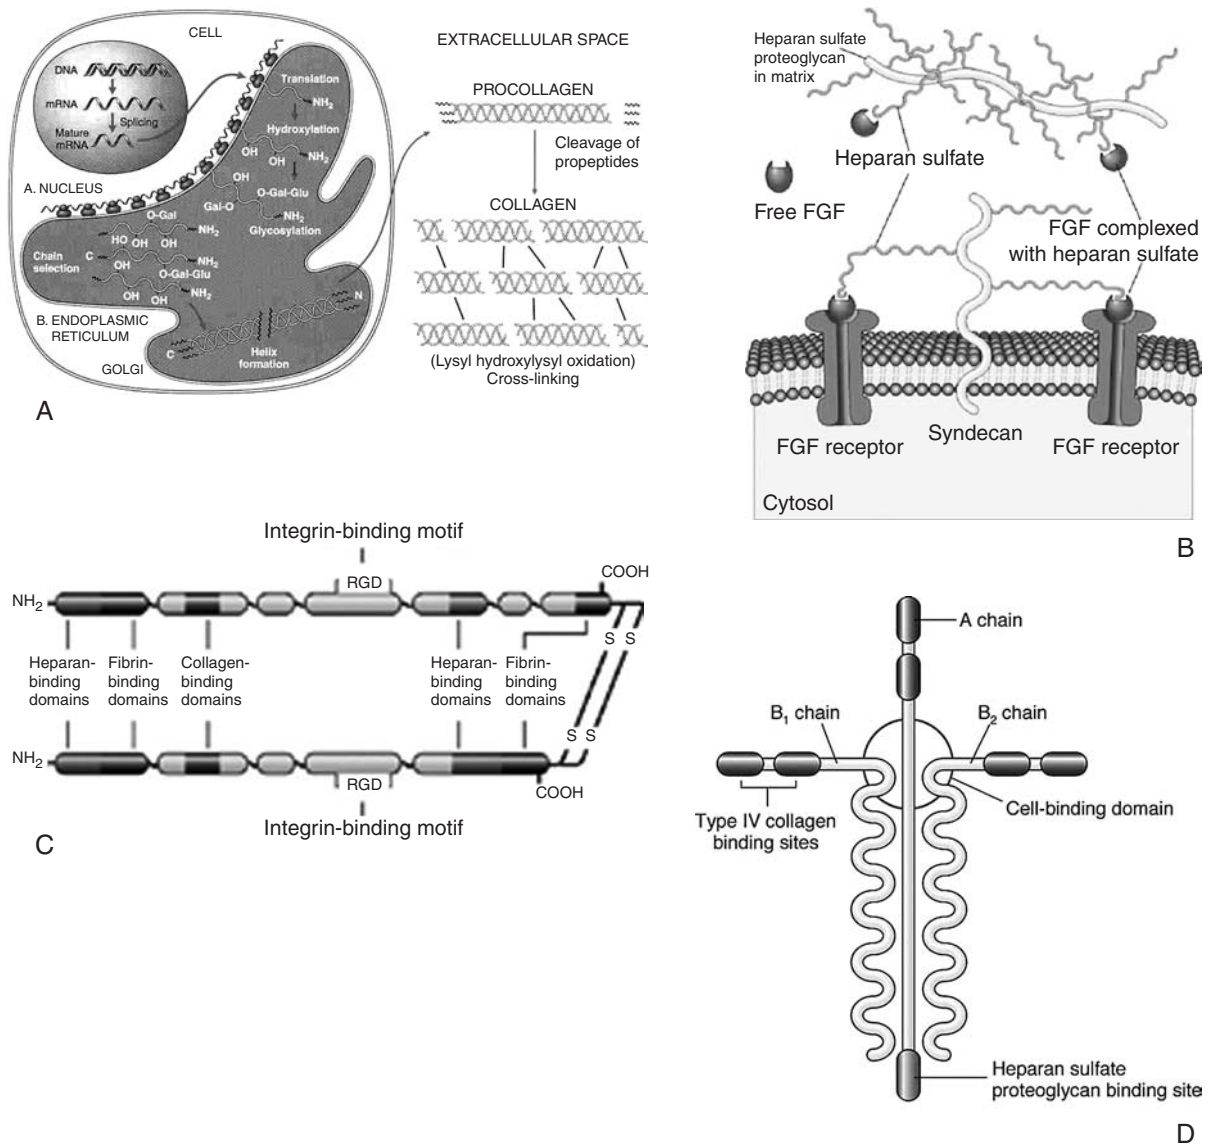

FIG. 3. Key concepts of extracellular matrix. (A) Collagen synthesis (see text for explanation). (B) Proteoglycans. Heparan sulfate proteoglycan in matrix and syndecan, cell surface proteoglycan. Its core protein spans the plasma membrane and can modulate the activity of fibroblast growth factor (FGF). The fibronectin molecule (C) consists of a dimer held together by S–S bonds. Note the various domains that bind to extracellular matrix and the cell-binding domain containing an arginine-glycine-aspartic acid (RGD) sequence. The cross-shaped laminin (D) molecule spans basement membranes and has extracellular matrix (ECM)- and cell-binding domains. (Reproduced by permission from Cotran, R. S., Kumar, V., and Collins, T., 1999. *Robbins Pathologic Basis of Disease*, 6th ed. Saunders, Philadelphia.)

shown in Fig. 3A. After synthesis on ribosomes, the α chains are subjected to a number of enzymatic modifications, including hydroxylation of proline and lysine residues, providing collagen with a high content of hydroxyproline (10%). Vitamin C is required for hydroxylation of the collagen propeptide, a requirement that explains inadequate wound healing in vitamin C deficiency (scurvy). After the modifications, the procollagen chains align and form the triple helix. At this stage, the procollagen molecule is still soluble and contains N-terminal and C-terminal propeptides. During or shortly after

secretion from the cell, procollagen peptidases clip the terminal propeptide chains, promoting formation of fibrils, often called tropocollagen, and oxidation of specific lysine and hydroxylysine residues occurs by the extracellular enzyme lysyl oxidase. This results in cross-linkages between α chains of adjacent molecules stabilizing the array that is characteristic of collagen.

Elastic fibers confer passive recoil to various tissues; they are critical components of heart valves and the aorta, where repeated pulsatile flow would cause unacceptable shears on noncompliant tissue, and of intervertebral disks, where the

repetitive forces of ambulation along the spine are dissipated. Elastin also forms layers called laminae in the walls of arteries. Unlike collagen, elastin can be stretched. The stretching of an artery every time the heart pumps blood into an artery is followed by the recoil of elastin, which restores the artery's former diameter between heartbeats.

Amorphous Matrix: Glycosaminoglycans (GAGs), Proteoglycans and Hyaluronan

Amorphous intercellular substances contain carbohydrate bound to protein. The carbohydrate is in the form of long-chained polysaccharides called glycosaminoglycans (GAGs). When GAGs are covalently bound to proteins, the molecules are called proteoglycans. GAGs are highly charged (usually sulfated) polysaccharide chains up to 200 sugars long, composed of repeating unbranched disaccharide units (one of which is always an amino sugar—hence the name glycosaminoglycan). GAGs are divided into four major groups on the basis of their sugar residues:

- Hyaluronic acid: a component of loose connective tissue and of joint fluid, where it acts as a lubricant
- Chondroitin sulfate and dermatan sulfate
- Heparan sulfate and heparin
- Keratin sulfate

With the exception of hyaluronic acid (which is unique among the GAGs because it is not sulfated), all GAGs are covalently attached to a protein backbone to form proteoglycans, with a structure that schematically resembles a bottle brush (Fig. 3B). Proteoglycans are remarkable in their diversity, owing to different core proteins, and different glycosaminoglycans. Proteoglycans are named according to the structure of their principal repeating disaccharide. Some of the most common are heparan sulfate, chondroitin sulfate, and dermatan sulfate. Proteoglycans can also be integral membrane proteins and are thus modulators of cell growth and differentiation. The syndecan family has a core protein that spans the plasma membrane and contains a short cytosolic domain as well as a long external domain to which a small number of heparan sulfate chains are attached. Syndecan binds collagen, fibronectin, and thrombospondin in the ECM and can modulate the activity of growth factors. Hyaluronan consists of many repeats of a simple disaccharide stretched end-to-end and binds a large amount of water, forming a viscous hydrate gel, which gives connective tissue turgor pressure and an ability to resist compression factors. This ECM component helps provide resilience as well as a lubricating feature to many types of connective tissue, notably that found in the cartilage in joints.

Adaptor/Adhesive Molecules

Adhesive proteins, including fibronectin, laminin, and entactin permit the attachment to and movement of cells within the ECM.

- Fibronectin is a ubiquitous, multidomain glycoprotein possessing binding sites for a wide variety of other ECM components, including collagen, heparins A and B, fibrin, and chondroitin sulfate (Fig. 3C). It is synthesized by

many different cell types, with the circulating form produced mainly by hepatocytes. Fibronectin is important for linking cells to the ECM via cell surface integrins; the adaptor molecules. Fibronectin's adhesive character also makes it a crucial component of blood clots and of pathways followed by migrating cells. Thus, fibronectin-rich pathways guide and promote the migration of many kinds of cells during embryonic development and wound healing.

- Laminin is an extremely abundant component of the basal lamina, a tough, thin, sheetlike substratum on which cells sit and important for cell differentiation and tissue remodeling. The basal lamina or basement membrane contains a meshlike type IV collagen framework, laminin, and heparan sulfate proteoglycan; laminin facilitates cell binding to the basal lamina. Laminin polypeptides are arranged in the form of an elongated cross, with individual chains held together by disulfide bonds (Fig. 3D). Like fibronectin, laminin has a distinct domain structure; different regions of the molecule bind to type IV collagen, heparin sulfate, entactin (a short protein that cross-links each laminin molecule to type IV collagen), and cell surface integrins.

Cell–Matrix Interactions

Like cell–cell interactions, cell–matrix interactions have a high degree of specificity, requiring initial recognition, physical adhesion, electrical and chemical communication, cytoskeletal reorganization, and/or cell migration. Moreover, adhesion receptors may also act as transmembrane signaling molecules that transmit information about the environment to the inside of cells and mediate the effects of signals initiated by growth factors or compounds controlling tissue differentiation (Fig. 4). Moreover, the components of the extracellular matrix (ligands) with which cells interact are immobilized and not in solution. However, soluble (secreted) factors also modulate cell–cell communication in the normal and pathologic regulation of tissue growth and maturation. Cell surface adhesion molecules that interact with ECM include the integrin adhesion receptors, and the vascular selectins.

The integrins comprise a family of cell receptors with diverse specificity that bind ECM proteins, other cell surface proteins and plasma proteins, and control cell growth, differentiation, gene expression, and motility (Bokel and Brown, 2002). Some integrins bind only a single component of the ECM, e.g., fibronectin, collagen, or laminin (see above). Other integrins can interact with several of these polypeptides. In contrast to hormone receptors, which have high affinity and low abundance, the integrins exhibit low affinity and high abundance, so that they can bind weakly to several different but related matrix molecules. This property allows the integrins to promote cell–cell interactions as well as cell–matrix binding.

Basic Tissues

Humans have more than 100 distinctly different types of cells variously allocated to four types of basic tissues (Table 1

FIG. 4. Integrin ECM interaction. Schematic showing the mechanisms by which ECM (e.g., fibronectin and laminin) and growth factors can influence cell growth, motility, differentiation, and protein synthesis. Integrins bind ECM and interact with the cytoskeleton at focal adhesion complexes (protein aggregates that include vinculin, α -actinin, and talin). This can initiate the production of intracellular messengers, or can directly mediate nuclear signals. Cell surface receptors for growth factors also initiate second signals. Collectively, these are integrated by the cell to yield various responses, including changes in cell growth, locomotion, and differentiation. (Reproduced by permission from Cotran, R. S., Kumar, V., and Collins, T., 1999. *Robbins Pathologic Basis of Disease*, 6th ed. Saunders, Philadelphia.)

TABLE 1 The Basic Tissues: Classification and Examples

Basic Tissues	Examples
Epithelial tissue	
Surface	Skin epidermis, gut mucosa
Glandular	Thyroid follicles, pancreatic acini
Special	Retinal or olfactory epithelium
Connective tissue	
Connective tissue proper	
Loose	Skin dermis
Dense (regular, irregular)	Pericardium, tendon
Special	Adipose tissue
Hemopoietic tissue, blood and lymph	Bone marrow, blood cells
Supportive tissue	Cartilage, bone
Muscle tissue	
Smooth	Arterial or gut smooth muscle
Skeletal	Limb musculature, diaphragm
Cardiac muscle	Heart
Nerve tissue	Brain cells, peripheral nerve

and Fig. 5): (1) epithelium, (2) connective tissue, (3) muscle, and (4) nervous tissue. The basic tissues play specific functional roles and have distinctive microscopic appearances. They have their origins in embryological development; early

events include the formation of a tube with three layers in its wall: (1) an outer layer of ectoderm, (2) an inner layer of endoderm, and (3) a middle layer of mesoderm (Fig. 6).

Epithelium covers the internal and external body surfaces. It provides a protective barrier (e.g., skin epidermis), on an absorptive surface (e.g., gut lining), and can generate internal and external secretions (e.g., endocrine and sweat glands, respectively). Epithelium derives mostly from ectoderm and endoderm, but also from mesoderm.

Epithelia accommodate diverse functions. An epithelial surface can be (1) a protective dry, cutaneous membrane (as in skin); (2) a moist, mucous membrane, lubricated by glandular secretions (digestive and respiratory tracts); (3) a moist, membrane lined by mesothelium, lubricated by fluid that derives from blood plasma (peritoneum, pleura, pericardium); and (4) the inner lining of the circulatory system, called endothelium. Epithelial cells play fundamental roles in the directional movement of ions, water, and macromolecules between biological compartments, including absorption, secretion, and exchange. Therefore the architectural and functional organization of epithelial cells includes structurally, biochemically, and physiologically distinct plasma membrane domains that contain region-specific ion channels, transport proteins, enzymes and lipids, and cell-cell junctional complexes. These integrate multiple cells to form an interface between biological compartments in organs. Subcellular epithelial specializations are not apparent to the naked eye—or even necessary light microscopy; they are perhaps best studied by transmission electron microscopy (TEM) and by functional assays (e.g., assessing synthetic products, permeability and transport).

Supporting the other tissues of the body, connective tissue arises from mesenchyme, a derivative of mesoderm. Connective tissue also serves as a scaffold for the nerves and blood vessels that support the various epithelial tissues. Other types of tissue with varying functions are also of mesenchymal origin. These include dense connective tissue, adipose (fat) tissue, cartilage and bone, and circulating cells (blood cells and their precursors in bone marrow), as well as inflammatory cells that defend the body against infectious organisms and other foreign agents.

Muscle cells develop from mesoderm and are highly specialized for contraction. They have the contractile proteins actin and myosin in varying amounts and configuration, depending on cell function. Muscle cells are of three types: smooth muscle, skeletal muscle, and cardiac muscle. The latter two have a striated microscopic appearance, owing to their discrete bundles of actin and myosin organized into sarcomeres. Smooth muscle cells, which have a less compact arrangement of myofilaments, are prevalent in the walls of blood vessels and the gastrointestinal tract. Their slow, nonvoluntary contraction regulates blood vessel caliber and proper movement of food and solid waste, respectively.

Nerve tissue, which derives from ectoderm, is highly specialized with respect to irritability and conduction. Nerve cells not only have cell membranes that generate electrical signals called action potentials, but also secrete neurotransmitters, molecules that trigger adjacent nerve or muscle cells to either transmit an impulse or to contract.

FIG. 5. Photomicrographs of basic tissues, emphasizing key structural features. (A–D) Epithelium; (E, F) connective tissue; (G) muscle; and (H) nervous tissue. (A) Skin. Note the thin stratum corneum (c) and stratum granulosum (g). Also shown are the stratum spinosum (s), stratum basale (b), epidermal pegs (ep), dermal papilla (dp), and dermis (d). (B) Trachea, showing goblet cells (g), ciliated columnar cells (c), and basal cells (b). Note the thick basement membrane (bm) and numerous blood vessels (v) in the lamina propria (lp). (C) Mucosa of the small intestine (ileum). Note the goblet (g) and columnar absorbing (a) cells, the lamina propria (lp), muscularis mucosae (mm), and crypts (arrows). (D) Epithelium of a kidney collecting duct resting on a thin basement membrane (arrows). (E) Dense irregular connective tissue. Note the wavy unorientated collagen bundles (c) and fibroblasts (arrows). p, plasma cells. (F) Cancellous bone clearly illustrating the morphologic difference between inactive bone lining (endosteal, osteoprogenitor) cells (bl) and active osteoblasts (ob). The clear area between the osteoblasts and calcified bone represents unmineralized matrix or osteoid. cl, cement lines; o, osteocytes. (G) Myocardium (cardiac muscle). The key features are the centrally placed nuclei of the cardiac myocytes, intercalated discs (representing specialized end-to-end junctions of adjoining cells) and the sarcomeric structure visible as cross-striations. (H) Small nerve fascicles (n) with perineurium (p) separating it from two other fascicles (n). (A–F and H reproduced by permission from Berman, I., 1993. *Color Atlas of Basic Histology*. Saunders, Philadelphia, in press.) (See color plate)

FIG. 5. *Continued*

Organs

Several different types of tissues arranged into a functional unit constitute an organ. These have a composite structure in which epithelial cells typically perform the specialized work of the organ, while connective tissue and blood vessels support and provide nourishment to the epithelium. There are two basic organ patterns: tubular (or hollow) and compact (or solid) organs. Tubular organs include the blood vessels and the digestive, urinary–genital, and respiratory tracts; they have similar architectures in that each is composed of layers of tissue arranged in a specific sequence. For example, each has an inner coat consisting of a lining of epithelium, a middle coat consisting of layers of muscle (usually smooth muscle) and connective tissue, and an external coat consisting of connective tissue and often covered by epithelium for example the intestines or vascular walls (Fig. 7). Specific variations reflect organ-specific functional requirements. Whereas the outer coat of an organ that blends into surrounding structures is called the adventitia, the outside epithelial lining of an organ suspended in a body cavity is called a serosa.

The histologic composition and organization, as well as the thickness, of these three layers vary characteristically with

the physiologic functions performed by specific segments of the cardiovascular system and are particularly well exemplified in the circulation (Fig. 8). Blood vessels have three layers: an intima (primarily endothelium), a media (primarily smooth muscle and elastin), and an adventitia (primarily collagen). The amounts and relative proportions of layers of the blood vessels are influenced by mechanical factors (especially blood pressure, which determines the amount and arrangement of muscular tissue) and metabolic factors (reflecting the local nutritional needs of the tissues). Three features will illustrate the variation in site-specific structure–function correlations:

- As discussed earlier, capillaries have a structural reduction of the vascular wall to only endothelium and minimal supporting structures to facilitate exchange. Thus, capillaries are part of the tissues they supply and, unlike larger vessels, do not appear as a separate anatomic unit.
- Arteries and veins have distinctive structures. The arterial wall is generally thicker than the venous wall, in order to withstand the higher blood pressures that prevail within arteries compared with veins. Thickness of the arterial wall gradually diminishes as the vessels themselves become smaller, but the wall-to-lumen ratio becomes

greater in the periphery. Veins have a larger overall diameter, a larger lumen, and a narrower wall than corresponding arteries with which they course (Fig. 8B).

- In essence, the heart is a blood vessel specialized for rhythmic contraction; its media is the myocardium, containing muscle cells (cardiac myocytes).

The blood supply of an organ comes from its outer aspect. In tubular organs, large vessels penetrate the outer coat, perpendicular to it, and give off branches that run parallel to the tissue layers (Fig. 9). These vessels divide yet again to give off penetrating branches that course through the muscular layer, and branch again in the connective tissue parallel to the layers.

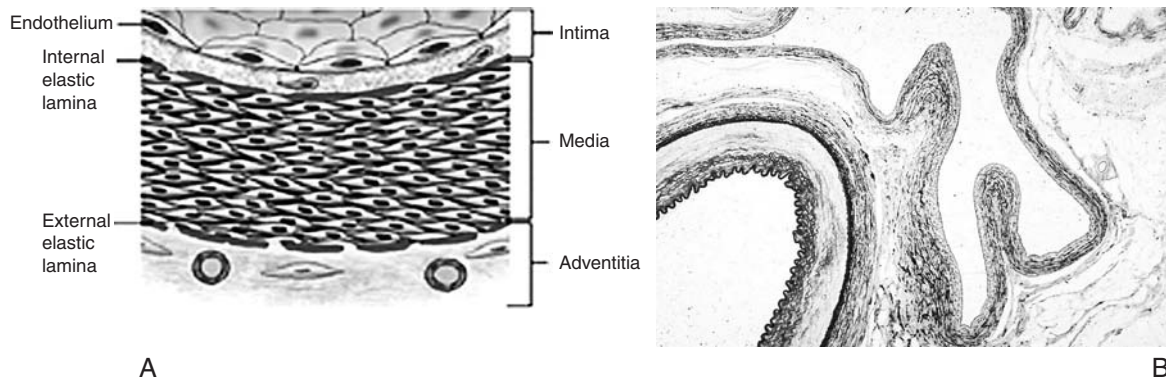

FIG. 8. The vascular wall. (A) Graphic representation of a small muscular artery (e.g., renal or coronary artery). (B) Photomicrograph of histologic section containing artery (A) and adjacent vein (V). Elastic membranes are stained black (internal elastic membrane of artery highlighted by arrow). Exposed to higher pressures, the artery has a thicker wall that maintains a circular lumen, even when blood is absent. Moreover, the elastin of the artery is more organized than in the corresponding vein. In contrast, the vein has a larger, but collapsed lumen and the elastin in its wall is diffusely distributed. FIG. 9. Vascularization of hollow organs. (Reproduced by permission from M. Borysenko and T. Beringer, *Functional Histology*, 3rd ed. Copyright 1989, Little, Brown, and Co.)

The small blood vessels have junctions (anastomoses) with one another in the connective tissue. These junctions may provide collateral pathways that can allow blood to bypass obstructions. Compact, solid organs have an extensive connective tissue framework, surrounded by a dense, connective tissue capsule (Fig. 10). Such organs have a hilus or area of thicker connective tissue where blood vessels and other conduits (e.g., airways in the lungs) enter the organ. From the hilus, strands of connective tissue extend into the organ and may divide it into lobules. The remainder of the organ has a delicate

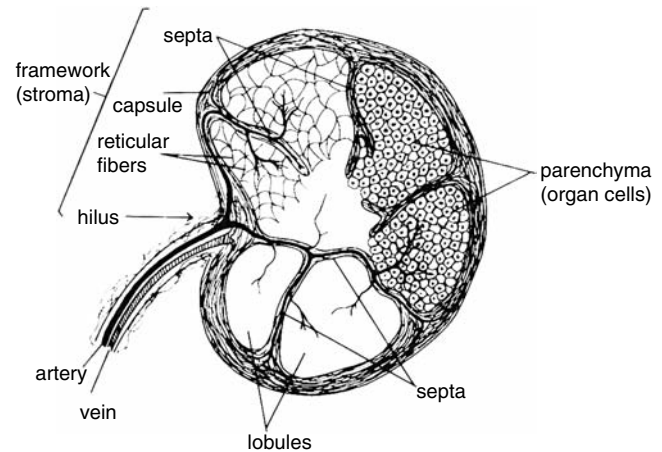

FIG. 10. Organization of compact organs. (Reproduced by permission from M. Borysenko and T. Beringer, *Functional Histology*, 3rd ed. Copyright 1989, Little, Brown, and Co.)

structural framework, including supporting cells, extracellular matrix, and vasculature (essentially the “maintenance” or “service core”), which constitutes the stroma.

The dominant cells in specialized tissues comprise the parenchyma (e.g., thyroglobulin-hormone-producing epithelial cells in the thyroid, or cardiac muscle cells in the heart). Parenchyma occurs in masses (e.g., endocrine glands), cords (e.g., liver), or tubules (e.g., kidney). Parenchymal cells can be arranged uniformly in an organ, or they may be segregated into a subcapsular region (cortex) and a deeper region (medulla), each performing a distinct functional role. In compact organs, the blood supply enters the hilus and then branches repeatedly to small arteries and ultimately capillaries in the parenchyma.

In both tubular and compact organs, veins and nerves generally follow the course of the arteries.

Parenchymal cells are generally more sensitive to chemical, physical, or ischemic (i.e., low blood flow) injury than is stroma. Moreover, when an organ is injured, orderly repair and regrowth of parenchymal cells requires an intact underlying stroma.

TISSUE RESPONSE TO INJURY

Inflammation and Repair

Inflammation and repair follow cell and tissue injury induced by various exogenous and endogenous stimuli. Inflammation is a protective response that eliminates (i.e., dilutes, destroys, or isolates) the cause of the injury (e.g., microbes or toxins) and disposes of both the necrotic cells and tissues that occur as a result of the injury. In doing so, the inflammatory response initiates the process that heals and reconstitutes the normal tissue. During the reparative phase, the injured tissue is replaced by native parenchymal cells, or by filling up the defect with fibroblastic scar tissue, or both. The outcome depends primarily on the tissue type and the extent and persistence of the injury (Fig. 11). When (1) tissue injury is transient or short-lived, (2) tissue destruction is small, and (3) the tissue is capable of regeneration, the outcome is restoration of normal structure and function; however, when the injury is extensive or occurs in tissues that do not regenerate, scarring results (Singer and Clark, 1999). An abscess is the outcome when an infection cannot be eliminated (i.e., localized) collection of acute inflammation and infectious organisms; the body “controls” the infection by creating a wall around it.

Inflammation and repair constitutes an overlapping sequence of several processes (Fig. 12):

- *Acute inflammation.* The immediate and early response to injury, of relatively short duration, is characterized by fluid and plasma protein exudation into the tissue, and by accumulation of neutrophils (polymorphonuclear leukocytes).
- *Chronic inflammation.* This phase is manifested histologically as lymphocytes and macrophages, often with concurrent tissue destruction, and can evolve into repair involving fibrosis and new blood vessel proliferation. A special type of inflammation characterized by activated macrophages and often multinucleated giant cells is called a granuloma or granulomatous inflammation. The pattern occurs in pathologic states where the inciting agent is not removable, including the foreign body reaction, a characteristic inflammatory reaction to the implantation of a biomaterial.
- *Scarring.* In situations where repair cannot be accomplished by regeneration, scarring occurs as a composite of three sequential processes: (1) formation of new blood vessels (angiogenesis), (2) deposition of collagen (fibrosis), and (3) maturation and remodeling of the scar (remodeling). The early healing tissue rich in new capillaries and proliferation of fibroblasts is called granulation tissue. The essential features of the healing process are usually advanced by 4–6 weeks although full scar remodeling may require much longer.

Inflammation is also associated with the release of chemical mediators from plasma, cells, or extracellular matrix, which regulate the subsequent vascular and cellular events

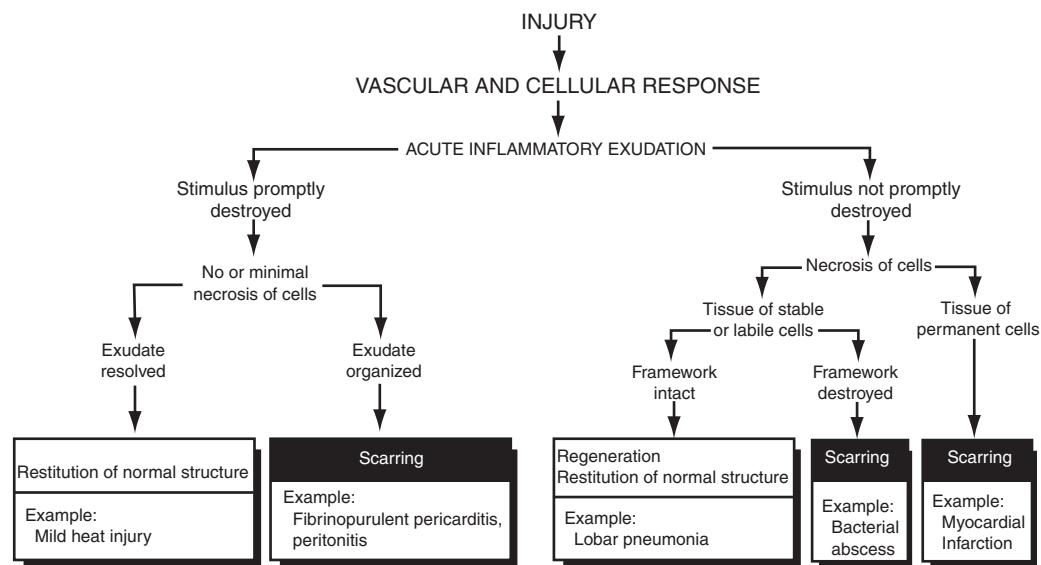

FIG. 11. Pathways of reparative responses after acute inflammatory injury. (Reproduced by permission from Cotran, R. S., Kumar, V., and Collins, T., 1999. *Robbins Pathologic Basis of Disease*, 6th ed. Saunders, Philadelphia.)

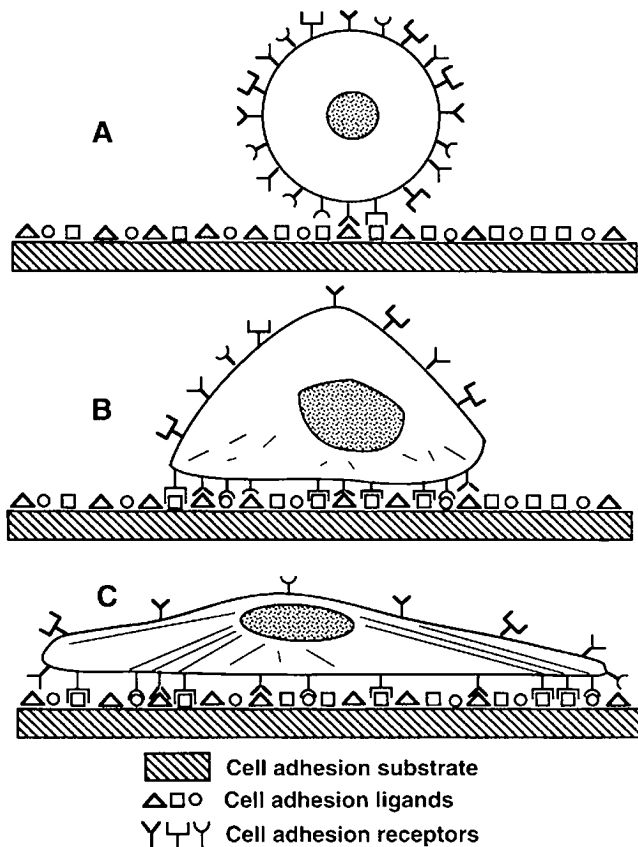

FIG. 12. Progression of anchorage-dependent mammalian cell adhesion. (A) Initial contact of cell with solid substrate. (B) Formation of bonds between cell surface receptors and cell adhesion ligands. Cell-extracellular matrix interactions relevant to vascular tissue engineering, in *Tissue Engineering of Prosthetic Vascular Grafts*, P. Zilla and H. P. Greisler, eds., RG Landes Co.)

and may modify their evolution. The chemical mediators of inflammation include the vasoactive amines (e.g., histamine), plasma proteases (of the coagulation, fibrinolytic, kinin, and complement systems), arachidonic acid metabolites (eicosinoids) produced in the cyclooxygenase pathway (the prostaglandins) and the lipoxygenase pathway (the leukotrienes), platelet-activating factor, cytokines [e.g., interleukin1 (IL-1), tumor necrosis factor- α (TNF- α), and interferon- γ (IFN- γ)], nitric oxide and oxygen-derived free radicals, and various intracellular constituents, particularly the lysosomal granules of inflammatory cells. Polypeptide growth factors also influence repair and healing by affecting cell growth, locomotion, contractility, and differentiation. Growth factors may act by endocrine (systemic), paracrine (stimulating adjacent cells) or autocrine (same cell carrying receptors for their own endogenously produced factors) mechanisms. Growth factors involved in mediating angiogenesis, fibroblast migration, proliferation, and collagen deposition in wounds include epidermal growth factor (EGF, important in proliferation of epithelial cells and fibroblasts), platelet-derived growth

factor (PDGF, involved in fibroblast and smooth muscle cell migration), fibroblast growth factors (FGFs), transforming growth factor- β (TGF- β , with a central role in fibrosis), and vascular endothelial growth factor (VEGF, with a central role in angiogenesis).

Cell Regenerative Capacity

Most types of cell populations can undergo turnover, but the process is highly regulated, and the production of cells of a particular kind generally ceases until some are damaged or another need arises. Rates of proliferation are different among various cell populations and are frequently divided into three categories: (1) renewing (also called labile) cells have continuous turnover, with proliferation balancing cell loss that accrues by death or physiological depletion; (2) expanding (also called stable) cells, normally having a low rate of death and replication, retain the capacity to divide following stimulation; and (3) static (also called permanent) cells not only have no normal proliferation, but have lost their capacity to divide. The relative proliferative (and regenerative) capacity of various cells is summarized in Table 2.

In renewing (labile) cell populations (e.g., skin, intestinal epithelium, bone marrow), stem cells proliferate to form daughter cells that can become differentiated and repopulate the damaged cells. A particular stem cell produces many such daughter cells, and, in some cases, several different kinds of cells can arise from a common multipotential ancestor cell (e.g., bone marrow multipotential cells lead to several different types of blood cells). In epithelia, the stem cells are at the base of the tissue layer, away from the surface; differentiation and maturation occur as the cells move toward the surface. In expanding (stable) populations, cells can increase their rate of replication in response to suitable stimuli. Stable cell populations include glandular epithelial cells, liver, fibroblasts, vascular smooth muscle cells, osteoblasts, and endothelial cells. In contrast, permanent (static) cells have minimal if any normal mitotic capacity and, in general, cannot be induced to regenerate. In labile or stable populations, cells that die are generally replaced by new ones of the same kind, but more specialized (i.e., permanent) cells are generally replaced by scar. The inability to regenerate certain tissue types results in a clinically important deficit, since the function of the damaged tissue is irretrievably lost. For example, an area of heart muscle that is damaged by ischemic injury (myocardial infarction) cannot be effectively replaced by viable cells; the necrotic area is repaired by scar, which itself has no contractile potential. Therefore, the remainder of the heart muscle must assume the workload of the lost tissue.

Although the classical concepts just enumerated continue to hold true from a practical standpoint, recent evidence suggests that some regeneration of neural tissue and heart muscle cells can occur under certain circumstances following injury. Both the extent to which this can occur and strategies to harness this potential and exciting source of new tissue are yet unknown (Nadal-Ginard *et al.*, 2003; Nadareishvili and Hallenbeck, 2003; Kokaia and Lindvall, 2003).

TABLE 2 Regenerative Capacity of Cells Following Injury

Category	Normal rate of replication	Response to stimulus/injury	Examples
Renewing/ labile	High	Modest increase	Skin, intestinal mucosa, bone marrow
Expanding/ stable	Low	Marked increase	Endothelium, fibroblasts, liver cells
Static/ permanent	None	No replication; replacement by scar	Heart muscle cells, nerves

Extracellular Matrix Remodeling

The maintenance of the extracellular matrix requires constant collagen remodeling, itself dependent on continued collagen synthesis and collagen catabolism. Turnover of the extracellular matrix is a unique biological problem because of the high collagen content of most extracellular matrix structures and the resistance of these triple helical molecules to the action of most proteases. Connective tissue remodeling, either physiological or pathological, is in most cases a highly organized process that involves the selective action of a group of related proteases that collectively can degrade most, if not all, components of the extracellular matrix. These proteases are known as the matrix metalloproteinases (MMPs). Subclasses include the interstitial collagenases, stromelysins, and gelatinases.

Enzymes that degrade collagen are synthesized by macrophages, fibroblasts, and epithelial cells. Collagenases are specific for particular types of collagens, and many cells contain two or more different such enzymes. For example, fibroblasts synthesize a host of matrix components, as well as enzymes involved in matrix degradation, such as MMPs and serine proteases. Particularly important in tissue remodeling are myofibroblasts, a particular phenotype of cells that show both features of smooth muscle cells (contractile proteins such as α -actin) and features of fibroblasts (rough endoplasmic reticulum in which proteins are synthesized). These cells may also be responsible for the production of (and likely respond to) tissue forces during remodeling, thereby regulating the evolution of tissue structure according to mechanical requirements.

Evidence suggests that growth factors and hormones (autocrine, paracrine, and endocrine) are pivotal in orchestrating both synthesis and degradation of ECM components. Cytokines such as TGF- β , PDGF, and IL-1 clearly play an important role in the modulation of collagenase and TIMP expression. MMP enzymatic activities are regulated by tissue inhibitors of metalloproteinases (TIMPs), which are especially important during wound repair. These natural inhibitors of the MMPs are multifunctional proteins with both MMP inhibitor activity and cell growth modulating properties. Turnover of the extracellular matrix is mediated by an excess of MMP over TIMPs activity. Distortion of the balance between matrix synthesis and turnover may result in altered matrix composition and amounts.

CELL/TISSUE-BIOMATERIALS INTERACTIONS

For most applications, biomaterials are in contact with cells and tissues (hard tissue, including bone; soft tissue, including cardiovascular tissues; and blood in the case of cardiovascular implants or extracorporeal devices), often for prolonged periods. Thus, rational and sophisticated use of biomaterials and design of medical devices requires some knowledge of the general concepts concerning the interaction of cells with nonphysiological surfaces. This discussion complements that described in Chapter 9.3.

Cell interactions with the external environment are mediated by receptors in the cell membrane, which interact with proteins and other ligands that adsorb to the material surface from the surrounding plasma and other fluids (Lauffenburger and Griffith, 2001). Cell adhesion triggers multiple functional biochemical signaling pathways within the cell.

Most tissue-derived cells require attachment to a solid surface for viability, growth, migration, and differentiation. The nature of that attachment is an important regulator of those functions. Moreover, the behavior and function of adherent cells (e.g., shape, proliferation, synthetic function) depend on the characteristics of the substrate, particularly its adhesiveness.

Following contact with tissue or blood, a bare surface of a biomaterial is covered rapidly (usually in seconds) with proteins that are adsorbed from the surrounding body fluids. The chemistry of the underlying substrate (particularly as it affects wettability and surface charge) controls the nature of the adherent protein layer. For example, macrophage fusion and platelet adhesion/aggregation are strongly dependent on surface chemistry. Moreover, although cells are able to adhere, spread, and grow on bare biomaterials surfaces *in vitro*, proteins absorbed from the adjacent tissue environment or blood and/or secreted by the adherent cells themselves markedly enhance cell attachment, migration, and growth. Cell adhesion to biomaterials is mediated by cytoskeletally associated receptors in the cell membrane, which interact with cell adhesion proteins that adsorb to the material surface from the surrounding plasma and other fluids (Fig. 12) (Saltzman, 2000).

Cell binding to the extracellular matrix through specific cell-substratum contacts is critical to cell-growth control through mechanical forces mediated through associated changes in cell shape and cytoskeletal tension (Ingber, 2002). Focal adhesions are considered to represent the strongest such interactions. They comprise a complex assembly of intra- and extracellular proteins, coupled to each other through transmembrane integrins. Cell-surface integrin receptors promote cell attachment to substrates, and especially those covered with the extracellular proteins fibronectin and vitronectin. These receptors transduce biochemical signals to the nucleus by activating the same intracellular signaling pathways that are used by growth factor receptors. The more cells spread, the higher their rate of proliferation. The importance of cell spreading on their proliferation has been emphasized by experiments that used endothelial cells cultured on microfabricated substrates containing fibronectin-coated islands of various defined shapes and sizes of a micrometer scale (Fig. 13) (Chen *et al.*, 1997).

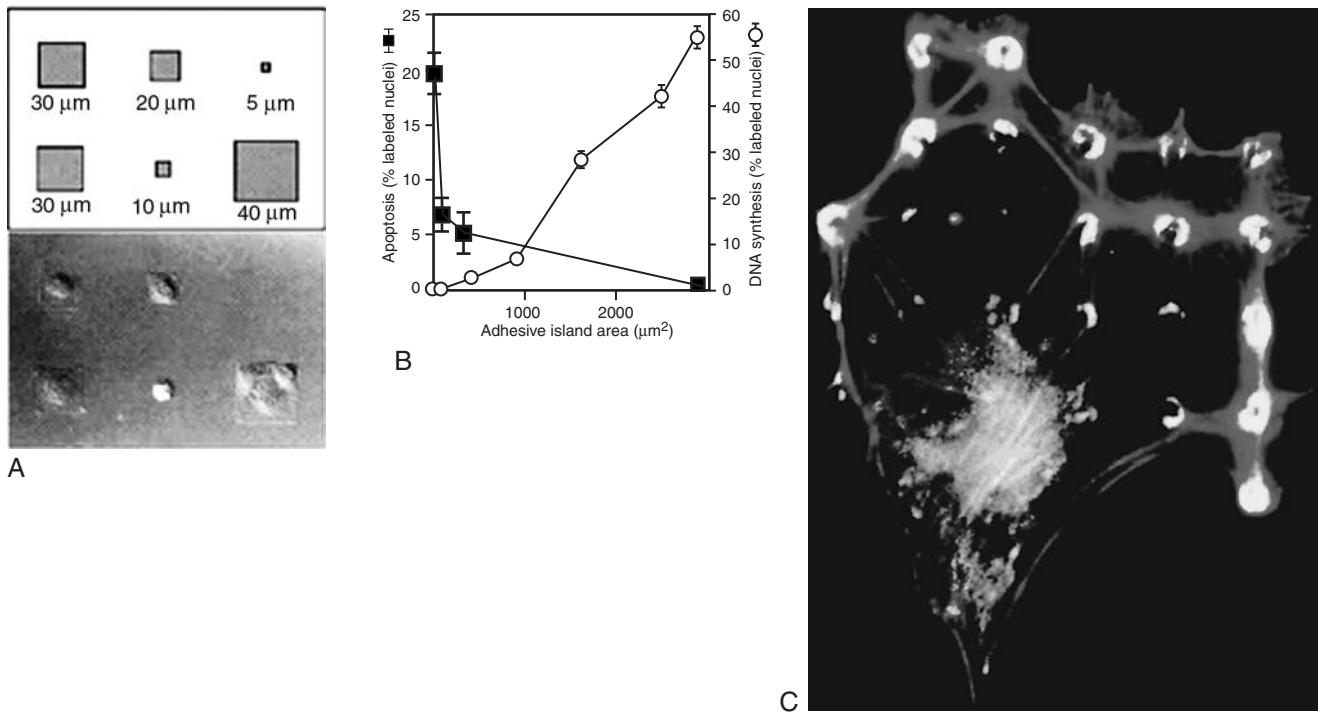

FIG. 13. Effect of spreading on cell growth and apoptosis. (A) Schematic diagram showing the initial pattern design containing different-sized square adhesive islands and Nomarski views of the final shapes of bovine adrenal capillary endothelial cells adherent to the fabricated substrate. Distances indicate lengths of the squares' sides. (B) Apoptotic index (percentage of nuclei exhibiting positive TUNEL staining) and DNA synthesis index (percentage of nuclei labeled with 5-bromodeoxyuridine) after 24 hours, plotted as a function of the projected cell area. Data were obtained only from islands that contained single adherent cells; similar results were obtained with circular or square islands and with human or bovine endothelial cells. (C) Fluorescence micrograph of an endothelial cell spread over a substrate containing a regular array of small ($5\text{-}\mu\text{m}$ -diameter) circular ECM islands separated by nonadhesive regions created with a microcontact printing technique. Yellow rings and crescents indicate colocalization of vinculin (green) and F-actin (red) within focal adhesions that form only on the regulatory spaced circular ECM islands. (A, B, Reproduced by permission from Chen, C. S., *et al.*, 1997. Geometric control of cell life and death. *Science* 276: 1425. C, Reproduced by permission from Ingber, D. E., 2003. Mechanosensation through integrins: Cells act locally but think globally. *Proc. Natl. Acad. Sci. USA* 100: 1472.) (See color plate)

Cells spread to the limits of the islands containing a fibronectin substrate; cells on circular islands were circular while cells on square islands became square in shape and had 90° corners. When the spreading of the cells was restricted by small adhesive islands ($10\text{--}30\ \mu\text{m}$), proliferation was arrested, whereas larger islands ($80\ \mu\text{m}$) permitted proliferation. When the cells were grown on micropatterned substrates with 3- to $5\text{-}\mu\text{m}$ dots forming multiple adhesive islands that permitted the cells to extend over multiple islands while maintaining a total ECM contact similar to that of one small island (that was associated with inhibited growth), they proliferated. This confirmed that the ability to proliferate depended directly on the degree to which the cells were allowed to distend physically, and not on the actual surface area of substrate binding. Thus, cell distortion is a critical determinant of cell behavior.

Interactions of cells with ECM differ from those with soluble regulatory factors owing to the reciprocal interactions between the ECM and the cell's actin cytoskeleton (Ingber, 2003). For example, rigid substrates promote cell spreading and growth in the presence of soluble mitogens; in contrast, flexible scaffolds that cannot resist cytoskeletal forces promote cell retraction, inhibit growth, and promote differentiation. Thus, the properties of the nature and configuration of the

surface-bound ECM on a substrate and the properties of the substrate itself can regulate cell-biomaterials interactions. The key concept is that a biomaterial surface can contain specific chemical and structural information that controls tissue formation, in a manner analogous to cell-cell communication and patterning during embryological development.

The exciting potential of this strategy is exemplified by tissue engineering approaches that employ biomaterials with surfaces designed to stimulate highly precise reactions with proteins and cells at the molecular level. Such materials provide the scientific foundation for molecular design of scaffolds that could be seeded with cells *in vitro* for subsequent implantation or specifically attract endogenous functional cells *in vivo*.

The binding domains of the extracellular matrix (ECM) environment can be mimicked by a multifunctional cell-adhesive surface created by specific proteins, peptides, and other biomolecules immobilized onto a material. For example, molecular modifications of resorbable polymer systems drive specific interactions with cell integrins (an important class of adhesion receptors that bind to ECM) and thereby direct cell proliferation, differentiation, and ECM production. The prototypical binding site present in the adhesive proteins fibronectin and vitronectin is the three amino acid sequence

arginine-glycine-aspartic acid (RGD) which binds to a specific type ($\alpha_4\beta_1$) of integrin receptors on the cell surface (see Fig. 3C). Proteins (such as those with RGD sequences) that induce desirable cell behaviors (e.g., cell adhesion, spreading, and other functions) have been incorporated into biomaterials to control tissue reactions. This sequence supports the adhesion and spreading of human endothelial cells but not smooth muscle cells, fibroblasts, or blood platelets (Hubbell, 1999). Moreover, cellular responses induced can vary with the surface density of RGD peptides immobilized (Koo *et al.*, 2002). Through judicious selection of ligands, surfaces can be designed to reduce protein and cell adhesion, to prevent coagulation, to encourage endothelial cell attachment and retention, to promote capillary infiltration, and to prevent excessive smooth-muscle proliferation and collagen production. This manipulation of cell–integrin interactions with engineered ligands on synthetic biomaterials could improve function in existing applications such as the healing of vascular grafts.

A particularly exciting and active area is the use of chemically patterned surfaces to control cell behavior by creating adhesive and non-adhesive regions and perhaps even

chemical gradients. By varying the size and chemistry of the various regions, and thereby the type, architecture, directional migration, and function of cells, a sort of two-dimensional organ can be grown. With photolithography, self-assembly, and other new technologies for micropatterning, the opportunity to truly engineer biological responses is emerging. Thus, the possibility emerges to design devices with surfaces that have selective cell adhesion and potentially can sort and organize a complex mixture of cells that form a specialized tissue (Fig. 14). This strategy has been used to “engineer” constructs of hepatic tissue in which hepatocytes and endothelial cells self-sort to form endothelium-lined liver cell plates (Kim *et al.*, 1998). A key challenge in tissue engineering is to understand quantitatively how cells respond to molecular signals and integrate multiple inputs to generate a given response, and to control nonspecific interactions between cells and a biomaterial, so that cell responses specifically follow desired receptor–ligand interactions. Exquisite control of scaffold architecture and overall and regional surface chemistry is now also possible; these features (and potentially the mechanical properties of the substrate) may precisely regulate cell behavior (Makohliso *et al.*, 1998; Bhatia *et al.*, 1999; Huang and Ingber, 2000).

Hepatocyte/Endothelial Cell Sorting

Light microscopy (top view)

Histology (vertical cut; hematoxylin and eosin stain)

endothelial cells hepatocytes

FIG. 14. Different levels of type 1 collagen coating on a culture dish result in different organization of endothelial cells and hepatocytes. High collagen levels cause both cell types to spread across the substratum (left). On intermediate collagen levels, endothelial cells form a layer on the substratum whereas hepatocytes form a layer on top of the endothelial cells (center). Low levels of collagen result in an inner layer of hepatocyte aggregate surrounded by endothelial cells (right). (Reproduced by permission from Lauffenburger, D. A., *et al.*, 2001. Who’s got pull around here? Cell organization in development and tissue engineering. *Proc. Natl. Acad. Sci. USA* 98: 4282.) (See color plate)

In addition, special relationships may accrue for biodegradable polymers, especially in tissue engineering applications, since the polymer disappears as functional tissue regenerates. Thus, polymer degradation may yield a dynamic surface whose chemistry might be unpredictable, but could possibly be manipulated to provide an additional level of control over cell interactions. Moreover, covalently immobilized growth factor, for example epidermal growth factor, can retain its biological activity, and potentially DNA delivered upon a biomaterial surface can be efficiently taken up by cells and the encoded gene expressed in a wound-healing environment (Swindle *et al.*, 2001; Richardson *et al.*, 2001).

Topography has also been studied for its effect on cell behavior, including depth and width of groove, and roughness (Von Recum and van Kooten, 1995). Surface texture influences cell behavior, including adhesion and movement attachment, spreading area, proliferation, orientation of cells to the topography, biochemical activity, and neurite (nerve) growth. Moreover, fibroblasts, neurons, and other cells will orient along fibers, ridges, and grooves with potential therapeutic application in nerve regeneration, and texture has been shown to influence macrophage spreading and fibroblast growth. This is particularly demonstrated by the correlations of tumorigenicity with substrate structural features, including roughness, perforations, and more complex surface features (see Chapter 4.7).

TECHNIQUES FOR ANALYSIS OF CELLS AND TISSUES

A number of techniques are available to observe living cells directly in culture systems; these are extremely useful in investigating the structure and functions of isolated cell types. Cells in culture (*in vitro*) often continue to perform many of the normal functions they have in the body (*in vivo*). Through measurement of changes in secreted products under different conditions, for example, culture methods can be used to study how cells respond to certain stimuli. However, since cells in culture do not have the usual intercellular organizational environment, normal physiological function may not always be present.

Techniques commonly used to study the structure of either normal or abnormal tissues, and the purpose of each mode of analysis, are summarized in Table 3 and Fig. 15. The most widely used technique for examining tissues is light microscopy, described below. Details of other useful procedures are available (Schoen, 1989).

Light Microscopy

The conventional light microscopy technique involves obtaining the tissue sample, followed by fixation, paraffin embedding, sectioning, mounting on a glass slide, staining, and examination. Photographs of conventional tissue sections taken through a light microscope (photomicrographs) were illustrated in Fig. 5. Photographs of a tissue sample, paraffin block, and resulting tissue section on a glass slide are shown

TABLE 3 Techniques for Studying Cells and Tissues^a

Technique	Purpose
Gross examination	Overall specimen configuration; many diseases and processes can be diagnosed at this level
Light microscopy (LM)	Study overall microscopic tissue architecture and cellular structure; special stains for collagen, mucin, elastin, organisms, etc. are available.
Transmission electron microscopy (TEM)	Study ultrastructure (fine structure) and identify cells and their organelles and environment
Scanning electron microscopy (SEM)	Study topography and structure of surfaces
Enzyme histochemistry	Demonstrate the presence and location of enzymes in gross or microscopic tissue sections
Immunohistochemistry	Identify and locate specific molecules, usually proteins, for which a specific antibody is available
<i>In situ</i> hybridization	Localizes specific DNA or RNA in tissues to assess tissue identity or recognize a cell gene product
Microbiologic cultures	Diagnose the presence of infectious organisms
Morphometric studies (at gross, LM or TEM levels)	Quantitate the amounts, configuration, and distribution of specific structures
Chemical, biochemical, and spectroscopic analysis	Assess concentration of molecular or elemental constituents
Energy-dispersive X-ray analysis (EDXA)	Perform site-specific elemental analysis on surfaces
Autoradiography (at LM or TEM levels)	Locate the distribution of radioactive material in sections

in Fig. 16. The key processing steps are summarized in the following paragraphs.

Tissue Sample

The tissue is obtained by surgical excision (removal), biopsy (sampling), or autopsy (postmortem examination). A sharp instrument is used to remove and dissect the tissue to avoid distortion from crushing. Specimens should be placed in fixatives as soon as possible after removal.

Fixation

To preserve the structural relationships among cells, their environment, and subcellular structures in tissues, it is necessary to cross-link and preserve (i.e., fix) the tissue in a permanent state. Fixative solutions prevent degradation of the tissue

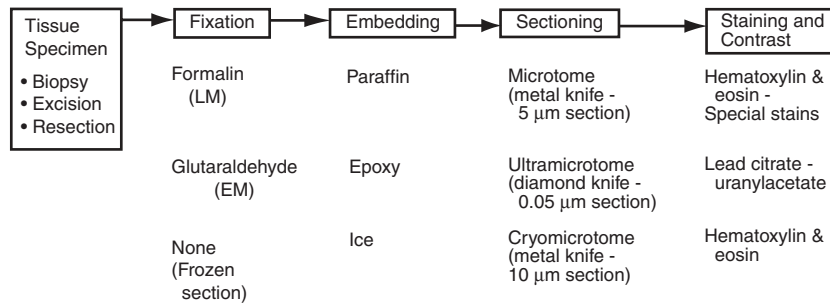

FIG. 15. Key features of tissue processing for examination by light and electron microscopy.

FIG. 16. Tissue processing steps for light microscopy. (A) Tissue section. (B) Paraffin block. (C) Resulting histologic section.

when it is separated from its source of oxygen and nutrition (i.e., autolysis) by coagulating (i.e., cross-linking, denaturing, and precipitating) proteins. This prevents cellular hydrolytic enzymes, which are released when cells die, from degrading tissue components and spoiling tissues for microscopic analysis. Fixation also immobilizes fats and carbohydrates, reduces or eliminates enzymic and immunological reactivity, and kills microorganisms present in tissues.

A 37% solution of formaldehyde is called formalin; thus, 10% formalin is approximately 4% formaldehyde. This solution is the routine fixative in pathology for light microscopy. For TEM and scanning electron microscopy (SEM), glutaraldehyde preserves structural elements better than formalin. Adequate fixation in formalin and/or glutaraldehyde requires tissue samples less than 1.0 and 0.1 cm, respectively, in

largest dimension. For adequate fixation, the volume of fixative into which a tissue sample is placed should generally be at least 5 to 10 times the tissue volume.

Dehydration and Embedding

In order to support the specimen during sectioning, specimen water (approximately 70% of tissue mass) must be replaced by paraffin wax or other embedding medium, such as glycol methacrylate. This is done through several steps, beginning with dehydration of the specimen through increasing concentrations of ethanol (eventually to absolute). However, since alcohol is not miscible with paraffin (the final embedding medium), xylol (an organic solvent) is used as an intermediate solution.

Following dehydration, the specimen is soaked in molten paraffin and placed in a mold larger than the specimen, so that tissue spaces originally containing water, as well as a surrounding cube, are filled with wax. The mold is cooled, and the resultant solid block containing the specimen can then be easily handled.

Sectioning

Tissue specimens are sectioned on a microtome, which has a blade similar to a single-edged razor blade and is progressively advanced through the specimen block. The shavings are picked up on glass slides. Sections for light microscopic analysis must be thin enough to both transmit light and avoid superimposition of various tissue components. Typically sections are approximately 5 μm thick—slightly thicker than a human hair, but thinner than the diameter of most cells. If thinner sections are required (e.g., approximately 0.06- μm -thick ultrathin sections are necessary) for TEM analysis, a harder supporting (embedding) medium (usually epoxy plastic) and a correspondingly harder knife (usually diamond) are used. Sections for TEM analysis are cut on an ultramicrotome. Because the conventional paraffin technique requires overnight processing, frozen sections can be used to render an immediate diagnosis (e.g., during a surgical procedure that might be modified according to the diagnosis). In this method, the specimen itself is frozen, so that the solidified internal water acts as a support medium, and sections are then cut in a cryostat (i.e., a microtome in a cold chamber). Although frozen sections are extremely useful for immediate tissue examination, the quality of the appearance is inferior to that obtained by conventional fixation and embedding methods.

Staining

Tissue components have no intrinsic contrast and are of fairly uniform optical density. Therefore, in order for tissue to be visible by light microscopy, tissue elements must be distinguished by selective adsorption of dyes (Luna, 1968). Since most stains are aqueous solutions of dyes, staining requires that the paraffin in the tissue section be removed and replaced by water (rehydration). The stain used routinely in histology involves sequential incubation in the dyes hematoxylin and eosin (H&E). Hematoxylin has an alkaline (basic) pH that stains blue-purple; substances stained with hematoxylin typically have a net negative charge and are said to be “basophilic” (e.g., cell nuclei containing DNA). In contrast, substances that stain with eosin, an acidic pigment that colors positively charged tissue components pink-red, are said to be “acidophilic” or “eosinophilic” (e.g., cell cytoplasm, collagen). The tissue sections shown in Fig. 5 were stained with hematoxylin and eosin.

Special Staining

There are special staining methods for highlighting components that do not stain well with routine stains (e.g., microorganisms) or for indicating the chemical nature or the location of a specific tissue component (e.g., collagen, elastin; Table 4). There are also special techniques for demonstrating the specific chemical activity of a compound in tissues (e.g.,

TABLE 4 Stains for Light Microscopic Histology^a

To demonstrate	Stain
Overall morphology	Hematoxylin and eosin (H & E)
Collagen	Masson's trichrome
Elastin	Verhoeff-van Gieson
Glycosaminoglycans (GAGs)	Alcian blue
Collagen-elastic-GAGs	Movat
Bacteria	Gram
Fungi	Methenamine silver or periodic acid-Schiff (PAS)
Iron	Prussian blue
Calcium phosphates (or calcium)	von Kossa (or alizarin red)
Fibrin	Lendrum or phosphotungstic acid hematoxylin (PTAH)
Amyloid	Congo red
Inflammatory cell types	Esterases (e.g., chloroacetate esterase for neutrophils, nonspecific esterase for macrophages)

enzyme histochemistry). In this case, the specific substrate for the enzyme of interest is reacted with the tissue; a colored product precipitates in the tissue section at the site of the enzyme. In contrast, immunohistochemical staining takes advantage of the immunological properties (antigenicity) of a tissue component to demonstrate its nature and location by identifying sites of antibody binding. Antibodies to the particular tissue constituent are attached to a dye, usually a compound activated by a peroxidase enzyme, and reacted with a tissue section (immunoperoxidase technique), or the antibody is attached to a compound that is excited by a specific wavelength of light (immunofluorescence). Although some antigens and enzymatic activity can survive the conventional histological processing technique, both enzyme activity and immunological reactivity are often largely eliminated by routine fixation and embedding. Therefore, histochemistry and immunohistochemistry are frequently done on frozen sections; special preservation and embedding techniques now available often allow immunological methods to be carried out on carefully preserved tissue.

Electron Microscopy

Contrast in the electron microscope depends on relative electron densities of tissue components. Sections are stained with salts of heavy metals (osmium, lead, and uranium), which react differentially with different structures, creating patterns of electron density that reflect tissue and cellular architecture. An example of an electron photomicrograph is shown in Fig. 1B.

It is often possible to derive quantitative information from routine tissue sections using various manual or computer-aided

methods. Morphometric or stereologic methodology, as these techniques are called, can be extremely useful in providing an objective basis for otherwise subjective measurements (Loud and Anversa, 1984).

Three-Dimensional Interpretation

Interpretation of tissue sections depends on the reconstruction of three-dimensional information from two-dimensional observations on tissue sections that are usually thinner than a single cell. Therefore, a single section may yield an unrepresentative view of the whole. A particular structure (even a very simple one) can look very different, depending on the plane of section. Figure 17 shows how multiple sections must be

FIG. 17. Considerations for three-dimensional interpretation of two-dimensional information. Sections through a subject in different levels and orientations can give different impressions about its structure, here illustrated for a hard-boiled egg. (Modified by permission from D. H. Cormack: *Essential Histology*, Copyright 1993, Lippincott.)

examined to appreciate the actual configuration of an object or a collection of cells.

Artifacts

Artifacts are unwanted or confusing features in tissue sections that result from errors or technical difficulties in obtaining, processing, sectioning, or staining the specimen. Recognition of artifacts avoids misinterpretation. The most frequent and important artifacts are autolysis, tissue shrinkage, separation of adjacent structures, precipitates formed by poor buffering or by degradation of fixatives or stains, folds or wrinkles in the tissue sections, knife nicks, or rough handling (e.g., crushing) of the specimen.

Identification, Genotyping, and Functional Assessment of Cells, Including Synthetic Products, in Cells or Tissue Sections

It is frequently necessary to accurately ascertain or verify the identity of a cell, or to determine some aspect of its function, including the production of synthetic molecules. For such an assay, either isolated cells or whole tissues are used, depending on the objective of the study. Isolated cells or minced tissue have the advantage of allowing molecular and/or biochemical analyses on the cells and/or products, and often allow the acquisition of quantitative data. Nevertheless, the major advantage of whole-tissue preparations is the ability to spatially localize molecules of interest in the context of architectural features of the tissue.

Cellular apoptosis and proliferation can be quantified (Watanabe *et al.*, 2002). Immunohistochemical markers allow detection of proteins that are highly expressed in a tissue section. However, the relevant antibodies to proteins expressed in high concentration must be available and the expense of such studies limits their usefulness. *In situ* hybridization permits similar investigation of gene expression but, as with immunohistochemistry, only a discrete panel of previously predicted genes can be probed.

Several very exciting new and evolving techniques are available. Gene expression profiling shows the complete array of genes expressed in cells or tissues; the technology may identify pathogenetically distinct subtypes of any lesion and search for fundamental mechanisms even when candidate genes are unknown (Todd *et al.*, 2002; Bertucci *et al.*, 2003). Confocal microscopy helps localize a particular component in a living cell by observing a series of optical sections (planes) that are reconstructed into a three-dimensional image (Howell *et al.*, 2002). Tissue microassays permit the comparative examination of potentially hundreds of individual specimens in a single paraffin block. In addition, laser-assisted microdissection techniques permit isolation of individual or a homogenous population of cells on selected cell populations under direct visualization from a routine histological section of complex, heterogeneous tissue (Eltoum *et al.*, 2002). Very exciting new imaging technology, termed molecular imaging, may permit analysis of viable and *in vivo* tissues (Stephens and Allan, 2003; Weissleder and Ntziachristos, 2003; Webb *et al.*, 2000).

3.5 MECHANICAL FORCES ON CELLS

Larry V. McIntire, Suzanne G. Eskin, and Andrew Yee

INTRODUCTION

Mechanical properties of materials have already been covered in Chapter 1.2 on bulk properties of materials. In this chapter, we will cover the effects of mechanical forces on cells within tissues, on the surfaces of biomaterials, or within polymer scaffolds. Because host cells interact with implanted materials, or because cells are implanted as therapeutic entities in themselves, often within a biomaterial scaffold, the response of cells to mechanical forces is important to consider in order to predict the success of an implant. Cells that are particularly adapted for functioning in concert with physical forces are those of the cardiovascular and musculoskeletal systems. In fact, the local mechanical environment may be crucial for maintenance of proper cell phenotype. Cells that make up the blood vessels are constantly subjected to blood flow and pulsatile pressure. Skeletal support tissues (bone, cartilage, tendon, and ligament) are made up of cells that withstand gravitational forces and directional stresses developed by muscle contraction.

VASCULAR CELL RESPONSES TO MECHANICAL FORCES

Mechanical forces resulting from blood flow directly affect cellular functions and thus, the physiology of the cardiovascular system. Providing insight into the cellular reactions to mechanical forces, the “response to injury” hypothesis describes how atherosclerosis results from wound repair (Ross and Glomset, 1976). To repair the localized injury of the arterial wall, underlying smooth muscle cells proliferate, eventually constricting the vessel and disrupting the blood flow pattern; the resulting complex flow ultimately accelerates the disease progression, leading to potentially lethal conditions. Localization of atherosclerotic plaques in humans at bifurcations and areas in the vasculature characterized by low shear stress and often by complex or recirculating flow patterns support this hypothesis (Glagov *et al.*, 1988). Constricted flow further affects other areas of the cardiovascular system, leading to vascular remodeling. Occlusions of supply arteries may lead to arteriogenesis, a condition in which preexisting collateral arterioles enlarge in response to increased blood flow (Carmeliet, 2000). For example, an *in vivo* study by van Gieson *et al.* illustrates the dilation of mesenteric microvessels in response to a rise in pressure and circumferential strain (van Gieson *et al.*, 2003). Ligation of mesenteric arteries and veins adjacent to an implanted observation window redirected blood flow to the “collateral zone” without a change in the measured shear rate of the observed microvascular network. Accompanying the enlargement of the microvasculature, immature smooth-muscle cells surrounding the microvessels differentiate, exhibiting a quiescent, contractile phenotype. The mechanism(s) leading to this phenomenon remain to be determined.

The principles behind the effects of mechanical forces on cells also apply to vascular grafts. Regardless of the material

used (autologous vein or synthetic graft), small-diameter arterial grafts (less than 6 mm) often fail within the first 5 years (Greenwald and Berry, 2000). Long-term failure of these conduits results from stress localization and flow disturbance at the anastomosis and from compliance mismatch. At anastomotic sites, flow separation, vortex formation, flow stagnation, and circumferential tension gradients occur. Moreover, intimal hyperplasia correlates with anastomotic sites, suggesting that these forces alone or in concert contribute to the eventual stenosis of vascular substitutes (Remuzzi *et al.*, 2003). However, as observed by Mattson *et al.*, increasing the flow rate in vascular grafts while maintaining laminar flow prevents neointimal thickening in the central region of the graft where flow is not complex (Fig. 1). Presumably, the increased shear stress signals inhibition and regression of intimal hyperplasia through the endothelium (Mattson *et al.*, 1997).

Endothelial cells form the endothelium that lines the entire lumen of the vasculature. The forces imparted on this lining by blood flow include shear stress, circumferential strain, and normal stress (Fig. 2). The flow of blood over the endothelium generates viscous drag forces in the direction of flow. The resulting tangential force exerted per unit area of vessel surface at the blood–endothelium surface defines shear stress. Mathematically, the product between the viscosity and the velocity gradient at the wall, also known as the shear rate, equates to shear stress. With ventricular contraction, momentum propagates as waves down the aorta, but diminishes in amplitude down the arterial side of the circulation, giving rise to pulsatile arterial flow and thus pulsatile shear stress. Typical mean arterial values of shear stress range from 6 to 40 dyn/cm² but can vary from 0 to well over 100 dyn/cm² elsewhere in the vasculature (Patrick and McIntire, 1995). While pulsing down the arterial tree, blood flow remains mostly laminar; however, it often becomes complex and/or disturbed (reversing and/or recirculating) at areas of arterial branching, triggering spatial and/or temporal gradients in shear stress.

Along with momentum, pressure propagates as waves down the arterial tree, leading to a periodic normal stress across the vessel lumen. Since the arterial wall is compliant, this periodic pressure difference gives rise to a cyclic wall strain. Since native blood vessels and synthetic substrates on which cells are cultured are nearly elastic, cyclic strain can be measured as the percent change in diameter between the systolic and diastolic pressures. In normal circulation, the internal diameter, and thus, circumference of large mammalian arteries increases cyclically between 2% and 18% over the cardiac cycle at a frequency of approximately 1 Hz (60 cycles/min) (Dobrin, 1978). The normal stress is measured as the blood pressure within the particular branch of the arterial tree; typical systole/diastole values in normal physiology of large human arteries range from 90/50 mm Hg to 120/80 mm Hg (Mills *et al.*, 1970).

Extensive studies that apply shear stress and cyclic strain *in vitro* confirm that endothelial cells actively participate in vascular physiology (Papadaki and Eskin, 1997; Vouyouka *et al.*, 1998). Although only one cell thick, the endothelium provides a permeability barrier; controls thrombosis and hemostasis by maintaining an active thromboresistant surface, which no biomaterial has yet been able to match; and acts as a mechanosensor for the underlying tissue. Lying beneath the

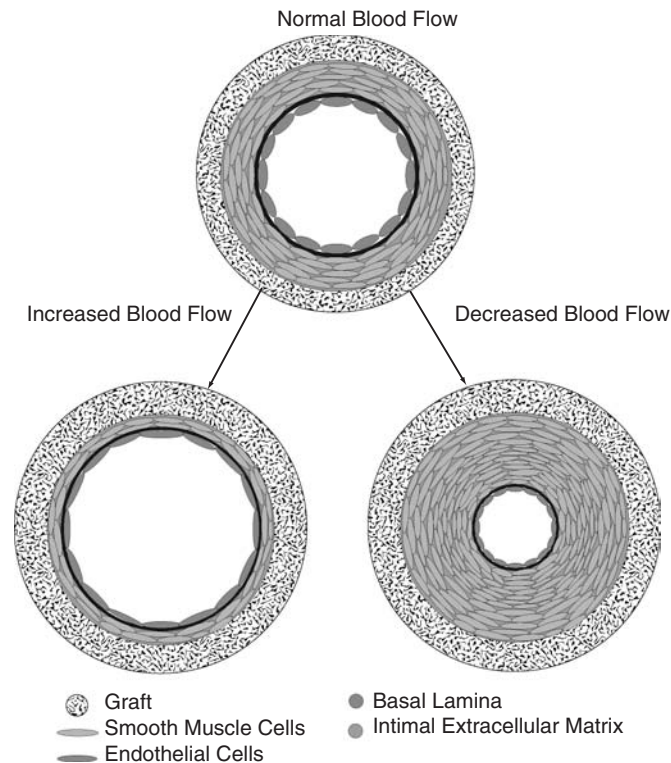

FIG. 1. Intimal hyperplasia in synthetic arterial grafts. Polytetrafluorethylene (PTFE) grafts endothelialized by transmural capillary ingrowth under normal blood flow result in neointimal thickening from proliferation of smooth muscle cells, which narrows the lumen. Ligating adjacent, native vessels diverts all blood flow through the graft, increasing the shear stress over the endothelium, which signals the underlying smooth muscle cells to atrophy since vasodilation is impossible because of the rigidity of PTFE. This response demonstrates that the endothelium regulates shear stress by decreasing the shear rate.

basal lamina in the medial layer of the tissue, smooth muscle cells contract, relax, proliferate, or migrate in response to shear stress, cyclic strain, and paracrine factors (biochemical signals) from endothelial cells. Vessels denuded of the endothelium expose the smooth muscle cells to blood flow, resulting in binding of platelets and subsequently, thrombosis.

As a mechanosensor, the endothelium, in response to changing shear stress, biochemically signals (via the production of compounds such as nitric oxide and prostacyclin; Frangos *et al.*, 1985) the smooth muscle cells to dilate or contract. Vasomotor control over lumen diameter primarily resides with smooth muscle cells. Responding to changes in blood flow and pressure, smooth muscle cells contract/relax and secrete a matrix of collagen and elastin, which confer strength and elasticity, respectively, to modulate the circumferential tension. By increasing the flow rate while holding the viscosity constant or increasing the viscosity but sustaining a constant flow rate through an excised cremaster arteriole, Koller *et al.* demonstrated that vasodilation does not depend on the mass transport of vasoactive agents but on the response of the endothelium to shear stress (Koller *et al.*, 1993). Treating the arterioles with indomethacin abrogated the dilative response of the vessel,

implicating prostaglandin E_2 and I_2 as primary mediators. Furthermore, denudation of the arterioles elicited similar responses to those treated with indomethacin, confirming the role of the endothelial cells in modulating vascular tone in response to changing shear stress (Du *et al.*, 1995). However, smooth muscle cells also react to shear stress (from interstitial fluid flow) and to cyclic strain (from pulse pressures of blood flow). Excessive cyclic strain may be a more injurious force than shear stress, since it affects the whole thickness of the artery wall, including smooth muscle cells, fibroblasts (connective tissue cells in the adventitial layer), and the extracellular matrix (Carosi *et al.*, 1994).

To determine the effects of mechanical forces on vascular cells, investigators have isolated different cell types in culture and individually subjected them to specific forces. *In vitro* studies of steady, laminar shear stress, although more prevalent in capillaries and veins *in vivo* than in large arteries, provide the necessary baseline for interpreting the effects of more complex flow regimes. The parallel-plate flow chamber and the cone and plate viscometer are normally used to study shear-stress effects on endothelial and smooth muscle cells cultured on rigid surfaces, usually glass slides, coverslips, or tissue culture

FIG. 2. Diagram of forces acting on blood vessel wall. (A) Cross-sectional view of cylindrical vessel showing normal and tensile forces due to hydrostatic pressure and circumferential deformation, respectively. (B) The forces on the endothelial lining include normal and tangential forces. The tangential force due to fluid flow is shown by the horizontal arrow. A tensile force on the endothelium would result from the normal force causing expansion in the circumferential direction. The resulting tensile force would be perpendicular to both normal and tangential forces.

dishes coated with extracellular matrix protein(s). For the parallel-plate flow chamber, a continuously filled supply reservoir elevated above a receiving reservoir creates a pressure drop proportional to the difference in height between the two reservoirs (Fig. 3). Since the two reservoirs are held at constant but different heights, gravity drives flow, and shear stress is steady. A small channel height allows viscous forces to dominate over momentum forces for a wide range of flow rates, making flow laminar (Frangos *et al.*, 1998). The Reynolds number quantifies the ratio between these two forces:

$$\text{Re} = \frac{Uh\rho}{\mu} \quad (1)$$

where U = bulk velocity, h = channel height, ρ = density, and μ = viscosity. For a Newtonian fluid flowing through a parallel-plate flow chamber with a rectangular geometry, the steady, laminar shear stress at the wall is:

$$\tau_w = \frac{6\mu Q}{bh^2} \quad (2)$$

where τ_w = wall shear stress, Q = flow rate, b = channel width, and h = channel height. By varying the chamber geometry, the flow rate, or the viscosity, the entire physiological range of wall shear stresses can be investigated.

For the cone and plate viscometer, cells are similarly cultured on a protein-coated rigid surface but recessed flush into

the plate (Bussolari and Dewey, 1982). For small cone angles, the shear rate (and therefore the shear stress) is essentially constant throughout the flow field.

Recently, methods to investigate shear stresses with a more physiological waveform have been developed for both of these devices (Yee *et al.*, unpublished). The flow or shear rate measured from an artery through magnetic resonance imaging or ultrasound serves as input for the controller. Instead of gravity-driven flow, a computer-controlled pump regulates the instantaneous flow rate through a parallel-plate flow chamber. Similarly, a stepper motor can control the rotational speed of the cone of the viscometer (Blackman *et al.*, 2000), giving rise to pulsatile shear stress on the endothelial cells cultured on the plate.

If the cell property studied responds to shear stress in a dose-dependent fashion (i.e., varies directly with the level of shear stress imposed), it is referred to as shear stress dependent. If the property under study responds to changes in shear rate, but not directly with the level of shear stress imposed, it is referred to as flow dependent. The difference arises from inclusion of mass-transport phenomena (convection and diffusion) in flow-dependent processes, whereas the term “shear-stress dependent” specifies the mechanical force only. Differences between effects due to shear stress alone and those due to flow (mass and momentum transfer) can be examined by circulating media of different viscosities (with the addition of high molecular weight dextrans).

To study cyclic strain effects, the cells must be cultured on deformable substrates, usually silicone rubber or segmented polyurethane coated with an extracellular matrix proteins. In general, two kinds of devices have been used to impose cyclic strain on cells—(1) uniaxial or biaxial strain devices driven mechanically by an eccentric cam (Fig. 4), which imposes a uniform strain across the substrates, and (2) the Flexercell Strain Unit (Flexcell International, Corp.), driven by vacuum pressure pulled beneath the substrate on which cells are cultured, thus deforming substrate and cells (Haseneen *et al.*, 2003). The Flexercell unit applies a maximum strain of 25% around the edges of the substrate, decreasing to a minimum of less than 3% at the center (Gilbert *et al.*, 1994). However, it should be noted that not only do the mechanical forces that impinge on a population of cultured cells alter their function, but also the substrate on which the cells are cultured may affect cell response.

Modulation of vascular cell function by mechanical forces takes place at several levels, with the most central being gene regulation in the nucleus. Specific DNA sequences (genes) encode for synthesis of specific proteins (via mRNA), which have different roles in cell function. To affect the cell at the gene level, the stimulus (mechanical force) must be (1) perceived at the cell membrane (e.g., by receptors, ion channels, or integrins), (2) transmitted through the cytoplasm, perhaps physically (mechanotransduction through the cytoskeleton), biochemically, or both, and (3) stimulate (or inhibit) transcription in the nucleus (Fig. 5).

Significant progress has been made in the past decade in understanding many of the signal transduction pathways involved in mammalian cell sensing of mechanical forces (Hojo *et al.*, 2002; Shyy and Chien, 2002; Li *et al.*, 1997; Tai *et al.*, 2002; Wittstein *et al.*, 2000). The relative

FIG. 3. Schematic diagram of the flow loop with parallel-plate flow chamber, showing side view of chamber assembled with loop components, and exploded view on lower left. The exploded view includes the polycarbonate base with two slits through which medium enters and exits the channel, the Silastic gasket that determines the channel height, and the glass slide on which the cells are cultured. The flow rate is controlled by the relative distance between the two reservoirs. The medium is recirculated from the lower to the upper reservoir by a roller pump. The channel depth is normally 220 μm ; the area of cells exposed to flow is approximately 16 cm^2 . The entire circuit is gassed with 5% CO_2 in humidified air and run at 37°C. Medium samples can be removed from the lower reservoir without disturbing the flow field. The medium volume is about 20 ml and the residence time in the flow chamber and its tubing is about 10 sec (modified from Frangos *et al.*, 1988).

contribution of diffusable second messengers (Ca^{2+} , pH, etc.) and direct mechanical transmission via cytoskeletal elements (tensegrity theory) is still a matter of some debate (Gudi *et al.*, 2003; Ingber, 2003).

To elucidate potential signal transduction elements and pathways, specific inhibitors such as calcium chelators (BAPTA-AM for intracellular Ca^{2+} and EGTA for extracellular Ca^{2+}), G-protein inhibitors (pertussis toxin and cholera toxin), ion-channel inhibitors, and kinase inhibitors are typically employed while changes in cellular activities such as

transcription factor regulation, intracellular pH, phosphorylation events, membrane perturbation, and cytoskeletal remodeling are monitored. However, to determine the effects of deformation and displacement of subcellular structures on cellular properties and activities, new optical methods such as atomic force microscopy, optical sectioning, and high resolution, four-dimensional (4D) fluorescence microscopy have been developed (Barbee, 2002; Helmke and Davies, 2002; Stamatatos and McIntire, 2001). These new techniques have revealed the heterogeneity in the mechanical properties of the

FIG. 4. Schematic diagram of cyclic strain unit: (A) Side view of polycarbonate unit connected to motor-gear assembly. Placement of the adjustable offset pin determines the level of elastic membrane strain. Frequency is set by controlling current to direct current motor with gear box. (B) Top view of unit showing two cell culture chambers; the top chamber shows the membrane clamped at both ends to impose cyclic strain. In the bottom chamber the membrane is fixed to the polycarbonate and clamped at only one end to provide a fluid motion control. Both chambers are maintained at 37°C and gassed with 5% CO₂ in humidified air.

cytoskeletal proteins and their putative roles in mechanotransduction, perhaps explaining the spatial dependence on signal transduction at the intracellular level (Butler *et al.*, 2001).

Following mechanotransduction of shear stress, cyclic strain, or normal stress, vascular cells may alter the production levels of many substances at the genetic level. To claim gene regulation of a protein requires the following: (1) the corresponding mRNA level must change, (2) the change in mRNA must not be the result of stabilization or destabilization of the mRNA, and (3) the protein production must also change in response to the stimulus. Although less than 2% of the DNA functionally encodes for proteins, analysis of the effects of mechanical stress on the 30,000 to 40,000 protein-encoding human genes remains a daunting task (Consortium IHGS, 2001; Venter, 2001). Before DNA microarray technology, the choice of which gene to study was based on the suspected physiological significance of the corresponding protein in vasodilation or vasoconstriction (endothelin-1, or nitric oxide synthase), in thrombosis (tPA and PAI-1, thrombomodulin), in proliferation (growth factors), in permeability

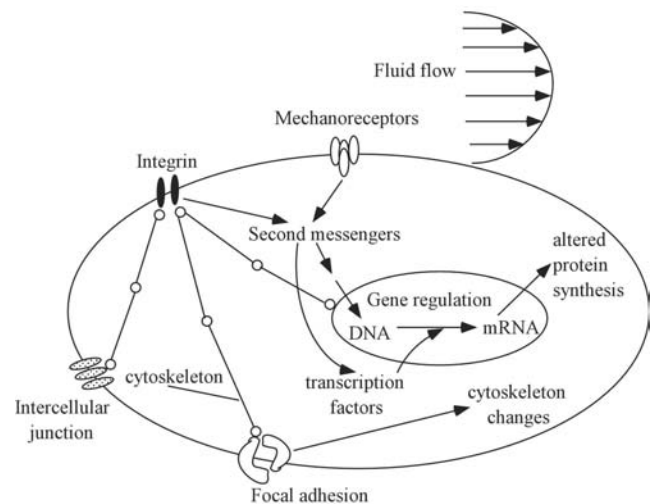

FIG. 5. Some of the possible mechanotransduction pathways in vascular cells. Putative mechanoreceptors on the luminal cell membrane may alter their conformation in response to mechanical stimuli, activating a signal transduction cascade involving diffusible second messengers. This cascade of chemical reactions leads to activation of gene transcription in the nucleus. Alternatively, mechanotransduction may be direct via elements of the cytoskeleton. Forces may be transmitted through these networks from the luminal cell membrane to focal adhesion sites, intracellular junctions or directly to the nucleus. Translation of the mechanical force to a chemical signal at these sites would then lead to alterations of cell function and gene regulation.

(cadherins, connexins), or in adhesion of blood borne substances to the endothelium (VCAM-1, MCP-1). Functional assays verify the expected protein function(s) and can further illustrate protein quantity alterations, caused by the mechanical stimulus, at the transcriptional level. Factors that directly influence DNA transcription, such as changes in transcription factors in response to shear stress on endothelial cells, have been reported (Chien *et al.*, 1998; Nagel *et al.*, 1999; Bao *et al.*, 2000). Some of the base sequences in the promoter regions of the DNA that are required for the gene specific shear stress response have been identified (Korenaga *et al.*, 1997; Resnick *et al.*, 1993). Tables 1 and 2 list some responses to shear stress of endothelial and smooth muscle cells, respectively. Table 3 shows some effects of cyclic strain on endothelial cells and smooth muscle cells.

To interpret and understand the effects of mechanical forces *in vivo*, *in vitro* shear stress studies can be compared to *in vitro* cyclic strain studies of the same cell type. Typically, cells are subjected to one type of force at a time, but *in vitro* studies with both forces acting in concert are beginning to appear as more suitable substrates are developed. Two ways to approach such a study are (1) to choose a cell product that varies in a dose-dependent manner throughout the physiological range of shear stresses, has a large amplitude variation, and responds differently under cyclic strain than under shear stress, then proceed to study how it is controlled by other physiologically relevant inputs (e.g., growth factors, cytokines, cytoskeletal elements); (2) to compare many genes in parallel, using DNA microarray techniques or differential display, and

TABLE 1 Shear Stress Mediated Endothelial Cell Responses

Response	Effect
<i>General functions</i>	
Morphology	Alignment and elongation
Actin stress fibers	Formation and alignment
Pinocytosis	Increase
LDL uptake	Slight increase
Cation channel	Activation
DNA synthesis	No effect (if laminar flow)
DNA synthesis	Stimulated (if turbulent flow)
G proteins	Activation
Apoptosis	Decrease
<i>Protein synthesis and secretion</i>	
Tissue plasminogen activator	Increase
Endothelin-1	Decrease
Plasminogen activator inhibitor	No effect
Fibronectin	Slight decrease
VCAM-1	Decrease
ICAM-1	Transient increase
Protease activated receptor-1	Decrease
Nitric oxide synthase	Increase
<i>mRNA levels</i>	
Tissue plasminogen activator	Increase
Endothelin-1	Decrease
Fibroblast growth factor-2	No effect
Glyceraldehyde-3-phosphate dehydrogenase	No effect
VCAM-1	Decrease
ICAM-1	Increase
Protease activated receptor-1	Decrease
Monocyte chemoattractant protein-1	Transient increase then decrease
<i>Arachidonic acid metabolism</i>	
PGI ₂ synthesis	Large increase
Arachidonate uptake	Increase for phosphatidylinositol
<i>Second messengers</i>	
Inositol trisphosphate	Increase
Intracellular Ca ²⁺	Increase (ATP mediated)
cAMP	Increase mediated (PGI ₂ mediated)
Diacylglycerol	Increase
Nitric oxide (NO)	Increase
pH	Decrease (HUVEC)

TABLE 2 Shear Stress Mediated Smooth Muscle Cell Responses

Response	Effect
Morphology	No alignment and orientation
Proliferation	Decrease
Tissue plasminogen activator	Increase
Protease activated receptor-1	Decrease
Nitric oxide	Increase
Prostaglandins E ₂ , I ₂	Increase
Intracellular pH	Increase
Intracellular Ca ²⁺	No change

TABLE 3 Cyclic Strain Mediated Endothelial and Smooth Muscle Cell Responses

Response	Effect
<i>Endothelial cells</i>	
Endothelin 1	Increase
Tissue plasminogen activator	No change
Plasminogen activator inhibitor-1	Increase
Prostaglandin I ₂	Increase
Platelet-derived growth factor-B	No change
c-fos	Increase
c-jun	Increase
Nuclear factor kappa-B	Increase
Nitric Oxide	Increase
MCP-1	Increase
VCAM-1	Decrease
<i>Smooth muscle cells</i>	
Proliferation	Increase
Platelet-derived growth factor	Increase
Fibroblast growth factor-2	Release
Protease activated receptor-1	Increase
Matrix metalloprotease-1	Decrease

focus on genes that yield the greatest differences by these techniques. Recently, with rapid progress in the genome sequencing projects, molecular biological techniques have been developed that allow investigators to examine a large number of genes in populations of cells subjected to shear stress or cyclic strain. Sequences from up to several thousand known genes can be arranged on a single chip or microtiter plate.

An example of the first approach is a study of the control of thrombin receptor, or protease activated receptor-1 (PAR-1), in vascular smooth-muscle cells by shear stress and cyclic strain (Papadaki, *et al.*, 1998). Thrombin receptor *in vivo* is upregulated in injured arteries, presumably in order to bind thrombin for cleavage of fibrinogen, leading to thrombus formation. Thus up-regulation of PAR-1 can be considered a thrombogenic response. However, activation of PAR-1 by thrombin is also a potent mitogenic stimulus for vascular smooth-muscle cells. PAR-1 protein decreases by two-thirds in smooth muscle cells subjected to 25 dyn/cm² shear stress for 24 hours. Under cyclic strain (20%, 1 Hz) PAR-1 protein increases 2.5-fold after 24 hours (Nguyen *et al.*, 2001). Thus smooth muscle cells under cyclic strain express a thrombogenic product, whereas arterial levels of fluid-induced shear stress down-regulate this protein.

In the second approach, the gene expression profiles are initially unknown, and genes of interest are selected after comparing treated cells to untreated cells at the genomic (1000–10,000 genes) or pathway-specific (~100 genes) level. For example, differences in gene expression between endothelial cells subjected to shear stress and endothelial cells kept under static culture are detected with microarrays (Chen *et al.*, 2001; Garcia-Cardena *et al.*, 2001; McCormick *et al.*, 2001). In the McCormick *et al.* study, shear stress of 25 dyn/cm² for 24 or 6 hours altered the expression of 52 genes (32 up-regulated, 20 down-regulated). Genes were considered up-regulated or down-regulated if the expression increased or

decreased two-fold, respectively. Changes in the most notably altered genes—CYP1A1, CYP1B1, CTGF, ET-1, PGHS-2, NADH dehydrogenase—were verified by Northern blot densitometry. Particularly, up-regulation of CYP1A1 and CYP1B1 and down-regulation of CTGF, ET-1, and MCP-1 support the theory that laminar shear stress protects the endothelium from fibrotic and atherosclerotic disease. Data analysis of the huge data set is a challenge in these studies. Statistical methods for microarray data analysis continue to evolve into significance tests that leave fewer genes suspected of altered expression to chance.

An example of the second approach is the differential display study of Topper *et al.* (1996), in which mRNAs from shear stressed versus control endothelial cells were examined for differences in expression using oligonucleotide primer sets, and then amplifying the mRNAs that differ most. As in DNA microarray studies, the genes of interest are not chosen by the investigators. Three “atheroprotective genes,” manganese superoxide dismutase, cyclooxygenase-2, and endothelial nitric oxide synthase, were up-regulated by steady laminar shear stress (10 dyn/cm² for 1 or 6 hours), but not by turbulent shear stress for the same exposure times at the same average wall shear stress.

SKELETAL CELL RESPONSES TO MECHANICAL FORCES

Bone, cartilage, ligament and tendon are all skeletal tissues derived from mesenchymal stem cells. In the specific tissue environments, musculoskeletal cells differ in the composition of the matrix they secrete, which results in different tissue mechanical properties. It has been known for more than 100 years that bone density patterns are a function of load (Wolff's law) (Stoltz *et al.*, 2003). Bone remodels in response to stress and loses density in unstressed regions. Studies under the aegis of NASA have dramatically enhanced appreciation of the effects of weightlessness in promoting bone loss in astronauts. Bone loss from microgravity produced by space flight has provided conclusive *in vivo* evidence for the positive effects of physiological loading of skeletal tissues (Duncan and Turner, 1995).

Exercise-stimulated bone remodeling may be the response of osteoblasts to interstitial fluid flow (IFF) (Hillsley and Frangos, 1994; Reich *et al.*, 1991). Furthermore, temporal gradients in IFF, imposed by pulsatile shear stress, stimulate osteoblast proliferation *in vitro* (Jiang *et al.*, 2002), whereas steady shear stress does not stimulate osteoblast signal transduction or proliferation. Continually changing flow regimens (such as pulsatility) *in vivo* simulate the increase in temporal gradients in blood flow that occur with increased physical activity.

Bone tissue comprises bone cells (osteocytes), osteoblasts (responsible for bone formation), osteoclasts (responsible for bone resorption), and an extracellular matrix composed of hydroxyapatite (a complex molecule of hydrated calcium phosphate) and collagen, which becomes calcified or ossified.

Mechanical loading generates fluid shear stress, hydrostatic compression, uniaxial stretch, or biaxial stretch on bone cells.

FIG. 6. Compressive force on long bone due to gravity and/or locomotion gives rise to shear stress on the bone cells due to interstitial fluid flow. Loading of porous bone or cartilage structure (or porous polymer scaffolds in load-bearing tissue-engineering applications) leads to interstitial fluid motion through small channels, leading to generation of significant shear stress on cells attached to the polymer matrix.

Cortical (long) bone tissue is porous, and interstitial fluid flow due to mechanical loading is thought to be the primary mechanism for action of mechanical forces on bone (Fig. 6). Devices for studying osteoblast response to these forces have been reviewed (Basso and Heersche, 2002). In addition, there is evidence that low-level vibrations are key to determining the structure of bone (Rubin *et al.*, 2001). Rats with depressed bone formation due to suspension of their hind legs had dramatically improved bone formation after 10 min per day vibration therapy (0.25 g, 90 Hz) for 28 days.

Cartilage, located on the articulating surfaces of joints, provides low friction for freely moving joints. In the growing embryo, cartilage is the precursor to bone. Cartilage cells (chondrocytes) secrete a matrix of collagen fibers embedded in mucopolysaccharide (e.g., chondroitin sulfate). Cartilage responds to mechanical loading similarly to bone. Increased load leads to increased matrix production, resulting in stronger tissue. Cartilage must withstand tensile and shear forces in addition to compression (Kim *et al.*, 1994). Most of the work on cartilage loading focuses on compression and hydrostatic pressure. Cyclic compression of explants (0.1 Hz, 2–3% compression) stimulated matrix synthesis by chondrocytes (Shieh and Athanasiou, 2003).

Tendons and ligaments join muscle to bone and bone to bone, respectively. These tissues withstand unidirectional tension. Tendons are primarily composed of collagen (86%

dry weight), secreted by fibroblasts and aligned unidirectionally. Tendon has one of the highest tensile strengths of any tissue (50–150 MPa). When resected, the tendon retracts and must be mechanically loaded for healing to occur (although this is not well studied as to timing or load). Ligaments, like tendons, are primarily composed of collagen fibers, but the fibers are less densely packed (70% dry weight) and woven, unlike the parallel arrangement in tendon. Ligaments contain more elastin, and thus are more extensible. Both are viscoelastic, and both dissipate energy and show hysteresis in the stress–strain curves.

Biomaterials problems related to skeletal tissues are mainly of two types: joint replacements and bone defect or loss replacement. By far most joint replacements are hip or knee arthroplasties (covered in Chapter 7.7 on orthopedic applications). These prostheses must replace the functions of bone, cartilage, and tendon. Most implants consist of metal alloys, materials with long fatigue life and high corrosion resistance. Articulating surfaces have more recently been coated with materials of low coefficient of friction and low wear rate. Joint replacement requires the presence of both load-bearing compressive forces on the bones and periodic flexing and extending of the bone for functional healing of bone, cartilage, and tendon to occur. To replace bone defects (e.g., as the result of tumor removal) presents a different challenge and has previously required autologous bone. As in the case of vascular cells, applied forces are transduced across the cell membranes of the skeletal cells leading to cell responses, most notably tissue remodeling.

Bone, which appears inert macroscopically, is a very dynamic tissue with high cell turnover rates, much higher than those of noninjured vascular cells. In addition, there are important differences between bone and cartilage tissue structure. Bone is highly vascularized, cellular, and innervated, whereas cartilage has low cell density, little blood supply, and no innervation. The effects of mechanical forces on bone and cartilage cells have been studied *in vitro* using devices similar to those employed for vascular cells. The relative quantities of collagen and glycosaminoglycans (GAGs) and cell density in tissue-engineered cartilage (chondrocytes seeded on polyglycolic acid scaffolds) are functions of the mechanical environment in which they are cultured (Gooch *et al.*, 1998). Table 4 gives a summary of mechanical force effects on skeletal tissue.

Bone cement, poly(methyl methacrylate), has been used for years to fill defects in bone. However, it is not biodegradable, and since the cement bears the load (stress shielding), the healing bone does not regenerate and the implant ultimately fails. However, resorting to degradable polymers seeded with cells requires considering the cell type, the mechanical properties of the polymer, and the strategy to maintain cell survivability. Some recent studies have begun to study mechanical loading of musculoskeletal cells grown in three-dimensional polymer scaffolds. This would give an environment much closer to that seen by the cells *in vivo*, which is inherently three-dimensional for these tissues. There are, however, significant problems in knowing the actual forces and strains the cells experience in these constructs and also what fluid motion is induced by the external loading. Thus separating mechanical strain and fluid shear stress effects on cell metabolism and tissue growth is difficult.

TABLE 4 Effect of Mechanical Forces on Skeletal Cell Responses

Cell/tissue	Force	Effect/responses
Cultured osteoblasts	Shear stress	Increase cAMP Increase PGE ₂
Cultured osteocytes	Cyclic strain	Increase IP ₃ Increase c-fos Increase COX-2 Increase osteopontin Activates focal adhesion kinase
Cortical bone	Bending load	Increase osteopontin Decrease myeloperoxidase
Cartilage disks	Static compression Cyclic strain	Decrease glycosaminoglycan Increase glycosaminoglycan
Chondrocytes	Cyclic strain	Increase collagen type II Increase aggrecan No change in B ₁ integrin

In addition, specifying the macroscopic strain at the boundaries does not specify the local strain seen by the cells in these porous three-dimensional scaffolds. The mechanical properties of the polymer and those of the cells are quite different.

MARK SHIRTLIFF, AND PAUL STOODLEY

4.1 INTRODUCTION

Frederick J. Schoen

Biomaterials and medical devices are now commonly used as prostheses in cardiovascular, orthopedic, dental, ophthalmological, and reconstructive surgery, in interventions such as angioplasty (stents) and hemodialysis (membranes), in surgical sutures or bioadhesives, and as controlled drug release devices. Most implants serve their recipients well for extended periods by alleviating the conditions for which they were implanted. However, some implants and extracorporeal devices ultimately develop complications—adverse interactions of the patient with the device, or vice versa—which constitute device failure and thereby may cause harm to or death of the patient. Complications result largely as a consequence of biomaterial–tissue interactions, which all implants have with the environment into which they are placed. Effects of both the implant on the host tissues and the host on the implant are important in mediating complications and device failure (Fig. 1).

Chapter 4 contains overview discussions of the most important host reactions to biomaterials and their evaluation, including nonspecific inflammation and specific immunological reactions, systemic effects, blood–materials interactions, tumor formation, and infection. To a great extent, these interactions arise from alterations of physiological (normal) processes (e.g., immunity, inflammation, blood coagulation) comprising host defense mechanisms that function to protect an organism from the deleterious external threats (such as bacteria and other microbiologic organisms, injury and foreign materials). Chapter 6 addresses degradation mechanisms in biomaterials (i.e., the effect of the host on biomaterials). Several key concepts of biomaterials–tissue interactions are emphasized here in an effort to guide the reader and facilitate the use of this chapter.

THE INFLAMMATORY REACTION TO BIOMATERIALS

In their respective chapters, Anderson, Mitchell, and Johnson describe the inflammatory and potential

immunological interactions that occur with biomaterials. In contrast to living organ transplants, biomaterials are not generally “rejected.” The process of organ rejection denotes an inflammatory process that results from a specific immune response and which causes tissue death, which synthetic biomaterials typically do not generate. The usual response to biomaterials comprises nonspecific inflammation (see Chapters 4.2, 4.3, and 4.4).

However, as summarized by Mitchell (2001), tissue-derived biomaterials (such as bioprosthetic heart valves) may express foreign histocompatibility antigens and be antigenic and capable of eliciting an immune response, including antibodies and antigen-specific T cells. Nevertheless, it is important to understand the following:

1. Tissue immunogenicity does not necessarily induce immunologically mediated device dysfunction.
2. Specific immunological responses can be not only a cause of but can result from device failure.
3. Although mononuclear inflammatory cell infiltrates (containing macrophages and lymphocytes) are characteristically associated with organ/tissue rejection on histological examination, mononuclear inflammatory infiltrates are themselves nonspecific and comprise a largely stereotyped and generic response to tissue injury. Therefore, the presence of mononuclear cells does not necessarily denote a rejection pathogenesis.

In order to invoke an immunological reaction to a biomaterial as the cause of a device failure, an immunological variant of the classical Koch’s postulates, which are the objective criteria for concluding that a disease is infectious and caused by a specific microbiologic agent, would be appropriate. The classic Koch’s postulates state that:

1. A suspected infectious agent should be recoverable from the pathologic lesions of the human host.
2. The agent should cause the pathologic lesions when inoculated into an animal host.
3. The agent should then be recoverable from the pathologic lesions in the animal.

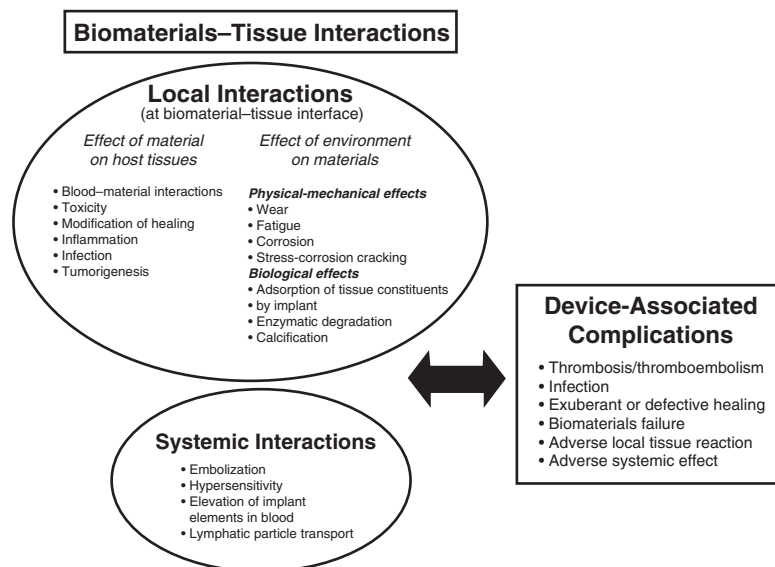

FIG. 1. Biomaterials-tissue interactions (reproduced from Schoen FJ). In: *Advances in Cardiovascular Medicine* (Harvey 1602-2002 Symposium, on the 4th Centenary of William Harvey's Graduation at the University of Pauda), Thiene G, Pessina AC (eds.), Universita degli Studi di Padova, 2002; 289-307.

Mitchell describes an immunological variant of Koch's postulates to test an immunological hypothesis for calcific and non-calcific bioprosthetic valve failure (Schoen, 1999) as follows:

1. Antigen-specific elements (antibodies or cells) should be directly associated with failing valves. Moreover, control experiments should be performed to demonstrate that any antibodies or cells on implanted valves are not simply present because of surgical manipulation or aberrant flow conditions.
2. Antibodies or cells from experimental animals that have dysfunctional implanted valves transferred into an appropriate second host (immunologically matched to the original valve donor) should cause valve failure.
3. Adoptively transferred cells or antibodies should be detectable on a failed valve in the second recipient.

Although some evidence for these criteria can be obtained in humans, carefully designed animal investigations provide the only rigorous way to satisfy them. With respect to tissue heart valves, although some investigators have demonstrated that such tissues can be immunogenic, there exists no evidence that valve destruction or loss of function is mediated by immune elements, or that blockade of immune mechanisms by immunosuppression prevents that outcome.

Most biomaterials of potential clinical interest typically elicit the foreign body reaction (FBR), a special form of non-specific inflammation. The most prominent cells in the FBR are macrophages, which attempt to phagocytose the material and are variably successful, but complete engulfment and degradation are often difficult. The macrophages, activated in the process of interacting with a biomaterial, may elaborate cytokines that stimulate inflammation or fibrosis. Multinucleated giant cells in the vicinity of a foreign body are generally considered evidence of a more severe FBR. The

more "biocompatible" the implant, the more quiescent (less inflammation in) the ultimate response. When the implant is a source of particles not easily controlled, such as wear debris from articulating joint surfaces (Jacobs *et al.*, 2001), the inability of inflammatory cells to adhere to but not phagocytose particles larger than a critical size ("frustrated phagocytosis") can lead to release of enzymes (exocytosis) and cytokines and other chemical mediators (e.g., prostaglandin, tumor necrosis factor-alpha, and interleukin-1) and cause harm to the extracellular environment. Thus, inflammatory cell products that are critical in killing microorganisms in typical inflammation can damage tissue adjacent to foreign bodies.

The nature of the reaction is largely dependent on the chemical and physical characteristics of the implant. For most inert biomaterials, the late tissue reaction is encapsulation by a relatively thin fibrous tissue capsule (composed of collagen and fibroblasts). Tissue interactions can be modified by changing the chemistry of the surface (e.g., by adding specific chemical groupings to stimulate adhesion or bone formation in orthopedic implants), inducing roughness or porosity to enhance physical binding to the surrounding tissues, incorporating a surface-active agent to chemically bond the tissue, or using a bioresorbable component to allow slow replacement by tissue to simulate natural healing properties.

SYSTEMIC AND REMOTE EFFECTS

Hensten-Petersen and Jacobsen summarize biomaterials-related systemic toxicity and hypersensitivity reaction (through lymphatics and the bloodstream) in animals and patients with either stainless steel or cobalt-base orthopedic total joint replacement components, elevations of metallic components occur in tissue (at both local and remote sites) and in serum

and urine. Transport of particulates over large distances by macrophages to regional lymph nodes and to the lungs has been considered a systemic and remote effect. As a consequence of silicone migrated through lymphatic vessels to lymph nodes, an enlarged, hard axillary lymph node in a woman who received a silicone-gel breast prosthesis for reconstruction following mastectomy for a carcinoma can be misdiagnosed as tumor.

“Metal allergy” is well-recognized and is frequently associated in women with the use of cheap, high-nickel-alloy costume jewelry or earrings and can occur in association with metallic implants (Hallab *et al.*, 2001). By themselves, metal ions lack the structural complexity required to challenge the immune system. However, when combined with proteins, such as those available in the skin, connective tissues, and blood, a wide variety of metals induce immune responses and this can have clinical effects. Cobalt, chromium, and nickel are included in this category, with nickel perhaps the most potent; at least 10% of a normal population will be sensitive by skin test to one or more of these metals, at some threshold level.

THROMBOEMBOLIC COMPLICATIONS

Hanson emphasizes that exposure of blood to an artificial surface can induce thrombosis, embolization, and consumption of platelets and plasma coagulation factors, as well as the systemic effects of activated coagulation and complement products, and platelet activation. It is clear that no synthetic or modified biological surface generated by man is as resistant to thrombosis (thromboresistant) as normal unperturbed endothelium (the cellular lining of the circulatory system). However, it is important to understand that under some circumstances endothelial cells can be “dysfunctional” and although physically intact can express prothrombotic molecules that can induce thrombosis (Bonetti *et al.*, 2003).

Thromboembolic complications are a major cause of mortality and morbidity with cardiovascular devices. Both fibrin (red) thrombus and platelet (white) thrombus form in association with valves and other cardiovascular devices. As in the cardiovascular system in general, Virchow’s triad (i.e., the conditions of surface thrombogenicity, hypercoagulability, and locally static blood flow) largely predicts the relative propensity toward thrombus formation and often the location of thrombotic deposits with cardiovascular prostheses (Anderson and Schoen, 1992). However, despite over a quarter century of intense research, the physical and chemical characteristics of materials that control the outcome of blood–surface interaction are incompletely understood.

When non-physiologic surfaces contact blood, three events comprise thrombotic interactions: 1) plasma protein deposition, 2) adhesion of platelets and leukocytes, and 3) bulk fibrin formation (blood coagulation). All foreign materials exposed to blood spontaneously and rapidly (seconds) absorb a film of plasma protein, largely fibrinogen. This is followed by cellular thrombogenesis (beginning with platelet adhesion to the first adsorbed plasma proteins). If conditions of relatively static flow are present, the fiber-forming steps of the coagulation process occur, and macroscopic thrombus ensues.

Considerable evidence implicates a primary regulatory role for blood platelets in the thrombogenic response to artificial surfaces. Platelet adhesion to artificial surfaces strongly resembles that of adhesion to the vascular subendothelium that has been exposed by injury. Nevertheless, the major clinical approach to controlling thrombosis in cardiovascular devices is the use of systemic anticoagulants, particularly coumadin (warfarin), which inhibits thrombin and fibrin formation but does not inhibit platelet-mediated thrombosis.

TUMORIGENESIS

Schoen emphasizes that although animals frequently have sarcomas at the site of an experimental biomaterial implant, neoplasms in humans occurring at the site of implanted medical devices are rare, despite the large numbers of implants used clinically over an extended duration. Moreover, the presence of a neoplasm at an implant site does not prove that the implant had a causal role. Cancers associated with foreign bodies can appear at any postoperative interval but tend to occur many years postoperatively. The pathogenesis of implant-induced tumors is not well understood; most experimental data indicate that the physical rather than chemical characteristics of the foreign body primarily determine tumorigenicity.

INFECTION

Infection occurs in as many as 5 to 10% of patients with implanted prosthetic devices and is a major source of morbidity and mortality (Jansen and Peters, 1993; Klug *et al.*, 1997; Kunin *et al.*, 1988; Mulcahy, 1999; Schierholz and Beuth, 2001; Tanner *et al.*, 1997; Vlessis *et al.*, 1997). Infections associated with medical devices are often resistant to antibiotics and host defenses, often persisting until the devices are removed. Early implant infections (less than approximately 1 to 2 months postoperatively) are most likely due to intraoperative contamination from airborne sources or nonsterile surgical technique, or to early postoperative complications such as wound infection. In contrast, late infections likely occur by a hematogenous (blood-borne) route and are often initiated by bacteremia induced by therapeutic dental or genitourinary procedures. Perioperative prophylactic antibiotics and periodic antibiotic prophylaxis given shortly before diagnostic and therapeutic procedures protect against implant infection. Infections associated with foreign bodies are characterized microbiologically by a high prevalence of *Staphylococcus epidermidis* and other staphylococci, especially *S. aureus*. Ordinarily, *S. epidermidis* is an organism with low virulence and thus an infrequent cause of non-prosthesis-associated deep infections. This emphasizes the unique environment in the vicinity of a foreign body.

The presence of a foreign body per se potentiates infection. A classic experiment indicated that the staphylococcal bacterial inoculum required to cause infection in the presence of a foreign implant was 10,000 less than that when no foreign body was present (Elek and Conen, 1957). Devices could facilitate infection in several ways. Microorganisms are provided access to the circulation and to deeper tissue by damage to natural barriers

against infection during implantation or subsequent function of a prosthetic device. Moreover, an implanted foreign body could (1) limit phagocyte migration into infected tissue or (2) interfere with inflammatory cell phagocytic mechanisms, through release of soluble implant components or surface-mediated interactions, thus allowing bacteria to survive adjacent to the implant. As Costerton *et al.* emphasize, adhesion of bacteria to the prosthetic surface and the formation of microcolonies within an adherent biofilm are fundamental steps in the pathogenesis of clinical and experimental infections associated with foreign bodies.

4.2 INFLAMMATION, WOUND HEALING, AND THE FOREIGN-BODY RESPONSE

James M. Anderson

Inflammation, wound healing, and foreign body reaction are generally considered as parts of the tissue or cellular host

TABLE 1 Sequence/Continuum of Host Reactions Following Implantation of Medical Devices

Injury
Blood–material interactions
Provisional matrix formation
Acute inflammation
Chronic inflammation
Granulation tissue
Foreign-body reaction
Fibrosis/fibrous capsule development

responses to injury. Table 1 lists the sequence/continuum of these events following injury. Overlap and simultaneous occurrence of these events should be considered; e.g., the foreign body reaction at the implant interface may be initiated with the onset of acute and chronic inflammation. From a biomaterials perspective, placing a biomaterial in the *in vivo* environment requires injection, insertion, or surgical implantation, all of which injure the tissues or organs involved.

The placement procedure initiates a response to injury by the tissue, organ, or body and mechanisms are activated to maintain homeostasis. The degrees to which the homeostatic mechanisms are perturbed and the extent to which pathophysiologic conditions are created and undergo resolution are a measure of the host reactions to the biomaterial and may ultimately determine its biocompatibility. Although it is convenient to separate homeostatic mechanisms into blood–material or tissue–material interactions, it must be remembered that the various components or mechanisms involved in homeostasis are present in both blood and tissue and are a part of the physiologic continuum. Furthermore, it must be noted that host reactions may be tissue-dependent, organ-dependent, and species-dependent. Obviously, the extent of injury varies with the implantation procedure.

OVERVIEW

Inflammation is generally defined as the reaction of vascularized living tissue to local injury. Inflammation serves to contain, neutralize, dilute, or wall off the injurious agent or process. In addition, it sets into motion a series of events that may heal and reconstitute the implant site through replacement of the injured tissue by regeneration of native parenchymal cells, formation of fibroblastic scar tissue, or a combination of these two processes.

Immediately following injury, there are changes in vascular flow, caliber, and permeability. Fluid, proteins, and blood cells escape from the vascular system into the injured tissue in a process called exudation. Following changes in the vascular system, which also include changes induced in blood and its components, cellular events occur and characterize the inflammatory response. The effect of the injury and/or biomaterial *in situ* on plasma or cells can produce chemical factors

TABLE 2 Cells and Components of Vascularized Connective Tissue

that mediate many of the vascular and cellular responses of inflammation.

Blood-material interactions and the inflammatory response are intimately linked, and in fact, early responses to injury involve mainly blood and vasculature. Regardless of the tissue or organ into which a biomaterial is implanted, the initial inflammatory response is activated by injury to vascularized connective tissue (Table 2). Since blood and its components are involved in the initial inflammatory responses, blood clot formation and/or thrombosis also occur. Blood coagulation and thrombosis are generally considered humoral responses and may be influenced by other homeostatic mechanisms such as the extrinsic and intrinsic coagulation systems, the complement system, the fibrinolytic system, the kinin-generating system, and platelets. Thrombus or blood clot formation on the surface of a biomaterial is related to the well-known Vroman effect (see Chapter 3.2), in which a hierarchical and dynamic series of collision, absorption, and exchange processes, determined by protein mobility and concentration, regulate early time-dependent changes in blood protein adsorption. From a wound-healing perspective, blood protein deposition on a biomaterial surface is described as provisional matrix formation. Blood interactions with biomaterials are generally considered under the category of hematocompatibility and are discussed elsewhere in this book.

Injury to vascularized tissue in the implantation procedure leads to immediate development of the provisional matrix at the implant site. This provisional matrix consists of fibrin, produced by activation of the coagulation and thrombosis systems, and inflammatory products released by the complement system, activated platelets, inflammatory cells, and endothelial cells. These events occur early, within minutes to hours following implantation of a medical device. Components within

or released from the provisional matrix, i.e., fibrin network (thrombosis or clot), initiate the resolution, reorganization, and repair processes such as inflammatory cell and fibroblast recruitment. The provisional matrix appears to provide both structural and biochemical components to the process of wound healing. The complex three-dimensional structure of the fibrin network with attached adhesive proteins provides a substrate for cell adhesion and migration. The presence of mitogens, chemoattractants, cytokines, and growth factors within the provisional matrix provides for a rich milieu of activating and inhibiting substances for various cellular proliferative and synthetic processes. The provisional matrix may be viewed as a naturally derived, biodegradable, sustained release system in which mitogens, chemoattractants, cytokines, and growth factors are released to control subsequent wound-healing processes. In spite of the increase in our knowledge of the provisional matrix and its capabilities, our knowledge of the control of the formation of the provisional matrix and its effect on subsequent wound healing events is poor. In part, this lack of knowledge is due to the fact that much of our knowledge regarding the provisional matrix has been derived from *in vitro* studies, and there is a paucity of *in vivo* studies that provide for a more complex perspective. Little is known regarding the provisional matrix which forms at biomaterial and medical device interfaces *in vivo*, although attractive hypotheses have been presented regarding the presumed ability of materials and protein adsorbed materials to modulate cellular interactions through their interactions with adhesive molecules and cells.

The predominant cell type present in the inflammatory response varies with the age of the inflammatory injury (Fig. 1). In general, neutrophils predominate during the first several days following injury and then are replaced by monocytes as the predominant cell type. Three factors account for this change in cell type: neutrophils are short lived and disintegrate and disappear after 24–48 hour; neutrophil emigration from the vasculature to the tissues is of short duration; and chemotactic factors for neutrophil migration are activated early in the inflammatory response. Following emigration from the vasculature, monocytes differentiate into macrophages and these cells are very long-lived (up to months). Monocyte emigration

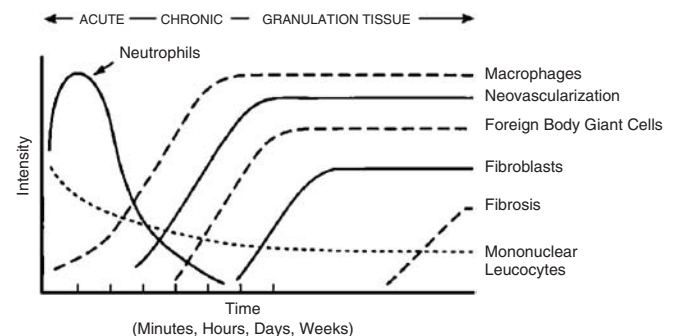

FIG. 1. The temporal variation in the acute inflammatory response, chronic inflammatory response, granulation tissue development, and foreign-body reaction to implanted biomaterials. The intensity and time variables are dependent upon the extent of injury created in the implantation and the size, shape, topography, and chemical and physical properties of the biomaterial.

may continue for day to weeks, depending on the injury and implanted biomaterial, and chemotactic factors for monocytes are activated over longer periods of time.

The temporal sequence of events following implantation of a biomaterial is illustrated in Fig. 1. The size, shape, and chemical and physical properties of the biomaterial may be responsible for variations in the intensity and duration of the inflammatory or wound-healing process. Thus, intensity and/or time duration of the inflammatory reaction may characterize the biocompatibility of a biomaterial.

While injury initiates the inflammatory response, the chemicals released from plasma, cells, or injured tissue mediate the inflammatory response. Important classes of chemical mediators of inflammation are presented in Table 3. Several points must be noted in order to understand the inflammatory response and how it relates to biomaterials. First, although chemical mediators are classified on a structural or functional basis, different mediator systems interact and provide a system of checks and balances regarding their respective activities and functions. Second, chemical mediators are quickly inactivated or destroyed, suggesting that their action is predominantly local (i.e., at the implant site). Third, generally the lysosomal proteases and the oxygen-derived free radicals produce the most significant damage or injury. These chemical mediators are also important in the degradation of biomaterials.

TABLE 3 Important Chemical Mediators of Inflammation Derived from Plasma, Cells, or Injured Tissue

Mediators	Examples
Vasoactive agents	Histamines, serotonin, adenosine, endothelial-derived relaxing factor (EDRF), prostacyclin, endothelin, thromboxane α_2
Plasma proteases	
Kinin system	Bradykinin, kallikrein
Complement system	C3a, C5a, C3b, C5b-C9
Coagulation/fibrinolytic system	Fibrin degradation products, activated Hageman factor (FXIIA), tissue plasminogen activator (tPA)
Leukotrienes	Leukotriene B ₄ (LTB ₄), hydroxyeicosatetraenoic acid (HETE)
Lysosomal proteases	Collagenase, elastase
Oxygen-derived free radicals	H ₂ O ₂ , superoxide anion
Platelet activating factors	Cell membrane lipids
Cytokines	Interleukin 1 (IL-1), tumor necrosis factor (TNF)
Growth factors	Platelet-derived growth factor (PDGF), fibroblast growth factor (FGF), transforming growth factor TGF- α or (TGF- β), epithelial growth factor (EGF)

ACUTE INFLAMMATION

Acute inflammation is of relatively short duration, lasting for minutes to hours to days, depending on the extent of injury. Its main characteristics are the exudation of fluid and plasma proteins (edema) and the emigration of leukocytes (predominantly neutrophils). Neutrophils (polymorphonuclear leukocytes, PMNs) and other motile white cells emigrate or move from the blood vessels to the perivascular tissues and the injury (implant) site. Leukocyte emigration is assisted by "adhesion molecules" present on leukocyte and endothelial surfaces. The surface expression of these adhesion molecules can be induced, enhanced, or altered by inflammatory agents and chemical mediators. White cell emigration is controlled, in part, by chemotaxis, which is the unidirectional migration of cells along a chemical gradient. A wide variety of exogenous and endogenous substances have been identified as chemotactic agents. Specific receptors for chemotactic agents on the cell membranes of leukocytes are important in the emigration or movement of leukocytes. These and other receptors also play a role in the transmigration of white cells across the endothelial lining of vessels and activation of leukocytes. Following localization of leukocytes at the injury (implant) site, phagocytosis and the release of enzymes occur following activation of neutrophils and macrophages. The major role of the neutrophil in acute inflammation is to phagocytose microorganisms and foreign materials. Phagocytosis is seen as a three-step process in which the injurious agent undergoes recognition and neutrophil attachment, engulfment, and killing or degradation. In regard to biomaterials, engulfment and degradation may or may not occur, depending on the properties of the biomaterial.

Although biomaterials are not generally phagocytosed by neutrophils or macrophages because of the disparity in size (i.e., the surface of the biomaterial is greater than the size of the cell), certain events in phagocytosis may occur. The process of recognition and attachment is expedited when the injurious agent is coated by naturally occurring serum factors called "opsonins." The two major opsonins are immunoglobulin G (IgG) and the complement-activated fragment, C3b. Both of these plasma-derived proteins are known to adsorb to biomaterials, and neutrophils and macrophages have corresponding cell-membrane receptors for these opsonization proteins. These receptors may also play a role in the activation of the attached neutrophil or macrophage. Other blood proteins such as fibrinogen, fibronectin, and vitronectin may also facilitate cell adhesion to biomaterial surfaces. Owing to the disparity in size between the biomaterial surface and the attached cell, frustrated phagocytosis may occur. This process does not involve engulfment of the biomaterial but does cause the extracellular release of leukocyte products in an attempt to degrade the biomaterial.

Henson has shown that neutrophils adherent to complement-coated and immunoglobulin-coated nonphagocytosable surfaces may release enzymes by direct extrusion or exocytosis from the cell. The amount of enzyme released during this process depends on the size of the polymer particle, with larger particles inducing greater amounts of enzyme release. This suggests that the specific mode of cell activation in the inflammatory response in tissue depends upon the size of the implant

FIG. 2. Acute inflammation, secondary to infection, of an ePTFE vascular graft. A focal zone of polymorphonuclear leukocytes is present at the luminal surface of the vascular graft, surrounded by a fibrin cap, on the blood-contacting surface of the ePTFE vascular graft. Hematoxylin and eosin stain. Original magnification 4 \times . (See color plate)

and that a material in a phagocytosable form (i.e., powder or particulate) may provoke a different degree of inflammatory response than the same material in a nonphagocytosable form (i.e., film).

Acute inflammation normally resolves quickly, usually less than 1 week, depending on the extent of injury at the implant site. However, the presence of acute inflammation (i.e., PMNs) at the tissue/implant interface at time periods beyond 1 week (i.e., weeks, months, or years) suggests the presence of an infection (Fig. 2).

CHRONIC INFLAMMATION

Chronic inflammation is less uniform histologically than acute inflammation. In general, chronic inflammation is characterized by the presence of macrophages, monocytes, and lymphocytes, with the proliferation of blood vessels and connective tissue. Many factors can modify the course and histologic appearance of chronic inflammation.

Persistent inflammatory stimuli lead to chronic inflammation. While the chemical and physical properties of the biomaterial in themselves may lead to chronic inflammation, motion in the implant site by the biomaterial or infection may also produce chronic inflammation. The chronic inflammatory response to biomaterials is usually of short duration and is confined to the implant site. The presence of mononuclear cells, including lymphocytes and plasma cells, is considered chronic inflammation, whereas the foreign-body reaction with the development of granulation tissue is considered the normal wound healing response to implanted biomaterials (i.e., the normal foreign-body reaction). Chronic inflammation with the presence of collections of lymphocytes and monocytes

FIG. 3. Chronic inflammation, secondary to infection, of an ePTFE arteriovenous shunt for renal dialysis. (A) Low-magnification view of a focal zone of chronic inflammation. (B) High-magnification view of the outer surface with the presence of monocytes and lymphocytes at an area where the outer PTFE wrap had peeled away from the vascular graft. at extended implant times (weeks, months, years) also may suggest the presence of a long-standing infection (Fig. 3A, B).

Lymphocytes and plasma cells are involved principally in immune reactions and are key mediators of antibody production and delayed hypersensitivity responses. Although they may be present in nonimmunologic injuries and inflammation their roles in such circumstances are largely unknown. Little is known regarding humoral immune responses and cell-mediated immunity to synthetic biomaterials. The role of macrophages must be considered in the possible development

TABLE 4 Tissues and Cells of MPS and RES

Tissues	Cells
Implant sites	Inflammatory macrophages
Liver	Kupffer cells
Lung	Alveolar macrophages
Connective tissue	Histiocytes
Bone marrow	Macrophages
Spleen and lymph nodes	Fixed and free macrophages
Serous cavities	Pleural and peritoneal macrophages
Nervous system	Microglial cells
Bone	Osteoclasts
Skin	Langerhans' cells
Lymphoid tissue	Dendritic cells

of immune responses to synthetic biomaterials. Macrophages process and present the antigen to immunocompetent cells and thus are key mediators in the development of immune reactions.

Monocytes and macrophages belong to the mononuclear phagocytic system (MPS), also known as the reticuloendothelial system (RES). These systems consist of cells in the bone marrow, peripheral blood, and specialized tissues. Table 4 lists the tissues that contain cells belonging to the MPS or RES. The specialized cells in these tissues may be responsible for systemic effects in organs or tissues secondary to the release of components or products from implants through various tissue–material interactions (e.g., corrosion products, wear debris, degradation products) or the presence of implants (e.g., microcapsule or nanoparticle drug-delivery systems).

The macrophage is probably the most important cell in chronic inflammation because of the great number of biologically active products it can produce. Important classes of products produced and secreted by macrophages include neutral proteases, chemotactic factors, arachidonic acid metabolites, reactive oxygen metabolites, complement components, coagulation factors, growth-promoting factors, and cytokines.

Growth factors such as platelet-derived growth factor (PDGF), fibroblast growth factor (FGF), transforming growth factor- β (TGF- β), TGF- α /epidermal growth factor (EGF), and interleukin-1 (IL-1) or tumor necrosis factor (TNF- α) are important to the growth of fibroblasts and blood vessels and the regeneration of epithelial cells. Growth factors released by activated cells can stimulate production of a wide variety of cells; initiate cell migration, differentiation, and tissue remodeling; and may be involved in various stages of wound healing.

GRANULATION TISSUE

Within 1 day following implantation of a biomaterial (i.e., injury), the healing response is initiated by the action of monocytes and macrophages. Fibroblasts and vascular endothelial

FIG. 4. Granulation tissue in the anastomotic hyperplasia at the anastomosis of an ePTFE vascular graft. Capillary development (red slits) and fibroblast infiltration with collagen deposition (blue) from the artery form the granulation tissue (arrows). Masson's Trichrome stain. Original magnification 4 \times . (See color plate)

cells in the implant site proliferate and begin to form granulation tissue, which is the specialized type of tissue that is the hallmark of healing inflammation. Granulation tissue derives its name from the pink, soft granular appearance on the surface of healing wounds, and its characteristic histologic features include the proliferation of new small blood vessels and fibroblasts (Fig. 4). Depending on the extent of injury, granulation tissue may be seen as early as 3–5 days following implantation of a biomaterial.

The new small blood vessels are formed by budding or sprouting of preexisting vessels in a process known as neovascularization or angiogenesis. This process involves proliferation, maturation, and organization of endothelial cells into capillary vessels. Fibroblasts also proliferate in developing granulation tissue and are active in synthesizing collagen and proteoglycans. In the early stages of granulation tissue development, proteoglycans predominate but later collagen, especially type III collagen, predominates and forms the fibrous capsule. Some fibroblasts in developing granulation tissue may have the features of smooth muscle cells, i.e., actin microfilaments. These cells are called myofibroblasts and are considered to be responsible for the wound contraction seen during the development of granulation tissue. Macrophages are almost always present in granulation tissue. Other cells may also be present if chemotactic stimuli are generated.

The wound-healing response is generally dependent on the extent or degree of injury or defect created by the implantation procedure. Wound healing by primary union or first intention is the healing of clean, surgical incisions in which the wound edges have been approximated by surgical sutures. Healing under these conditions occurs without significant bacterial contamination and with a minimal loss of tissue. Wound healing by secondary union or second intention occurs when there is a large tissue defect that must be filled or there is extensive loss of cells and tissue. In wound healing by secondary intention, regeneration of parenchymal cells cannot completely reconstitute the original architecture and much

FIG. 5. *In vivo* transition from blood-borne monocyte to biomaterial adherent monocyte/macrophage to foreign-body giant cell at the tissue–biomaterial interface. Little is known regarding the indicated biological responses, which are considered to play important roles in the transition to FBGC development.

larger amounts of granulation tissue are formed that result in larger areas of fibrosis or scar formation. Under these conditions, different regions of tissue may show different stages of the wound-healing process simultaneously.

Granulation tissue is distinctly different from granulomas, which are small collections of modified macrophages called epithelioid cells. Langhans' or foreign-body-type giant cells may surround nonphagocytosable particulate materials in granulomas. Foreign-body giant cells are formed by the fusion of monocytes and macrophages in an attempt to phagocytose the material (Fig. 5).

FOREIGN-BODY REACTION

The foreign-body reaction to biomaterials is composed of foreign-body giant cells (FBGCs) and the components of granulation tissue (e.g., macrophages, fibroblasts, and capillaries) in varying amounts, depending upon the form and topography of the implanted material; (Fig. 6). Relatively flat and smooth surfaces such as that found on breast prostheses have a foreign-body reaction that is composed of a layer of macrophages one

FIG. 7. Foreign-body reaction with multinucleated foreign body giant cells and macrophages at the periadventitial (outer) surface of a Dacron vascular graft. Fibers from the Dacron vascular graft are identified as clear oval voids. Hematoxylin and eosin stain. Original magnification 20 \times . (See color plate)

to two cells in thickness. Relatively rough surfaces such as those found on the outer surfaces of expanded poly tetrafluoroethylene (ePTFE) or Dacron vascular prostheses have a foreign-body reaction composed of macrophages and foreign-body giant cells at the surface. Fabric materials generally have a surface response composed of macrophages and foreign body giant cells, with varying degrees of granulation tissue subjacent to the surface response (Fig. 7).

As previously discussed, the form and topography of the surface of the biomaterial determine the composition of the foreign-body reaction. With biocompatible materials, the composition of the foreign-body reaction in the implant site may be controlled by the surface properties of the biomaterial, the form of the implant, and the relationship between the surface area of the biomaterial and the volume of the implant. For example, high-surface-to-volume implants such as fabrics, porous

FIG. 6. (A) Focal foreign-body reaction to polyethylene wear particulate from a total knee prosthesis. Macrophages and foreign-body giant cells are identified within the tissue and lining the apparent void spaces indicative of polyethylene particulate. Hematoxylin and eosin stain. Original magnification 20 \times . (B) Partial polarized light view. Polyethylene particulate is identified within the void spaces commonly seen under normal light microscopy. Hematoxylin and eosin stain. Original magnification 20 \times . (See color plate)

materials, particulate, or microspheres will have higher ratios of macrophages and foreign-body giant cells in the implant site than smooth-surface implants, which will have fibrosis as a significant component of the implant site.

The foreign-body reaction consisting mainly of macrophages and/or foreign-body giant cells may persist at the tissue-implant interface for the lifetime of the implant (Fig. 1). Generally, fibrosis (i.e., fibrous encapsulation) surrounds the biomaterial or implant with its interfacial foreign-body reaction, isolating the implant and foreign-body reaction from the local tissue environment. Early in the inflammatory and wound-healing response, the macrophages are activated upon adherence to the material surface.

Although it is generally considered that the chemical and physical properties of the biomaterial are responsible for macrophage activation, the subsequent events regarding the activity of macrophages at the surface are not clear. Tissue macrophages, derived from circulating blood monocytes, may coalesce to form multinucleated foreign-body giant cells. It is not uncommon to see very large foreign-body giant cells containing large numbers of nuclei on the surface of biomaterials. While these foreign-body giant cells may persist for the lifetime of the implant, it is not known if they remain activated, releasing their lysosomal constituents, or become quiescent.

Figure 5 demonstrates the progression from circulating blood monocyte to tissue macrophage to foreign-body giant cell development that is most commonly observed. Indicated in the figure are important biological responses that are considered to play an important role in FBGC development. Material surface chemistry may control adherent macrophage apoptosis (i.e., programmed cell death) (see Chapter 3.3) that renders potentially harmful macrophages nonfunctional, while the surrounding environment of the implant remains unaffected. The level of adherent macrophage apoptosis appears to be inversely related to the surface's ability to promote diffusion of macrophages into FBGCs, suggesting a mechanism for macrophages to escape apoptosis.

Figure 8 demonstrates the sequence of events involved in inflammation and wound healing when medical devices are implanted. In general, the PMN predominant acute inflammatory response and the lymphocyte/monocyte predominant chronic inflammatory response resolve quickly (i.e., within 2 weeks) depending on the type and location of the implant. Studies using IL-4 or IL-13, respectively, demonstrate the role for Th2 helper lymphocytes in the development of the foreign body reaction at the tissue/material interface. Th2 helper lymphocytes have been described as "antiinflammatory" based on their cytokine profile, of which IL-4 is a significant component.

FIBROSIS/FIBROUS ENCAPSULATION

The end-stage healing response to biomaterials is generally fibrosis or fibrous encapsulation (Fig. 9). However, there may be exceptions to this general statement (e.g., porous materials inoculated with parenchymal cells or porous materials implanted into bone) (Fig. 10). As previously stated, the tissue response to implants is in part dependent upon the extent

of injury or defect created in the implantation procedure and the amount of provisional matrix.

Repair of implant sites can involve two distinct processes: regeneration, which is the replacement of injured tissue by parenchymal cells of the same type, or replacement by connective tissue that constitutes the fibrous capsule. These processes are generally controlled by either (1) the proliferative capacity of the cells in the tissue or organ receiving the implant and the extent of injury as it relates to the destruction, or (2) persistence of the tissue framework of the implant site. See Chapter 3.4 for a more complete discussion of the types of cells present in the organ parenchyma and stroma, respectively.

The regenerative capacity of cells allows them to be classified into three groups: labile, stable (or expanding), and permanent (or static) cells (see Chapter 3.3). Labile cells continue to proliferate throughout life; stable cells retain this capacity but do not normally replicate; and permanent cells cannot reproduce themselves after birth. Perfect repair with restitution of normal structure can theoretically occur only in tissues consisting of stable and labile cells, whereas all injuries to tissues composed of permanent cells may give rise to fibrosis and fibrous capsule formation with very little restitution of the normal tissue or organ structure. Tissues composed of permanent cells (e.g., nerve cells and cardiac muscle cells) most commonly undergo an organization of the inflammatory exudate, leading to fibrosis. Tissues of stable cells (e.g., parenchymal cells of the liver, kidney, and pancreas); mesenchymal cells (e.g., fibroblasts, smooth muscle cells, osteoblasts, and chondroblasts); and vascular endothelial and labile cells (e.g., epithelial cells and lymphoid and hematopoietic cells) may also follow this pathway to fibrosis or may undergo resolution of the inflammatory exudate, leading to restitution of the normal tissue structure.

The condition of the underlying framework or supporting stroma of the parenchymal cells following an injury plays an important role in the restoration of normal tissue structure. Retention of the framework with injury may lead to restitution of the normal tissue structure, whereas destruction of the framework most commonly leads to fibrosis. It is important to consider the species-dependent nature of the regenerative capacity of cells. For example, cells from the same organ or tissue but from different species may exhibit different regenerative capacities and/or connective tissue repair.

Following injury, cells may undergo adaptations of growth and differentiation. Important cellular adaptations are atrophy (decrease in cell size or function), hypertrophy (increase in cell size), hyperplasia (increase in cell number), and metaplasia (change in cell type). Other adaptations include a change by cells from producing one family of proteins to another (phenotypic change), or marked overproduction of protein. This may be the case in cells producing various types of collagens and extracellular matrix proteins in chronic inflammation and fibrosis. Causes of atrophy may include decreased workload (e.g., stress-shielding by implants), and diminished blood supply and inadequate nutrition (e.g., fibrous capsules surrounding implants).

Local and systemic factors may play a role in the wound-healing response to biomaterials or implants. Local factors include the site (tissue or organ) of implantation, the adequacy

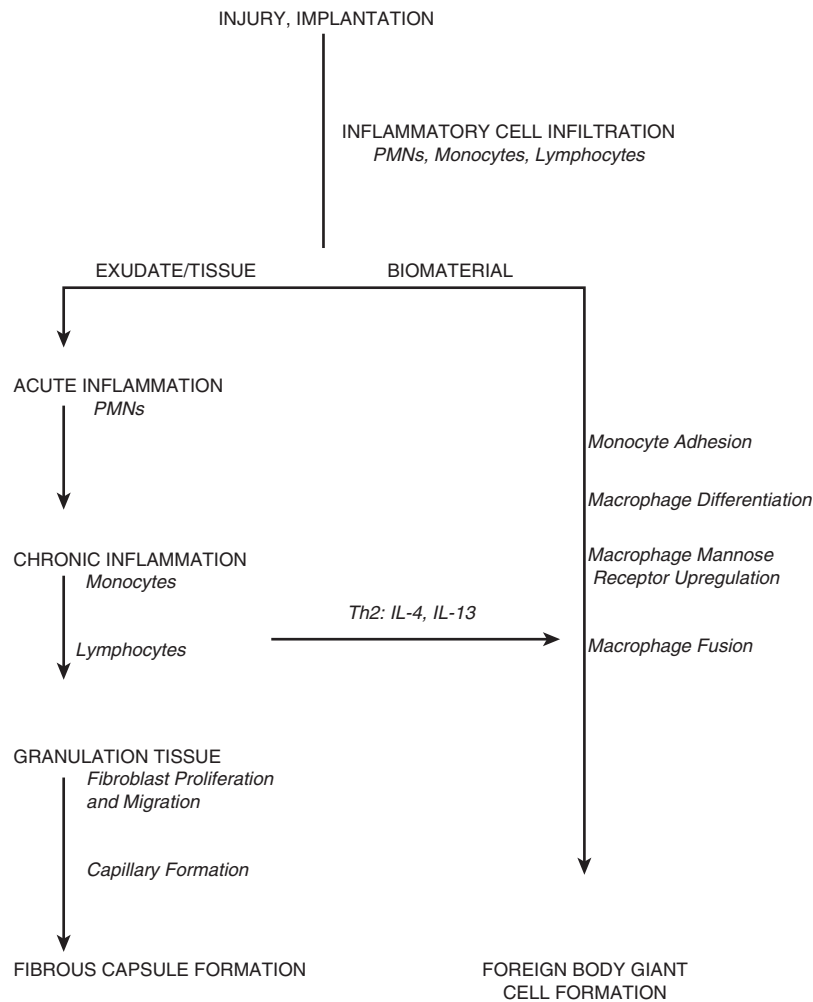

FIG. 8. Sequence of events involved in inflammatory and wound-healing responses leading to foreign-body giant cell formation. This shows the important of Th2 lymphocytes in the transient chronic inflammatory phase with the production of IL-4 and IL-13, which can induce monocyte/macrophage fusion to form foreign-body giant cells.

FIG. 9. Fibrous capsule composed of dense, compacted collagen. This fibrous capsule had formed around a Mediport catheter reservoir. Loose connective tissue with small arteries, veins, and a nerve is identified below the acellular fibrous capsule. (See color plate)

of blood supply, and the potential for infection. Systemic factors may include nutrition, hematologic derangements, glucocorticoid steroids, and preexisting diseases such as atherosclerosis, diabetes, and infection.

Finally, the implantation of biomaterials or medical devices may be best viewed at present from the perspective that the implant provides an impediment or hindrance to appropriate tissue or organ regeneration and healing. Given our current inability to control the sequence of events following injury in the implantation procedure, restitution of normal tissue structures with function is rare. Current studies directed toward developing a better understanding of the modification of the inflammatory response, stimuli providing for appropriate proliferation of permanent and stable cells, and the appropriate application of growth factors may provide keys to the control of inflammation, wound healing, and fibrous encapsulation of biomaterials.

FIG. 10. Fibrous capsule with a focal foreign-body reaction to silicone gel from a silicone gel-filled silicone-rubber breast prosthesis. The breast prosthesis–tissue interface is at the top of the photomicrograph. Oval void spaces lined by macrophages and a few giant cells are identified and a focal area of foamy macrophages (arrows) indicating macrophage phagocytosis of silicone gel is identified. Hematoxylin and eosin stain. Original magnification 10 \times . (See color plate)

4.3 INNATE AND ADAPTIVE IMMUNITY: THE IMMUNE RESPONSE TO FOREIGN MATERIALS

Richard N. Mitchell

This is a fairly extensive topic, typically encompassing an entire course (with its own introductory text) called “Immunology.” Thus, an overview chapter can only begin to acquaint the reader with the complexities of innate and adaptive immunity. Nevertheless, the goal here is to understand the broad organization of the immune system (specific and nonspecific components), how the different elements recognize perceived “invaders,” and what effector responses are elicited. The end result is to understand the response of the body to the insertion of a foreign device, and to predict the potential outcome. For more extensive discussion of some aspect of the immune system, you are encouraged to refer to any of a number of excellent basic immunology texts (Abbas and Lichtman, 2003; Benjamini *et al.*, 2000; Janeway, 2001).

OVERVIEW

The function of the immune system is ultimately to defend the host against infectious organisms. The immune system is triggered into action whenever the host perceives tissue injury, anticipating that with that injury, microbial agents either have been causal or will become secondarily involved. The immune system accomplishes its protective role by stratifying the plethora of molecules it may ultimately contact as either “self” or “non-self.” In general, the immune system does not react to self molecules or injure host tissues. However, when a particular molecule is perceived as non-self, the full gamut of immune responses are brought to bear in an attempt to remove or isolate it. In most cases, the immune response is so exquisitely specific and well-regulated that host tissues are not significantly affected. However, severe infections, persistent injury, or autoimmunity (inappropriate immune response to self) can lead to substantial tissue injury directly attributable to the host immune system. Thus, although the system evolved primarily to identify and eliminate infectious agents, noninfectious foreign materials also elicit immune responses, occasionally culminating (even if not infected) in severe tissue injury. Consequently, a more inclusive definition of immunity is a reaction to any foreign substance (microbes, proteins, polysaccharides, Silastic implants, etc.) regardless of the pathologic consequences. In order to understand the basics of the immune response, we will initially focus in this chapter on the physiologic pathways of immune responses to infectious agents. Once we understand those pathways, the

FIG. 1. Innate and adaptive immunity. Although with a limited ability to recognize invading organisms, the relatively primitive (evolutionarily speaking) components of innate immunity provide the first line of defense against microbial infections. Adaptive immunity, with exquisite specificity to any particular infectious agent, develops sometime later after innate components have responded. Notably, the elements of innate immunity not only respond first, but direct subsequent adaptive immunity; in turn, elements of the adaptive immune responses orchestrate a more efficient and vigorous response by the components of innate immunity. The specific kinetics of the responses shown are approximations and may vary depending on the inciting agent. Figure reprinted with permission from Abbas and Lichtman (2003).

mechanisms underlying a response to a foreign body will be briefly examined.

INNATE AND ADAPTIVE IMMUNITY

Defense against microbes is a two-stage process, beginning with a relatively nonspecific innate response to “injury,” followed by a targeted adaptive response more uniquely focused on the specific causal agent (Fig. 1, Table 1).

INNATE IMMUNITY

Rapid (hours) response to infection is accomplished by the components of innate immunity (also called “natural” or

TABLE 1 Components of Innate versus Adaptive Immunity

	Innate	Adaptive
Physical/chemical barriers	Skin, mucosal epithelium, antimicrobial proteins	Lymphocytes in epithelia, secreted antibodies
Blood proteins	Complement	Antibodies
Cells	Phagocytes (macrophages, neutrophils), natural killer cells	Lymphocytes

Adapted from Abbas and Lichtman (2003).

“native” immunity) (Medzhitov and Janeway, 2000). Innate immunity is an evolutionarily primitive system found even in invertebrates and to some extent in plants. Cells and proteins of this system constitute the first line of defense, and in many cases, can also quite capably eliminate infections on their own. The components of innate immunity are also critical in mobilizing all subsequent effectors—including elements of adaptive immunity—to clear invading microorganisms (Fig. 2). Innate immunity is triggered by molecular structures that are common to groups of related microbes (Fig. 3) (Janeway and Medzhitov, 2002). The receptors for recognition therefore have a fairly limited diversity (fewer than 20 different types of molecules) and have no capacity to make fine distinctions between different substances; each cell of the innate system also expresses essentially the same cohort of receptors. The components of innate immunity react in essentially the same way each time they encounter the same infectious agent, so that there is no functional memory to allow more rapid or specific responses upon second encounter with the same agent. The principal components of innate immunity are:

- Physical and chemical barriers such as epithelia and antimicrobial proteins (e.g., defensins)
- Phagocytic cells (neutrophils and macrophages) that ingest (phagocytize) and destroy microbes (Fig. 4) (Underhill and Ozinsky, 2002)
- Natural killer (NK) cells that kill non-self targets
- Circulating proteins (complement, coagulation factors, C-reactive protein, etc.) that either directly insert pore-forming proteins in microbes that lead to cell death

FIG. 2. Basic mechanisms of innate immunity. The two principal components of innate immunity in defense against microbial infection are phagocytes (cells) and complement (a collection of proteins, see also Chapter 4.3). Phagocytes (primarily the macrophage cell type shown here) will directly bind, ingest, and intracellularly degrade various microbes; in addition, macrophages can secrete cytokines to recruit and activate additional inflammatory cell types (e.g., neutrophils) to sites of infection and will help drive the activation of the T lymphocytes of the adaptive immune response. Note that macrophages may also require the production of cytokines by other cell types (in the figure, “IFN- γ ” is interferon- γ , a cytokine with a variety of activities) in order to be most active. Complement proteins form pores in the membranes of microbes to cause direct cell lysis; in addition, complement components will incite inflammatory cell recruitment, augment phagocytosis (opsonize microbes), and participate in the activation of B lymphocytes in the adaptive immune response. Figure reprinted with permission from Abbas *et al.* (2000).

(e.g., complement, see Chapter 4.3), or that opsonize microbes (rendering them more “attractive” and readily phagocytized) (Fig. 5) (Barrington *et al.*, 2001; Walport, 2001a, b).

- Cytokines: proteins secreted by cells of innate or adaptive immunity that regulate and coordinate the cellular response (Seder and Gazzinelli, 1998).

ADAPTIVE IMMUNITY

Cellular and circulating protein (also called humoral) mediators that temporally follow innate immunity in recognizing and resolving infections (also called “specific” or “acquired”

immunity) are termed adaptive immunity. Adaptive immunity is more evolutionarily advanced, first seen in phylogenetic development with the jawed vertebrates. It has the cardinal features of exquisite specificity for distinct macromolecules and memory, the latter being the ability to respond more vigorously to subsequent exposures of the same microorganism. Adaptive immunity also has a virtually limitless diversity, with the capacity to recognize 10^9 – 10^{11} distinct antigenic determinants (Fig. 3). Each cell of the adaptive immune system can recognize and respond to only a single antigenic determinant, so that the immense diversity of the system requires an equally large number of different cells. Foreign substances that induce these specific immune responses are called antigens and each antigen will typically activate only one (or a small set) of cells. The principal components of adaptive immunity (see also later discussion) are:

- T lymphocytes (also known as T cells), functionally divided into helper T cells (Th cells), which provide signals and soluble protein mediators (cytokines) to orchestrate the activity of other cell types, and cytotoxic T cells (Tc cells) which kill selected target cells
- B lymphocytes (also known as B cells), responsible for making antibodies
- Antibodies: proteins secreted by B lymphocytes with specificity for a specific antigen
- Cytokines: proteins secreted by cells of innate or adaptive immunity that regulate and coordinate the cellular response.

Innate and adaptive immunity are integrated components in the host defense response; the cells and proteins of each system function cooperatively. Thus, the initial innate response to microbes stimulates adaptive immune responses and influences how the adaptive immune system will respond (e.g., antibodies versus cellular mediators). Moreover, adaptive immunity directs and utilizes the effector mechanisms of innate immunity to clear infectious agents.

RECOGNITION AND EFFECTOR PATHWAYS IN INNATE IMMUNITY

The components of the innate system recognize structures that are characteristic of microbial pathogens and are not present on mammalian tissues; thus recognition via this pathway can distinguish self and non-self (Fig. 3) (Janeway and Medzhitov, 2002). Because the microbial products that are recognized are usually essential for survival of the microorganism, they cannot be discarded or mutated. These structures may be recognized by the cells or by humoral elements of the innate system and include:

- Double-stranded RNA found in cells containing replicating viruses. This induces cytokine production by infected cells leading to destruction of the intracellular virus.
- Unmethylated CpG DNA sequences characteristic of bacterial infections. These induce autocrine macrophage activation and more effective intracellular killing of phagocytosed organisms.

	Innate immunity	Adaptive immunity
Specificity	For structures shared by classes of microbes ("molecular patterns") 	For structural detail of microbial molecules (antigens); may recognize nonmicrobial antigens 
Receptors	Encoded in germline; limited diversity 	Encoded by genes produced by somatic recombination of gene segments; greater diversity 
Distribution of receptors	Nonclonal: identical receptors on all cells of the same lineage	Clonal: clones of lymphocytes with distinct specificities express different receptors
Discrimination of self and nonself	Yes; host cells are not recognized or they may express molecules that prevent innate immune reactions	Yes; based on selection against self-reactive lymphocytes; may be imperfect (giving rise to autoimmunity)

FIG. 3. Characteristics of innate and adaptive immunity. Cells of innate immunity have a limited number of receptors for foreign molecular structures; the same receptors are present on all cells, and because the number of different receptors is relatively small, they are all encoded in the germline. In comparison, the recognition of specific antigens by the adaptive immune system is specific and unique for each potential antigen. In order to encode such a huge diversity (10^9 – 10^{11} variations), antibodies and T cell receptors (TCR) are formed by somatic recombination of different gene segments. Moreover, each T or B cell will express only a single receptor type and can therefore recognize only one antigen. Lack of response to self is controlled by a number of mechanisms (not always perfect, hence the development of autoimmune disease), including destruction of self-reactive clones, or induction of specific "unresponsiveness." Figure reprinted with permission from Abbas and Lichtman (2003).

- N-Formylmethionine peptides from bacterial protein synthesis. Binding to receptors on neutrophils and macrophages causes chemotaxis (movement up a concentration gradient) and activation. Similar chemotaxis can be engendered by protein fragments released during complement activation, lipid mediators of inflammation, and chemokine proteins released by "stressed" cells.
- Mannose-rich oligosaccharides from bacterial or fungal cell walls. Engagement of receptors on macrophages induce phagocytosis; soluble mannose-binding protein in the plasma opsonizes or enhances phagocytosis of microbes bearing mannose.
- Bacterial or fungal wall oligosaccharides directly activate complement and induce either direct microbial lysis or microbial coating with complement that markedly enhance phagocytosis.
- Phosphorylcholine in bacterial cell walls binds to circulating C-reactive protein (CRP; also called pentraxin); CRP induces opsonization and also activates complement.
- Lipopolysaccharide (LPS) from certain (gram-negative) bacteria binds to circulating LPS-binding protein which in turn binds to CD14 surface molecules on macrophages. This binding elicits a wide range of cytokine responses

from the macrophages including tumor necrosis factor (TNF) and interleukin-12, which recruit and activate neutrophils and NK cells, respectively. By the same pathways, LPS induces severe systemic responses that culminate in septic shock (Hack *et al.*, 1997).

- Teichoic acid from gram-positive bacteria elicits responses comparable to LPS.

Components of the innate system also recognize sites of injury, anticipating that these either may be primarily caused by infection or may be subject to subsequent infection. Thus, components of the coagulation cascade or denatured connective tissue elements (such as might occur at sites of trauma) may bind to macrophage cell surface receptors and induce activation. These become especially important in the context of the implantation of foreign bodies where otherwise minor trauma and the presence of denatured ECM bound on "inert" surfaces lead to macrophage activation (Tang and Eaton, 1999).

The function of all these recruiting and activating factors is to attract phagocytes to ingest and destroy microbes. The primary responding cell type in the earliest stages of injury or infection is the neutrophil, a short-lived (hours) phagocytic cell capable of ingesting and destroying microbes, as well

FIG. 4. Phagocytosis and intracellular destruction of microorganisms. Surface receptors on phagocytes either can bind microbes directly or may bind opsonized microbes (for example, Mac-1 integrin binds microorganisms after they have been coated with complement proteins). After binding to one (or more) of the variety of surface receptors, microbes are internalized into phagosomes, which subsequently fuse with intracellular lysosomes to form phagolysosomes. Fusion results in generation of reactive oxygen intermediates (ROI) and nitric oxide (NO) which kill the microbes largely via free radical injury; fusion with lysosomes also results in release of lysosomal enzymes that will also digest the microbes. Figure reprinted with permission from Abbas and Lichtman (2003).

as releasing a variety of potent proteases. Macrophages are secondarily recruited to sites of injury but are much longer-lived (they can last the lifetime of the host!) and persist at sites of inflammation, making them the dominant effector cell type in late-stage innate immunity. These phagocytes are recruited to sites of injury by changes in adhesion molecule expression on endothelial cells in the vicinity, and by chemotactic signals (acting, e.g., through G-protein-coupled receptors

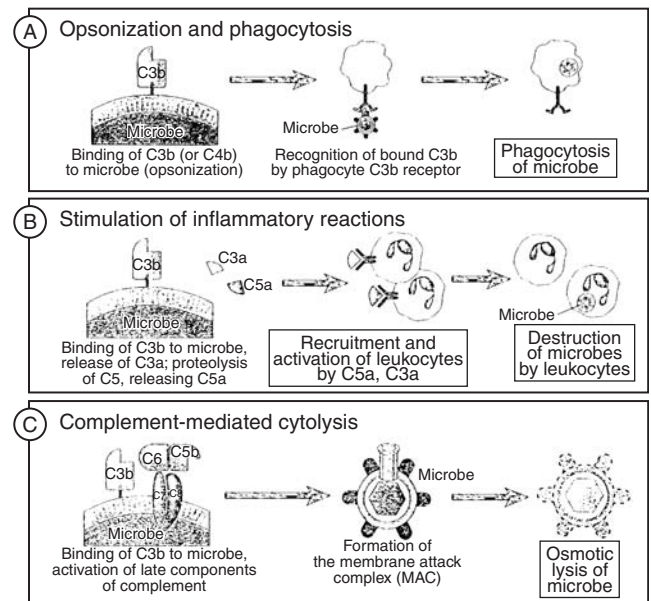

FIG. 5. Functions of complement. (A) Complement components will bind to microbe surfaces and render them more readily internalized by phagocytes (opsonization). (B) Fragments resulting from proteolytic activation of complement will recruit and activate inflammatory cells (shown here are neutrophils). (C) Complement also forms pores in the microbial membrane (so-called membrane attack complex or MAC) that result in osmotic rupture of microorganisms. Figure reprinted with permission from Abbas and Lichtman (2003).

on neutrophils) delivered by injured cells (i.e., chemokines), by complement components (generated during complement activation), and by microorganisms themselves (see the preceding list) (Fig. 6). The phagocytic cells clear opsonized microorganisms, kill them with reactive oxygen intermediates (superoxide, oxyhalide molecules, nitric oxide, and hydrogen peroxide), and degrade them with proteases (Fig. 4). However, release of such cytotoxic and degradative molecules into the neighboring environment can also cause local tissue injury. Severe local injury due to excessive neutrophil activation results in an abscess with total destruction of parenchyma and stroma.

In addition, activated macrophages release a variety of cytokines and other factors that can have both local and systemic effects (Fig. 6) (Seder and Gazzinelli, 1998):

- Tumor necrosis factor (TNF) recruits and activates neutrophils
- Interleukin-12 (IL-12) activates T cells and NK cells
- Coagulation pathways (tissue factor elaboration)
- Angiogenic factors (new blood vessel formation)
- Fibroblast activating factors (e.g., platelet-derived growth factor; PDGF) that induce fibroblast proliferation
- Transforming growth factor- β (TGF- β) expression increasing extracellular matrix (ECM) synthesis
- Matrix metalloproteinases that remodel the ECM

Thus, in the setting of prolonged activation, macrophages will ultimately mediate tissue fibrosis and scarring (Fig. 6).

FIG. 6. Macrophage recruitment and local tissue effects after activation. Circulating monocytes are recruited to sites of tissue injury by changes in adhesion molecule expression on endothelial cells in the vicinity, and by chemotactic signals (chemokines) delivered by injured cells or neutrophils, by complement components (generated during complement activation), and by microorganisms themselves. Once these monocytes emigrate into the tissues, they become macrophages and may be activated by $\text{IFN-}\gamma$ from various sources (including activated NK cells or T cells) or by nonimmunologic stimuli such as endotoxin. Activated macrophages will ingest microorganisms and necrotic debris, but will also make a number of eicosanoids (arachadonic acid or AA metabolites), reactive oxygen intermediates, and cytokine mediators that will affect the local tissue environment. Figure reprinted with permission from Kumar *et al.* (2003).

TYPES OF ADAPTIVE IMMUNITY

Adaptive immune responses adopt two basic (and inter-related) forms, humoral and cell-mediated immunity. These are accomplished by different components of the immune system and function to eliminate different types of microorganisms (Fig. 7).

- **Humoral immunity** is mediated by proteins called antibodies that are produced by B lymphocytes. Antibodies bind to unique microbial (or any molecular) antigens with exquisite specificity and target bound molecules or microbes for elimination by phagocytosis and digestion (e.g., via neutrophils and macrophages), direct killing (via NK cells), or lysis (via complement). Humoral immunity is the principal adaptive defense response against extracellular microorganisms (or their toxins), since antibodies can bind to them and assist in their clearance. Antibodies come in different types, e.g., IgA, IgG, IgM, IgE; IgG is the most common, although it is further subdivided into several different subtypes with different functionalities. The different antibody types are specialized to activate specific effector mechanisms (e.g., phagocytosis,

complement activation, or release of mediators from mast cells); the details are beyond the scope of this discussion.

- **Cellular immunity** is mediated by T lymphocytes, this form of immune response can participate in the elimination of extracellular microbes (Fig. 7). However, it is also the main mechanism by which intracellular pathogens (e.g., viruses and certain bacteria) that are not accessible to circulating antibodies can be targeted (Fig. 8).

T cells have surface receptors that cannot “see” intact foreign antigen, but rather recognize digested antigen fragments (“processed antigen”) presented on the surface of certain host cell types in association with major histocompatibility complex (MHC) molecules (see later discussion). For helper T cells, these accessory or antigen-presenting cells include macrophages, one of the major cell types of the innate immune response. Thus, the innate system directs the response of the adaptive immune system. In return, recognition of foreign peptides leads to T-cell activation. Helper T cells (identified by their expression of the CD4 surface marker) assist in B-cell activation, as well as in the recruitment and activation of macrophages and neutrophils in the activation of NK cells, as well as cytotoxic or killer T cells (identified by their expression of the CD8 surface marker); in this manner infected cells containing intracellular pathogens may be recognized and deleted (Fig. 8).

Not all the possible responses are elicited at the same time in response to a particular pathogen. In some cases, it may be more advantageous to induce primarily a B-cell antibody-mediated response; in other circumstances, a cytotoxic T-cell response may be most warranted. Moreover, the adaptive immune response needs to be tightly regulated to prevent ongoing tissue injury, and therefore a negative-regulatory feedback must exist. The central regulation of these potential outcomes derives from the helper T cells, and more specifically the nature of the cytokines that they produce. Two basic types of helper T cells are currently recognized, called Th1 and Th2, each secreting fairly distinct subsets of cytokines (other T cell subsets are increasingly being identified, but the basic Th1 vs Th2 paradigm is sufficient for this discussion) (Abbas *et al.*, 1996). Thus, whether helper T cells induce or inhibit macrophage activation (for example) is largely a function of their differentiation and their ultimate cytokine repertoires (Fig. 9). The regulatory pathways that determine helper T-cell differentiation are an extremely active area of investigation.

RECOGNITION AND EFFECTOR PATHWAYS IN ADAPTIVE IMMUNITY

Any given T or B cell can only recognize one antigen; we are therefore able to respond to the wide diversity of foreign molecules because of an enormous repertoire of cells arising as a consequence of somatic recombination (see earlier discussion), each with different antigen specificity. Although antibodies and B cells bind to intact foreign molecules, most B-cell responses also require interactions with helper T cells. It is important to reiterate that T cells cannot recognize

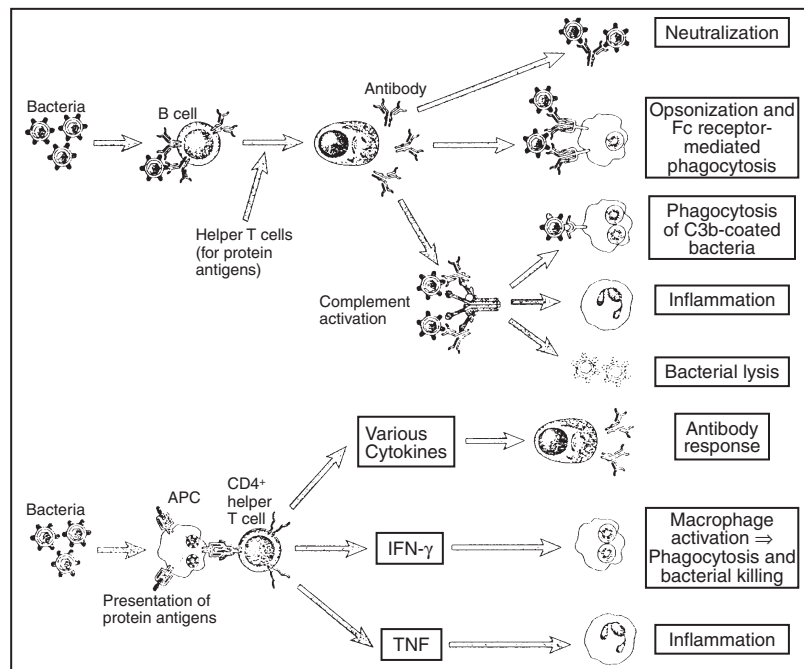

FIG. 7. T- and B-cell adaptive immune responses to extracellular microbes. Adaptive immune responses to extracellular microorganisms (and their toxins) include B-cell responses to generate antibody, and helper T-cell responses that can direct both B-cell antibody production and secondary cellular activation of macrophages and other inflammatory cells. Binding of antibodies can prevent microbes from entering host tissues (neutralization), can opsonize them for phagocytes, or can help activate complement more efficiently to increase inflammatory responses or induce microbial lysis. T-cell activation requires that antigen presenting cells (APC, such as macrophages) degrade the microbe first and present peptide fragments. After helper T-cell activation, and depending on the nature of the cytokines that are produced, B-cell responses can be augmented, or macrophages and other inflammatory cells may be activated. IFN- γ , interferon- γ ; TNF, tumor necrosis factor. Figure reprinted with permission from Abbas and Lichtman (2003).

proteins until they have been degraded into smaller fragments and been bound to self histocompatibility molecules on antigen-presenting cells. Thus, most of the adaptive immune response, involving both B and T cells, is dependent on recognition of processed antigen fragments in the context of self histocompatibility proteins (Fig. 10).

In all mammals, histocompatibility molecules are grouped together on chromosomes into clusters generically called major histocompatibility complexes or MHCs. Proteins of this complex are denoted as “histocompatibility” molecules because they were first recognized as the major determining element in tissue (“histo”) compatibility in organ transplantation. When inbred strains of animals shared the same MHC determinants, tissue grafts could be transplanted with relative impunity; if the donor and host were MHC-disparate, grafts were said to be histo-incompatible and the organs ultimately failed by a process called rejection (see discussion at the end of the chapter).

In humans, this MHC cluster occurs on chromosome 6, and the molecules are called human leukocyte antigens or HLA. There are two general categories of MHC molecules, called class I and class II. In humans, MHC class I (MHC I) molecules are called HLA-A, -B, and -C; MHC class II (MHC II)

molecules are called HLA-DP, -DQ, and -DR. The MHC class I molecules present peptide fragments derived from the antigens of intracellular pathogens to CD8⁺ cytotoxic T cells; MHC class II molecules present peptide fragments from the antigens of extracellular pathogens to CD4⁺ helper T cells (Fig. 10) (Klein and Sato, 2000a, b).

There is a basic dichotomy of responses depending on the original source of a particular antigen. Thus, proteins that come from the inside of cell (for example, viruses) associate with MHC I molecules and are recognized selectively by cytotoxic T cells (also called CD8⁺ T cells). Proteins that come from the outside of cells (for example, bacteria) associate with MHC II molecules and are selectively recognized by helper T cells (also called CD4⁺ T cells) (Fig. 10) (Germain, 1994).

When cytotoxic T cells encounter their specific antigen, their response is to kill the target cell bearing that antigen. When helper T cells encounter their specific antigen, their response is to make stimulatory molecules (cytokines) that cause the proliferation and activation of other cells; the major cytokine resulting in lymphocyte proliferation is interleukin-2 (IL-2). Besides increasing the numbers of T and B cells in the area of the immune response, helper T cells can also (a) activate B cells to secrete antibody; (b) activate macrophages and neutrophils

FIG. 8. Helper ($CD4^+$) and cytotoxic ($CD8^+$) T-cell collaboration in defense against intracellular microbes. Intracellular bacteria are partially degraded within the phagolysosomes of APC such as macrophages; the resulting peptide fragments are presented in the context of MHC molecules to activate helper and/or killer T cells. Cytokines elaborated by activated helper T cells can participate in turning on cytotoxic T cells, as well as in the activation of the original APC. In this manner, either cytotoxic T cells will directly kill the infected cell, or the additional booster activation of the APC by helper cytokines will enable them to completely destroy the microbe. Similar pathways exist to allow activated cytotoxic T cells or NK cells to kill cells infected with viruses. Figure reprinted with permission from Abbas and Lichtman (2003).

FIG. 9. Role of helper T-cell cytokines in determining immune responses. Naive $CD4^+$ helper T cells can differentiate into either Th1 or Th2 type cells, each with distinct cytokine profiles and with distinct functions in immune regulation. In the example shown, interferon- γ ($IFN-\gamma$) and TNF secreted by Th1-type helper T cells drive macrophage activation, whereas interleukins-4, -10, and -13 (IL-4, IL-10, and IL-13) made by Th2 helper T cells inhibit macrophage activation. A similar dichotomy exists for the activation of the other elements of both the innate and adaptive immune response. Figure reprinted with permission from Abbas and Lichtman (2003).

to help clear infectious agents; (c) activate natural killer cells to be more cytotoxic; and (d) activate endothelium lining blood vessels to recruit even more inflammatory cells (Figs. 7 and 8).

T-cell recognition of antigen fragments bound to MHC molecules results in T-cell activation (Garcia *et al.*, 1999). This recognition step is accomplished by T cell receptors (TCR) on the surface of T lymphocytes; the TCR interact with a group of molecules (collectively called the CD3 complex) and send a signal to the nucleus resulting in cellular stimulation. Complete activation of T cells also requires additional interplay between other molecules (called costimulator molecules) on the surface of T cells and antigen-presenting cells of the innate immune system. Incomplete activation of T cells (i.e., without the costimulators) may result in anergy (no response) to the antigen (Fig. 11).

It bears repeating that although many aspects of immunity involve exquisitely sensitive responses to only selected foreign molecules (antigens), the immune response also involves cells (macrophages, neutrophils, and natural killer cells) and proteins (complement and cytokines) which are antigen nonspecific. Antigen-specific and nonspecific pathways interact with each other.

PATHOLOGY ASSOCIATED WITH IMMUNE RESPONSES

The innate and adaptive immune system exists primarily to defend us against infection (immune surveillance to neoplasm was a later evolutionary adaptation). Unfortunately, immune activation leads not only to the activation of host defenses and production of protective immunoglobulins and T-cells, but also occasionally to the development of responses that may potentially damage host tissues.

Both innate and adaptive immune responses may be implicated in causing disease states. As highlighted earlier, in the setting of prolonged activation, macrophages of the innate immune response will ultimately mediate tissue fibrosis and scarring. Indeed, the response to foreign materials—causing much of the local pathology associated with implants—is attributable to such persistent macrophage activation. Moreover, certain bacterial toxins (LPS) nonspecifically stimulate macrophages (as well as other cell types) and result in systemic pathology from excessive cytokine elaboration.

By having increased specificity, adaptive immunity might be expected to lead overall to less secondary damage. Normally, an exquisite system of checks and balances optimizes the antigen-specific eradication of infecting organisms with only trivial innocent by-stander injury. However, certain types of infection (e.g., virus) may require destroying host tissues to eliminate the disease (see Fig. 10B). Still other types of infections (e.g., tuberculosis) may only be controlled by a cellular response that walls off the offending agent with activated macrophages and scar, often at the expense of adjacent normal parenchyma (similar to foreign-body responses). Even when the host response to an infectious agent is specific antibody, the antibody occasionally cross-reacts with self-antigens (e.g., anti-cardiac antibodies following certain streptococcal infections, causing rheumatic heart disease). Immune complexes

FIG. 10. Presentation of extracellular versus intracellular antigens to cytotoxic versus helper T cells. (A) Extracellular antigens (e.g., from extracellular bacteria) are ingested and degraded by macrophages or other APC (such as B cells), and are then presented in association with MHC II surface molecules to CD4⁺ helper T cells. Helper T cells activated in this manner lead to macrophage and/or B-cell activation that will eliminate the extracellular microbe antigens. (B) Intracellular antigens (e.g., from intracellular viruses) are degraded and presented in association with MHC I surface molecules to CD8⁺ cytotoxic T cells. Killer T cells activated in this manner then lyse (kill) the cell that originally harbored the intracellular pathogen. Figure reprinted with permission from Abbas and Lichtman (2003).

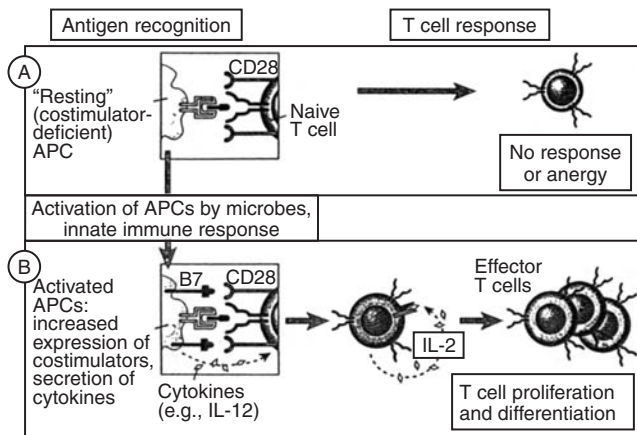

FIG. 11. Role of costimulation in T-cell activation. (A) Antigen-presenting cells (APC) that are not activated will express few or no costimulator molecules. In that setting, even though the APC display processed antigen in the appropriate MHC context, the T cells will fail to respond. Indeed, such costimulator-poor APC presentation may result in a long-term anergy (inability to respond) to particular antigens. (B) Microbes and cytokines produced during innate immune responses activate APC to make costimulator molecules (such as B7, shown here) that will result in "complete" activation of the T cells. Activated APC also produce additional cytokines such as interleukin-12 (IL-12) that also participate in stimulating T-cell activation and differentiation. Figure reprinted with permission from Abbas and Lichtman (2003).

composed of specific antibody and circulating antigens may precipitate at inappropriate sites (see later discussion) and cause injury by activation of the complement cascade, or by facilitating binding of neutrophils and macrophages (e.g., post-streptococcal glomerulonephritis). If the antibody made in response to a particular antigen is IgE, any subsequent response to that antigen will be immediate hypersensitivity (allergy), potentially culminating in anaphylaxis. Finally, not all antigens that attract the attention of lymphocytes are exogenous. The immune system occasionally (but fortunately, rarely) loses tolerance for endogenous antigens, which results in autoimmune disease.

All of these forms of immune-mediated injury are collectively denoted as hypersensitivity. As discussed below and in Chapter 4.5, they are traditionally subdivided into four types; three are variations on antibody (immunoglobulin or Ig)-mediated injury, while the fourth is cell-mediated:

- IgE-mediated "immediate hypersensitivity"; allergy and anaphylaxis
- Mediated by antibody against fixed or circulating tissue antigens
- Immune complex (antigen-antibody)-mediated
- Immune cell-mediated

Pathogenesis of Antibody-Mediated Disease

Antibodies involved in immune-mediated diseases may bind to antigenic determinants that are intrinsic to (synthesized by) a particular tissue or cell, or that are exogenous and have been passively adsorbed (e.g., certain antibiotics or foreign proteins). Regardless of what they recognize, or how they got there, antibodies bound to the surfaces of cells or to extracellular matrix cause injury by certain basic mechanisms.

IgE-Mediated (Immediate Hypersensitivity)

Mast cells and basophils express surface Fc-receptors that can bind the Fc constant region of immunoglobulin E (IgE), one of the five basic immunoglobulin isotypes (Kay, 2001a, b). When circulating IgE's bind to the Fc-receptors and are subsequently cross-linked by specific allergen (antigen), they induce mast cell or basophil degranulation with release of pre-formed mediators, as well as synthesis of other potent effectors (Fig. 12):

- Preformed mediators: amines such as histamine and serotonin (cause vasodilation and increased vascular permeability)
- Mediators synthesized de novo:

Prostaglandins (e.g., PGD₂) that can affect vessel and airway contraction and vascular permeability

Leukotrienes (e.g., LTC₄, LTD₄, and LTE₄) that are exceptional vasoconstrictors and bronchoconstrictors previously identified as “slow-reacting substance(s) of anaphylaxis” (SRS-A)

Platelet activating factor (PAF), a rapidly catabolized phospholipid derivative that increases vascular permeability and diminishes vascular smooth muscle tone; it also causes bronchoconstriction

Cytokines, in particular TNF (recruits sequential waves of neutrophils and monocytes), and IL-4 (interleukin 4, induces local epithelial and macrophage expression of chemokines such as eotaxin, and also induces endothelial adhesion molecule expression: the combined effect will be to recruit eosinophils).

In most vascular beds, the overall result is vasodilation and increased vascular permeability, with a variable infiltrate classically predominated by eosinophils. Eosinophils are an inflammatory cell type classically associated with parasitic infections, as well as with allergies; they contain specific granules with potent cytotoxic activity for a variety of cell types. In the respiratory tree, the net result of an allergic stimulus is increased mucus secretion and bronchoconstriction.

The nature of the symptoms in any particular instance will depend on the portal of antigen entry, e.g., cutaneous (hives and rash, although these can also occur with inhaled or ingested allergen), inhaled (wheezing, airway congestion), ingested (diarrhea, cramping), or systemic (hypotension). The associated diseases range from the merely annoying (seasonal rhinitis or “hay fever”) to debilitating (asthma) to life-threatening (anaphylaxis).

FIG. 12. Events in immediate-type hypersensitivity (allergy). Immediate hypersensitivity is initiated following contact with a specific allergen (an antigen that induces an IgE response). For unclear reasons, allergens induce in a susceptible host a predominant Th2 response that ultimately promotes an IgE antibody response. IgE then binds to mast cells in tissues (and basophils in the circulation, not shown) via specific IgE Fc receptors. Subsequent encounter with the relevant allergen results in IgE-Fc receptor cross-linking which activates the mast cells and basophils. Once activated, the cells secrete preformed mediators causing the characteristic immediate response (vasodilation and increased vascular permeability; may also cause bronchoconstriction). Over the next few hours (up to 24 hours), these activated cells will also synthesize and release additional mediators (prostaglandins, leukotrienes, PAF, and cytokines; see text). Figure reprinted with permission from Abbas and Lichtman (2003).

Antibody Bound to Cell Surfaces or Fixed Tissue Antigens

Antibodies bound to either intrinsic or extrinsic tissue antigens can induce tissue injury by promoting complement activation, inducing opsonization, or by interacting with important cell-surface molecules (Fig. 13).

Recall that complement may induce injury either by direct cytolysis via the C5b-9 membrane-attack complex (MAC)

FIG. 13. Effector mechanisms in antibody-mediated disease. (A) Antibodies, with or without complement activation, will opsonize cells leading to phagocytosis and destruction. (B) Antibodies and secondarily generated complement fragments bound to large non-phagocytosable cells or tissues will recruit inflammatory cells such as neutrophils and macrophages. If these inflammatory cells cannot complete ingest the target, frustrated phagocytosis will result in the release of lysosomal contents and reactive oxygen intermediates into the tissues with subsequent extracellular damage. (C) Antibodies can also elicit pathology without causing tissue damage. In the panel on the left, antibodies to the thyroid stimulating hormone (TSH) receptor will mimic authentic TSH and will cause hyperstimulation of the thyroid (Graves' disease). In the panel on the right, antibodies to the acetylcholine (ACh) receptor at the neuromuscular junction will block normal ACh stimulation of muscle contraction leading to weakness (myasthenia gravis). Figure reprinted with permission from Abbas and Lichtman (2003).

punching holes in a cell's plasma membrane, or by opsonization (via the C3b fragment), enhancing phagocytosis by macrophages and neutrophils. In addition to direct cell killing, local activation of the complement cascade will result in the generation of complement fragments such as C3a and C5a (Fig. 5 and Chapter 4.3) (Barrington *et al.*, 2001; Walport, 2001a, b).

- C3a and C5a (so-called anaphylotoxins) mediate increased vascular permeability and smooth muscle relaxation (vasodilation), mainly via releasing histamine from mast cells
- C5a also activates the lipoxygenase pathway in arachidonic acid catabolism, resulting in increased leukotriene synthesis

- C5a-mediated chemotaxis of PMN and monocytes
- On circulating blood cells, bound complement may directly mediate cell lysis; in addition, bound antibody and opsonizing complement fragments induce efficient uptake and destruction by cells of the splenic and hepatic mononuclear phagocyte system

Antibody binding in conjunction with C3b opsonization may also lead indirectly to tissue injury. Large, nonphagocytosable cells or tissue may promote "frustrated phagocytosis" by neutrophils or macrophages; the attempted intracellular lysis results instead in the extracellular release of proteases and toxic oxygen metabolites (Fig. 13B).

Instead of fixing complement, target cells coated with low concentrations of antibody can also attract a variety of non-sensitized cells of innate immunity with Fc-receptors, most importantly the natural killer (NK) cells. These bind to the exposed Fc portion of the bound immunoglobulin and induce cell lysis without phagocytosis.

Binding of antibodies to certain receptors can induce pathology even without causing tissue injury. For example, in the case of Graves' disease, antibodies bind to the thyroid stimulating hormone (TSH) receptor on thyroid epithelial cells and mimic authentic TSH ligand interaction; the result is autonomous stimulation of the gland with hyperthyroidism. Alternatively, antibodies that cross-react with the acetylcholine receptor at the nerve-muscle synapse can block binding of acetylcholine and result in the weakness seen in the disease myasthenia gravis (Fig. 13).

Immune Complex (IC)-Mediated Injury

In many circumstances, circulating antigen and antibody combine to form insoluble aggregates called immune complexes (IC). These are usually efficiently cleared by macrophages in the spleen and liver, but occasionally deposit in certain vascular beds. Once ICs are deposited, the mechanism of injury is basically the same regardless of where or for what reason ICs have accumulated; the major sources of pathology are complement activation (see above) and neutrophil and/or macrophage injury (Fig. 14).

Pathogenesis of Cell-Mediated Disease

T-cell-mediated responses are of two general types (Fig. 15):

- *T cell-mediated cytotoxicity (caused by antigen-specific CD8⁺ cytotoxic T lymphocytes or CTL).* In CTL-mediated reactions, cytotoxic lymphocytes recognize specific antigen in association with class I MHC and induce direct cytotoxicity. It is important to emphasize that CTL-mediated cytotoxicity is highly specific, without significant "innocent bystander" injury.
- *Delayed-type hypersensitivity (mediated by cytokines and antigen nonspecific effector cells).* In the case of cell-mediated immunity, CD4⁺ helper T-cells recognize specific antigen in the context of class II MHC, and respond by producing a host of soluble antigen-nonspecific cytokines. These soluble mediators induce further T-lymphocyte recruitment and proliferation, and attract

FIG. 14. Antibody-mediated pathology. (A) Direct binding of antibodies to tissue antigens will cause tissue injury by recruiting inflammatory cells and activating complement. (B) Circulating antigen-antibody complexes (also called immune complexes) can deposit in vessels and tissues also leading to inflammatory cell recruitment and complement activation. Figure reprinted with permission from Abbas and Lichtman (2003).

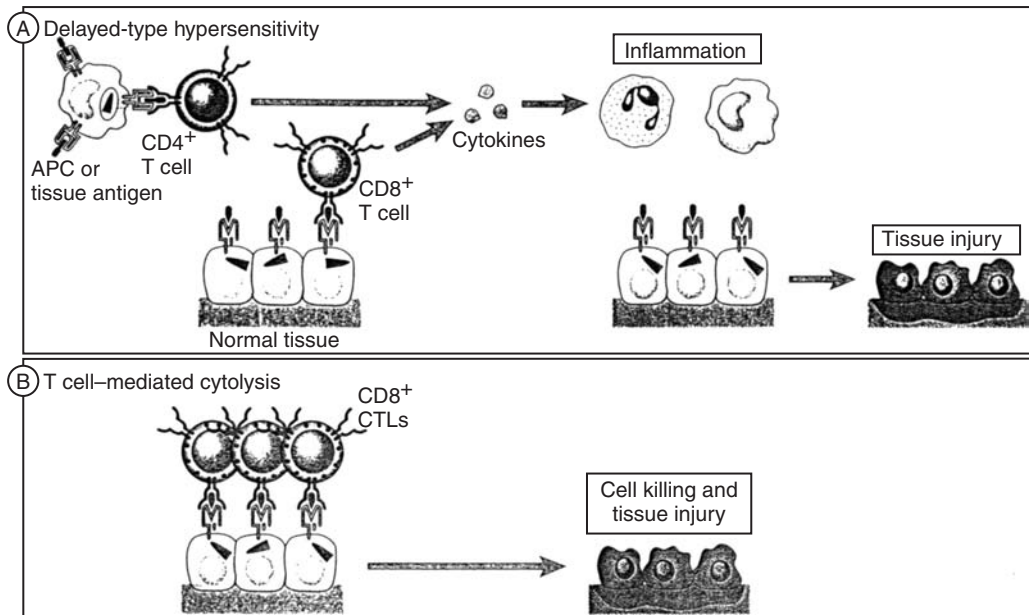

FIG. 15. Mechanisms of T-cell-mediated disease. (A) In delayed-type hypersensitivity responses, T cells (typically CD4⁺ helper T cells) respond to tissue or cellular antigens by secreting cytokines that stimulate inflammation, and ultimately promote tissue injury (APC, antigen-presenting cell). (B) In some diseases, CD8⁺ cytotoxic T cells directly kill tissue cells. Figure reprinted with permission from Abbas and Lichtman (2003).

FIG. 16. Granulomatous inflammation. (A) A histologic section of a lymph node showing numerous granulomas, in this case, in response to tuberculosis. Granulomas are aggregates of activated macrophages, surrounded by activated lymphocytes. Note the presence of numerous multinucleated forms of the macrophages, so-called giant cells, which result from cell-cell fusion of macrophages under the influence of certain T-cell cytokines. (B) Schematic illustration of the events that lead to granuloma formation in response to persistent antigens. Antigen-presenting cells (APC) of the innate immune system process antigen and subsequently present it to CD4⁺ helper T cells; the APC also provide interleukin-12 (IL-12) and other cytokines to drive T-cell activation. Activated T cells, in turn, elaborate cytokines such as tumor necrosis factor (TNF) that will recruit inflammatory cells, and interferon- γ (IFN- γ) that will induce the activation of the recruited cells, in particular macrophages. These cytokines can also induce macrophage fusion to generate giant cells. If the antigen is not effectively eliminated, the constant cycle of T-cell and macrophage activation leads to the accumulation of an aggregate of activated cells. Activated macrophages will also elaborate mediators that result in tissue injury, as well as cytokines resulting in tissue fibrosis (see also Fig. 6). The end result

and activate antigen nonspecific macrophages; at the site of a CD4⁺ T-cell mediated response, the vast majority (greater than 90%), of newly recruited cells are not specific for the original inciting antigen. Cytokine-mediated CMI is critical in clearing intracellular infections not accessible to antibodies or CTL (e.g., tuberculosis, leishmania, histoplasmosis), as well as a variety of large infectious agents not well controlled by antibodies alone (e.g., fungi, protozoans, parasites). Although tightly regulated, the relatively nonspecific effector components of cell-mediated immunity (cytokines and activated macrophages) are largely responsible for the injury seen in delayed-type hypersensitivity (DTH).

In comparison to CTL, cytokine-mediated immunity may ultimately develop an antigen-nonspecific component; that is, after the initial antigen-specific T-cell response, the recruited antigen-nonspecific T-cells and macrophages can cause significant bystander injury. Macrophages in particular are an important component of the recruited inflammatory cells in DTH and mediate much of the subsequent immune effector responses. By virtue of the release of reactive oxygen intermediates, prostaglandins, lysosomal enzymes, and cytokines such as TNF (which, in turn, have potent effects, e.g., on the synthetic function of fibroblasts, lymphocytes, and endothelium), activated macrophages can potentially wreak significant havoc.

An important variant of DTH with a prominent localized component of activated macrophages is called granulomatous inflammation (Fig. 16). Granulomas (the designation of a nodule of granulomatous inflammation is a granuloma) are the characteristic response of the immune system to foreign objects (such as implanted devices), and are thus important elements in most tissue-materials interactions. Granulomas can be mediated by the same basic DTH pathways (antigen-specific T-cells and recruited nonspecific macrophages) in the setting of persistent antigenic stimuli (such as tuberculosis bacteria that may be difficult to eradicate). With persistent antigen, chronic macrophage activation results in cytokine elaboration culminating in a surrounding fibrosis. Presumably by organizing a local accumulation of activated macrophages, granulomas serve to eradicate, or at least wall off, infectious organisms that would otherwise be difficult to contain.

Granulomas also occur in the setting of large, inert, or indigestible substances (see list below); in that case, direct macrophage activation occurs by binding to denatured or modified host proteins that have adsorbed on the surfaces of the foreign materials via the receptors used for innate immunity (Tang and Eaton, 1993, 1999; Tang *et al.*, 1996). A diagnosis of granuloma suggests only a limited number of disease entities; clinically, the most common are foreign body, tuberculosis, and sarcoidosis (see also Table 2). Final confirmation of the

is loss of tissue function and scar formation. In the case of "inert" foreign bodies, adsorption of host proteins onto the foreign-body surface with subsequent denaturation and modification can lead to direct macrophage activation via the receptors involved in innate immunity. Figure reprinted with permission from Kumar *et al.* (2003).

TABLE 2 Examples of Granulomatous Inflammation

Direct macrophage activation
Dusts, e.g., beryllium, silica
Foreign body, e.g., surgical suture, breast implant
Gout (urate crystals)
T-cell-mediated macrophage activation
Infections (TB, leprosy, syphilis, cat-scratch disease, schistosomiasis, fungus)
Necrotizing vasculitis with granulomas (Wegener's granulomatosis, temporal arteritis)
"Autoimmune" disorders with granulomas (Crohn's disease, de Quervain's thyroiditis)
Sarcoidosis (inciting agent unknown)

particular inciting agent requires cultures, serologies, or special stains, or may be a diagnosis of exclusion (e.g., sarcoidosis).

Injury associated with granulomas may be due to displacement, compression, and necrosis of adjacent healthy tissue, or may be a consequence of the persistent chronic inflammation that led to the granuloma in the first place (e.g., berylliosis). Granulomas associated with a variety of "autoimmune disorders," such as temporal arteritis, Crohn's disease, and Wegener's granulomatosis, presumably reflect diseases with persistent antigen stimulation, or a heightened DTH response to specific self antigens.

SIMILARITIES AND DIFFERENCES BETWEEN ORGAN REJECTION AND THE RESPONSE TO SYNTHETIC MATERIALS OR TISSUE-DERIVED BIOMATERIALS

When foreign cells or organs are transplanted into a new host, the histocompatibility proteins on the cell surfaces of the graft are recognized by the components of adaptive immunity as being non-self. Note that except for minor genetic polymorphisms, most of the structural proteins and other molecular components in a graft are nearly identical to those that the host will also express (e.g., the contractile proteins in heart muscle, the collagenous extracellular matrix, the usual housekeeping proteins). The MHC molecules, however, are distinctly different between most humans (except identical twins!) and will elicit helper and cytotoxic T-cell activation, as well as B-cell antibody production. Clearly, once these pathways have been activated, the usual physiologic effector mechanisms (direct cell killing, complement activation, phagocytosis, cytokine elaboration, etc.) will be brought to bear on the graft and will in most cases effect its destruction. Again, although components of innate immunity are recruited and activated in the process of graft damage, the initial recognition step and the driving force for transplant rejection is via the cells of adaptive immunity (you are also referred to the basic immunology texts for excellent overviews of the rejection phenomenon; see Abbas and Lichtman, 2003; Benjamini *et al.*, 2000; Janeway, 2001). To prevent or reverse such rejection requires a whole armamentarium of immunosuppressive agents (e.g., cytotoxic drugs or agents such as cyclosporine, which put the recipient at risk of serious infections and certain tumors).

The point is emphasized here because in the immunologic sense, the synthetic materials that make up implanted devices are not rejected. In addition, tissue- or collagen-based biomaterials (e.g., a biological heart valve substitute or a processed collagen) derived from the same species (or sufficiently related species so that there are not major antigenic differences in, e.g., collagen proteins) are also not rejected. Such materials/devices do not elicit specific (adaptive) immune responses, and therefore will not have antibodies or lymphocytes that recognize the materials and cannot therefore drive the overall response. Moreover, although tissue-derived biomaterials derived from non-self [e.g., heart valve from another person (homograft) or an animal (porcine aortic valve or bovine pericardial bioprostheses)] may express foreign histocompatibility antigens, be antigenic, and be capable of eliciting adaptive immune responses (including antibodies and antigen-specific T cells), any failure of the device does not necessarily equate to immune-mediated device dysfunction. Stated another way, even immunogenetic tissue does not necessarily progress to device failure. Moreover, specific immunological responses can even be secondarily induced by device failure, but have nothing to do causally with the actual failure of the device. As a corollary statement, simply finding inflammatory cells (and even T cells and antibodies) does not in any way prove that the response is "rejection"; such elements will accrue at any site of injury in a nonspecific way (recall that some 90% of T cells in a DTH response are not antigen-specific, but are nonspecifically recruited to the site of injury). This is much more than a semantic point, in that synthetic or natural biomaterial device functions or longevity are not likely to benefit from specific immunosuppression. Of course, if a device incorporates viable cells in its manufacture (e.g., endothelial cells lining a vascular conduit), those cells will express MHC proteins and will elicit adaptive immune responses that materially contribute to device failure. In that instance, it will be necessary in the long term either to engineer such devices using cells derived from the individual who will eventually receive the implant, or to rely on long-term immunosuppression much as is done for organ transplants.

It should also be emphasized that although synthetic and biomaterials are not rejected in the immunologic sense, components of the immune system (particularly innate immunity) can contribute to device dysfunction and failure. In particular, and as described above, nonspecific activation of macrophages and complement will lead to local tissue damage via proteolysis, accumulation of other inflammatory cells, and/or cytokine elaboration; in most cases, with an ongoing, persistent innate response to a device that cannot be eliminated, fibrous scar tissue will also develop.

Thus, under certain circumstances, synthetic materials and biomaterials can have failure modes that are attributable to activation of the immune system (particularly innate immunity). An "inert" Silastic-clad breast prosthesis, for example, can accumulate dense scar tissue around it (secondary to persistent macrophage activation) that is not aesthetically ideal. Similarly, a metal hip prosthesis can induce ongoing macrophage activation that in the bone will lead to cytokine production that ultimately drives bone resorption and prosthesis loosening. Although administration of steroids

in these settings may have some beneficial effect by limiting macrophage activation, it may also induce complications since steroids (among other side effects) also inhibit healing and increase susceptibility to infections.

4.4 THE COMPLEMENT SYSTEM

Richard J. Johnson

As discussed in the previous chapter, the immune system acts to protect each of us from the constant exposure to

pathogenic agents such as bacteria, fungi, viruses, and cancerous cells that pose a threat to our lives. The sheer multitude of structures that the immune system must recognize, differentiate from “self,” and mount an effective response against has driven the evolution of this system into a complex network of proteins, cells, and distinct organs. An immune response to any foreign element involves all of these components, acting in concert, to defend the host from intrusion. Historically, the immune system has been viewed from two perspectives: cellular or humoral. This is a somewhat subjective distinction, since most humoral components (such as antibodies, complement components, and cytokines) are made by cells of the immune system and, in turn, often function to regulate the activity of these same cells. The focus of this chapter will be on the basic biochemistry and pathobiology of the complement system, a critical element of the innate immune response, and its relevance to biomaterials research and development.

INTRODUCTION

Complement is a term devised by Paul Ehrlich to refer to plasma components that were known to be necessary for antibody-mediated bactericidal activity. We now know that complement is composed of more than 30 distinct plasma and membrane bound proteins involving three separate pathways: classical, alternative, and the more recently described lectin pathway. The complement system directly and indirectly contributes both to innate inflammatory reactions and to cellular (i.e., adaptive) immune responses. This array of effector functions is due to the activity of a number of complement components and their receptors on various cells. These activities are summarized in Table 1, along with the responsible complement protein(s). One of the principal functions of complement is to serve as a primitive self–nonself discriminatory defense system. This is accomplished by coating a foreign material with complement fragments and recruiting phagocytic cells that attempt to destroy and digest the “intruder.” Although the system evolved to protect the host from the invasion of adventitious pathogens, the nonspecific and spontaneous nature of the alternative pathway permits activation by various biomaterial surfaces. Because complement activation can follow three distinct but interacting pathways, the various ways of activating the cascade will be outlined separately below.

TABLE 1 Complement Activities

Activity	Complement protein
Identification/opsonization of pathogens	C3, C4
Recruitment/activation of inflammatory cells	C3a, C5a
Lysis of pathogens/cytotoxicity	C5b-9 (MAC)
Clearing immune complexes and apoptotic cells	C1q, C3b, C4b
Augment cellular immune responses (T and B cells)	C3, C4, C3a, C5a

CLASSICAL PATHWAY

The classical pathway (CP) is activated primarily by immune complexes (ICs) composed of antigen and specific antibody, although other proteins such as C-reactive protein, serum amyloid protein, and amyloid fibrils as well as apoptotic bodies can also activate the CP (Cooper, 1985). The proteins of this pathway are C1, C2, C4, C1 inhibitor (C1-Inh), and C4 binding protein (C4bp). Some of their basic biochemical characteristics are summarized in Table 2.

Complement activation by the CP is illustrated in Fig. 1. This system is an example of an enzyme cascade in which each step in the series, from initiation to the final product, involves

TABLE 2 Proteins of the Classical Pathway of Complement

Protein	Molecular weight	Subunits	Plasma concentration ($\mu\text{g/ml}$)
C1q	410,000	6A, 6B, 6C	70
C1r	85,000	1	35
C1s	85,000	1	35
C2	102,000	1	25
C4	200,000	$\alpha\beta\gamma$	600
C1-Inh	104,000	1	200
C4bp	570,000	8	230

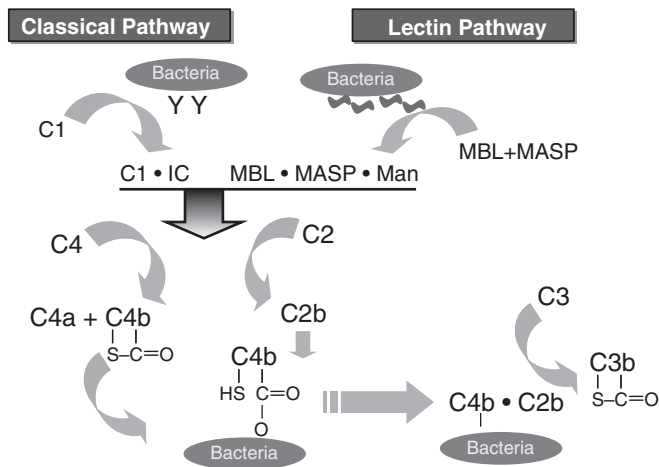

FIG. 1. Complement activation by the classical pathway (CP). Upon binding to the Fc region of an immune complex, C1 is activated and cleaves C4, exposing its thioester, which permits covalent attachment of C4b to the activating surface. C2 is cleaved, producing C2b, which binds to C4b to form the CP C3 convertase. C2b is a serine protease that specifically acts on C3 to generate C3b and C3a. The lectin pathway is also illustrated. MBL recognizes certain sugar residues (mannose, *N*-acetylglucosamine) on the surface of an activator (bacteria). MASP-1 appears to activate MASP-2, which then cleaves both C4 and C2 of the CP, generating the CP C3 convertase.

enzymatic reactions (in this case, proteolytic cleavage reactions) that result in some degree of amplification. Recent work with knockout mice (mice deficient in C1q, C2, C4, or IgG) has shown that the CP is in a state of continuous low-level activation, essentially primed to react vigorously in the presence of an IC. When an IC forms, the cascade is initiated when C1 binds to the Fc portion of an antigen-antibody complex. The C1 protein is composed of three different types of subunits called C1q, C1r, and C1s (Fig. 2). One end of C1q binds to an IC formed between an antigen and one molecule of (pentameric) immunoglobulin (Ig) M or several closely spaced IgG molecules. This interaction is believed to produce a conformational change in the C1q that results in activation (i.e., autocatalytic proteolysis) of the two C1r and then the two C1s subunits, bound to the other end of the C1q protein. Both C1r and C1s are zymogen serine proteases that are bound to the C1q in a calcium-dependent manner that is inhibited by calcium chelators such as citrate or EDTA. The proteolysis of C1s completes the activation of C1, which then proceeds to act on the next proteins in the cascade, C4 and C2.

C4 is composed of three separate chains, α , β and γ (Fig. 2), bound together by disulfide bonds. Activated C1s cleaves C4 near the amino-terminus of the α chain, yielding a 77-amino acid polypeptide called C4a and a much larger (190,000 Da) C4b fragment. The C4 protein contains a unique structural element called a thioester (Fig. 2). Thioesters have only been detected in two other plasma proteins, α 2-macroglobulin and C3. Upon cleavage of C4, the buried thioester becomes exposed and available to react with a surface containing amino or hydroxyl moieties. About 5% of the C4b molecules produced react through the thioester and become covalently attached to the surface. This represents the first amplification step in the pathway since each molecule of C1 produces a number of surface-bound C4b sites.

The C4b protein, attached to the surface, acts as a receptor for C2. After binding to C4b, C2 becomes a substrate for C1s. Cleavage of C2 yields two fragments: A smaller C2a portion diffuses into the plasma, while the larger C2b remains bound to the C4b. The C2b protein is another serine protease that, in association with C4b, represents the classical pathway C3/C5 convertase.

As the name implies, the function of the C4b-C2b complex is to bind and cleave C3. The C3 protein sits at the juncture of the classical and alternative pathways and represents one of the critical control points. Cleavage of C3 by C2b yields a 9000-Da C3a fragment and a 175,000-Da C3b fragment that is very similar to C4b in both structure and function. Cleavage of C3 produces a conformational change in the C3b protein that results in exposure of its thioester group (Fig. 2). Condensation with water or surface carbohydrates results in covalent attachment of 10–15% of the C3b to the surface of the activator. This is the second amplification step in the sequence since as many as 200 molecules of C3b can become attached to the surface surrounding every C4b-C2b complex. Eventually one of the C3b molecules reacts with a site on the C4b protein, creating a C3b-C4b-C2b complex that acts as a C5 convertase (Fig. 4).

In contrast to C3, which can be cleaved in the fluid phase (see later discussion), proteolytic activation of C5 occurs only after it is bound to the C3b portion of the C5 convertase on the

FIG. 2. Schematic illustration of C4 and C3 protein structures. O=C-S represents the reactive thioester bond that permits covalent attachment to surface nucleophiles (hydroxyl or amino groups). The pattern of proteolytic degradation and the resulting fragments are also shown. Although factor I is the relevant *in vivo* protease, some of these same fragments can be generated with trypsin, plasmin, and thrombin.

FIG. 3. Complement activation by the alternative pathway (AP). The spontaneous conversion of C3 to C3(H₂O) permits the continuous production of C3b from C3, a process called C3 tickover. In the presence of an activating surface, the C3b is covalently bound and becomes the focal point for subsequent interactions. The bound C3b is recognized by factor B, which is then cleaved by factor D to produce a surface-bound C3 convertase (C3b•Bb). This results in amplification of the original signal to produce more convertase.

surface of an activator (e.g., the immune complex). Like C3, C5 is also cleaved by C2b to produce fragments designated C5a (16,000 Da) and C5b (170,000 Da). The C5b molecule combines with the proteins of the terminal components to form the membrane attack complex described later. C5a is a potent inflammatory mediator and is responsible for many of the adverse reactions normally attributed to complement activation in various clinical settings.

LECTIN PATHWAY

In the 1990s, investigators working with a protein called mannose binding protein (or mannan binding lectin, MBL) discovered of a third pathway that leads to complement activation (Matsushita, 1996). This scheme is called the lectin pathway and is composed of lectins such as MBL and two MBL-associated serine proteases or MASPs (Table 3). MBL is an acute phase protein, so its concentration in plasma increases substantially during an infection. MBL binds to terminal mannose, *N*-acetylglucosamine, and *N*-acetylmannosamine residues in complex carbohydrate structures. MBL has long been recognized as an opsonin, i.e., a protein that facilitates phagocytosis of bacteria. Low concentrations of MBL in children are associated with recurrent bacterial infections. MBL is similar in structure to C1q, having an amino-terminal domain with a collagen-like structure that binds the MASP proteins, followed by a globular carbohydrate recognition domain (CDR) that binds to sugar residues. There are two MASP proteins, called MASP-1 and MASP-2, that are very similar in structure to C1r and C1s (Wong *et al.*, 1999). Upon activation of MBL·MASP-1·MASP-2, the MASP protease components cleave C4 and C2, forming a CP C3 convertase (Fig. 1).

ALTERNATIVE PATHWAY

The alternative pathway (AP) was originally discovered in the early 1950s by Pillemer *et al.* (1954). Pillemer's group studied the ability of a yeast cell wall preparation, called zymosan, to consume C3 without affecting the amount of C1, C2, or C4. A new protein, called properdin, was isolated and implicated

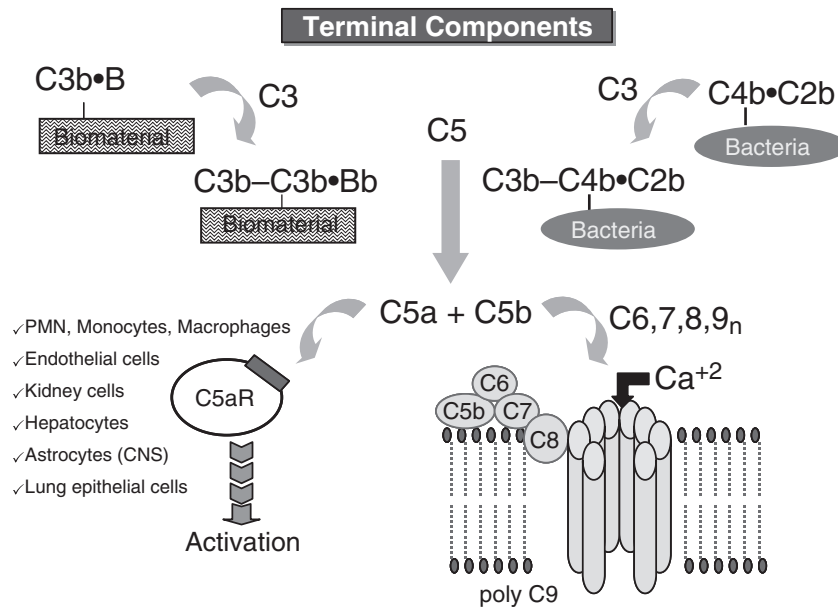

FIG. 4. Conversion of C5 produces C5a and leads to formation of the membrane attack complex (MAC). C5a binds to receptors on a variety of cells and results in numerous activities. C5b, formed by the CP, lectin, or the AP, binds C6 and C7 to form a complex that associates with the plasma membrane. This C5b67 multimer then binds C8, which results in the formation of a small hole in the lipid bilayer that allows small molecules to pass through. Association of multiple C9 proteins enlarges the pore, leading to loss of membrane integrity and cell death.

TABLE 3 Proteins of the Lectin Pathway of Complement

Protein	Molecular weight	Subunits	Plasma concentration ($\mu\text{g/ml}$)
MBL	270–650,000	18	1–3
MASP-1	93,000	2 (H,L)	6
MASP-2	76,000	2 (H,L)	

in initiating C3 activation independent of the CP. This new scheme was called the properdin pathway. However, this work fell into disrepute when it was realized that plasma contains natural antibodies against zymosan, which implied CP involvement in Pillemer's experiments. The pathway was rediscovered in the late 1960s with the study of complement activation by bacterial lipopolysaccharide and with the discovery of a C4-deficient guinea pig. The 1970s witnessed the isolation and characterization of each of the proteins of this pathway until it was possible to completely reconstruct the entire AP by recombining each of the purified proteins (Schreiber *et al.*, 1978). Most biomaterials activate complement through the AP, although there is evidence that the CP can also contribute (presumably subsequent to IgG binding).

The proteins of this pathway are described in Table 4. Their actions can be conceptually divided into three phases: initiation, amplification, and regulation (Figs. 3 and 5). Initiation is

a spontaneous process that is responsible for the nonselective nature of complement. During this stage, a small portion of the C3 molecules in plasma undergo a conformational change that results in hydrolysis of the thioester group, producing an activated form of C3 called C3(H₂O) ("C3-water"), that will bind to factor B. The C3(H₂O)·B complex is a substrate for factor D (another serine protease), which cleaves the B protein to form a solution-phase alternative pathway C3 convertase: C3(H₂O)·Bb. Analogous to C2b in the CP, Bb is a serine protease that (in association with C3(H₂O)) will cleave more C3 to form C3b. Under normal physiological conditions, most of the C3b produced is hydrolyzed and inactivated, a process that has been termed "C3 tickover." C3 tickover is a continuous process that ensures a constant supply of reactive C3b molecules to deposit on foreign surfaces, such as cellulose- or nylon-based biomaterials. Recognition of the C3b by factor B, cleavage by factor D, and generation of more C3 convertase leads to the amplification phase (Fig. 3). During this stage, many more C3b molecules are produced, bind to the surface, and in turn lead to additional C3b·Bb sites. Eventually, a C3b molecule attaches to one of the C3 convertase sites by direct attachment to the C3b protein component of the enzyme. This C3b–C3b·Bb complex is the alternative pathway C5 convertase and, in a manner reminiscent of the CP C5 convertase, converts C5 to C5b and C5a (Fig. 4).

Recent work with purified proteins and techniques to measure direct interactions with polymer surfaces has revealed an additional potential mechanism for alternative pathway activation (Andersson *et al.*, 2002). Both C3b and C3 will adsorb

TABLE 4 Proteins of the Alternative Pathway of Complement

Protein	Molecular weight	Subunits	Plasma concentration ($\mu\text{g/ml}$)
C3	185,000	$\alpha \beta$	1300
B	93,000	1	210
D	24,000	1	1
H	150,000	1	500
I	88,000	$\alpha \beta$	34
P	106–212,000	2–4	20

TABLE 5 Proteins of the Membrane Attack Complex

Protein	Molecular weight	Subunits	Plasma concentration ($\mu\text{g/ml}$)
C5	190,000	$\alpha \beta$	70
C6	120,000	1	60
C7	105,000	1	60
C8	150,000	$\alpha \beta$	55
C9	75,000	1	55
S-protein	80,000	1	500

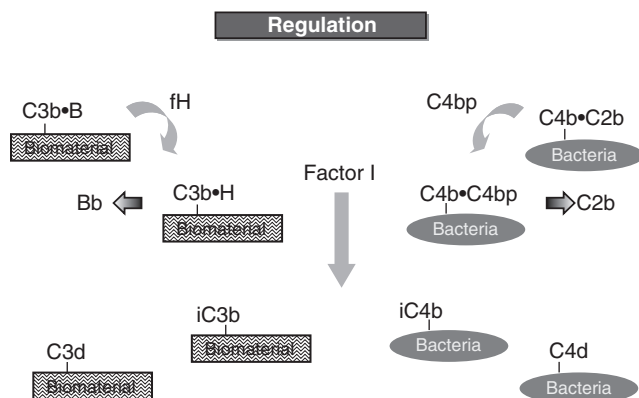

FIG. 5. Control of complement activation by factors H, I, and C4 binding protein. The extent to which complement activation occurs on different surfaces is dependent on the ability of fH or C4BP to recognize C3b or C4b on the surface. Degradation by factor I results in irreversible inactivation and the production of C3 and C4 fragments recognized by various complement receptors on WBC.

to (not react with) polystyrene. A portion (about 10%) of the bound C3 or C3b binds factor B. This complex is recognized by factor D, which then catalyzes the formation of an AP C3 convertase. This process is facilitated by properdin, which increases the amount of convertase formed under these conditions. Interestingly, while the C3b·Bb convertase is controlled by factors H and I (see later discussion), the surface-bound C3·Bb convertase is not. The adsorption of C3 does not occur if the polystyrene surface is precoated with fibrinogen, so the extent to which this occurs in whole blood, where many other proteins can compete with C3 for binding to a biomaterial surface, has not been demonstrated.

MEMBRANE ATTACK COMPLEX

All three pathways lead to a common point: cleavage of C5 to produce C5b and C5a. C5a is a potent inflammatory mediator and is discussed later in the context of receptor-mediated white-blood-cell activation. The production of C5b initiates the formation of a macromolecular complex of proteins called the membrane attack complex (MAC) that disrupts the cellular

lipid bilayer, leading to cell death (Table 5). The sequence of events in MAC formation is outlined in Fig. 4.

Following cleavage of C5 by C5 convertase, the C5b remains weakly bound to C3b in an activated state in which it can bind C6 to form a stable complex called C5b6. This complex binds to C7 to form C5b67, which has amphiphilic properties that allow it to bind to, and partially insert into, lipid bilayers. The C5b67 complex then binds C8 and inserts itself into the lipid bilayer. The C5b678 complex disrupts the plasma membrane and produces small pores ($r \sim 1 \text{ nm}$) that permit leakage of small molecules. The final step occurs when multiple copies of C9 bind to the C5b678 complex and insert into the membrane. This enlarges the pore to about 10 nm and can lead to lysis and cell death. Even at sublytic levels, formation of MAC on host cells results in a number of activation responses (elevated Ca^{2+} , arachidonic acid metabolism, cytokine production).

In addition to the usual means of generating C5b (i.e. through C5 convertase activity), several groups have shown that C5 can be modified by a variety of oxidizing agents (H_2O_2 , superoxide anion, and others) to convert C5 into a C5b-like structure that will bind C6. The oxidized C5·C6 complex can bind C7, C8, and C9 to form lytic MAC. This mechanism of MAC formation may be relevant at sites where neutrophils and macrophages attempt to phagocytize a biomaterial, producing a variety of reactive oxygen species, or in hypoxia/reperfusion settings (angioplasty, cardiopulmonary bypass [CPB]).

CONTROL MECHANISMS

Various types of control mechanisms have evolved to regulate the activity of the complement system at numerous points in the cascade (Liszewski *et al.*, 1996). These mechanisms are shown in Fig. 6 and include (1) decay (dissociation) of convertase complexes, (2) proteolytic degradation of active components that is facilitated by several cofactors, (3) protease inhibitors, and (4) association of control proteins with terminal components that interfere with MAC formation. Without these important control elements, unregulated activation of the cascade results in overt inflammatory damage to various tissues and has been demonstrated to contribute to the pathology of many diseases (discussed later).

Control of Complement Activation

Decay Acceleration	Cofactor Activity	Protease/Inhibitor	MAC Inhibitor
CR1	CR1	Factor I	CD59
Factor H	Factor H	C1Inh	S Protein
DAF/CD55	MCP/CD46	sCPN	Clusterin
C4BP	C4BP		

FIG. 6. Control of complement activation occurs by various mechanisms and is facilitated by a number of different proteins in the plasma (fH, fI, C1 Inh, C4BP, sCPN, S-protein, and clusterin) or on cell surfaces (CR1, DAF, MCP and CD59). Decay acceleration refers to the increased rate of displacement of either C2b or fBb from CP or AP convertases. Cofactor activity refers to the increase rate of factor I-mediated proteolysis facilitated by some proteins.

Starting at the top of the cascade, control of the classical and lectin pathway activation is mediated by a protein called C1 esterase inhibitor (C1-Inh). C1-Inh acts by binding to activated C1r and C1s subunits in C1 as well as MASP proteases bound to MBL. C1-Inh actually forms a covalent bond with these proteases, thus irreversibly inactivating these proteins. The effectiveness of this interaction is illustrated by the short half-life of C1s under physiological conditions (13 sec). The classical/lectin pathway C3/C5 convertase (C4b·C2b complex) spontaneously “decays” by dissociation of the C2b catalytic subunit. The rate of dissociation is increased by C4 binding protein (C4bp), which competes with C2 for a binding site on C4b. C4bp also acts as a cofactor for another control protein called factor I, which destroys the C4b by proteolytic degradation (Figs. 2 and 6).

The alternative pathway is also highly regulated by mechanisms that are very similar to the CP. The intrinsic instability of the C3b thioester bond (half-life = 60 μ sec) ensures that most of the C3b (80–90%) is inactivated in the fluid phase. Once formed, the C3 convertase (C3b·Bb complex) also spontaneously dissociates and the rate of “decay” is increased by factor H. Aside from accelerating the decay of C3 convertase activity, factor H also promotes the proteolytic degradation of C3b by factor I (Figs. 2 and 6). Factors H and I also combine to limit the amount of active C3(H₂O) produced in the fluid phase.

In addition to factor H, there are several cell-membrane-bound proteins that have similar activities and structures (Fig. 7). These proteins act to limit complement-mediated damage to autologous, bystander cells. Decay-accelerating factor, or DAF, displaces Bb from the C3 convertase and thus destroys the enzyme activity. DAF is found on all cells in the blood (bound to the plasma membrane through a unique lipid group) but is absent in a disease called proximal nocturnal hemoglobinuria (PNH), which manifests a high spontaneous rate of red blood cell lysis. In addition to DAF, there are two other cell-bound control proteins: membrane cofactor protein (MCP) and CR1 (complement receptor 1, see later discussion).

FIG. 7. Structure–activity relationships for complement control proteins. Each circle represents one short consensus repeat (SCR) domain, made up of about 60 amino acids. These SCR domains are strung together to create the different structures shown.

MCP is found on all blood cells except erythrocytes, while CR1 is expressed on most blood cells as well as cells in tissues such as the kidney. Both of these proteins display cofactor activity for the factor I-mediated cleavage of C3b. CR1 also acts like factor H and DAF to displace Bb from the C3 convertase. A soluble recombinant form of CR1 (sCR1) was originally described by Weisman *et al.* (1990) and later produced commercially (Avant Immunotherapeutics). A number of investigations have used sCR1 to limit complement activation in various disease models (Larsson *et al.*, 1997; Couser *et al.*, 1995).

In contrast to the inhibitory proteins discussed above, properdin, the protein originally discovered by Pillemer *et al.*, functions by binding to surface-bound C3b and stabilizing the C3 and C5 convertase enzymes. Although properdin is not necessary for activation of the alternative pathway, a genetic deficiency of this protein has been associated with an increased susceptibility to meningococcal infections.

As with the other stages of the cascade, there are several control mechanisms that operate to limit MAC formation and the potential for random lysis of “bystander” cells. The short half-life of the activated C5b (2 min) and the propensity of the C5b67 complex to self-aggregate into a nonlytic form help limit MAC formation. In addition, a MAC inhibitor, originally called S protein and recently shown to be identical to vitronectin, binds to C5b67 (also C5b678 and C5b6789) and prevents cell lysis. Recently another group of control proteins called homologous restriction factors (HRFs) have been discovered. They are called HRFs because they control assembly of the MAC on autologous cells (i.e., human MAC on human cells) but do not stop heterologous interactions (e.g., guinea-pig MAC on sheep red blood cells). One well-characterized member of this group is called CD59. It is widely distributed, found on erythrocytes, white blood cells, endothelial cells, epithelial cells, and hepatocytes. CD59 functions by interacting with C8 and C9, preventing functional expression of MAC complexes on autologous cells.

TABLE 6 Receptors for Complement Proteins

Receptors name/ligand	Structure	Cellular distribution/response
CR1/C3b, C4b	200,000-Da single chain	RBC, PMN, monocytes, B and T cells/clearance of immune complexes, phagocytosis, facilitates cleavage of C3b to C3dg by Factor I
CR2/C3dg	140,000-Da single chain	B cells/regulate B-cell proliferation
CR4	150,000-Da α chain 95,000-Da β chain	PMN, platelets, B cells/leukocyte-endothelial cell interaction
CR3/iC3b, ICAM-1, β glucan fibrinogen, factor Xa	185,000-Da α chain 95,000-Da β chain	PMN, monocyte/phagocytosis of microorganisms; respiratory burst activity
C5a/C5a		PMN, monocytes, T cells, epithelial cells, endothelial cells, hepatocytes, CNS, fibroblasts/chemotaxis, degranulation, hyperadherence, respiratory burst, cytokine production (IL-6, IL-8)
C3a/C3a	65,000 Da	Mast cells, eosinophils (various tissues)/histamine release, IL-6 production
C1q/C1q	70,000 Da	PMN, monocytes, B cells/respiratory burst activity
H/H	50,000 Da (three chains)	B cells, monocytes/secretion of factor I, respiratory burst activity

COMPLEMENT RECEPTORS

Except for the cytotoxic action of the MAC, most of the biological responses elicited by complement proteins result from ligand-receptor-mediated cellular activation (Sengelov, 1995). These ligands are listed in Table 6 and are discussed briefly here.

The ability of complement to function in the opsonization of foreign elements is accomplished in large part by a set of receptors that recognize various C3 and C4 fragments bound to these foreign surfaces. These receptors are called complement receptor 1, 2, 3, or 4 (CR1, CR2, etc.). CR1 is found on a variety of cells including RBCs, neutrophils, monocytes, B cells, and some T cells and recognizes a site within the C3c region of C3b (Fig. 2). On neutrophils and monocytes, activated CR1 will facilitate the phagocytosis of C3b- and C4b-coated particles. On RBCs, CR1 acts to transport C3b-immune complexes to the liver for metabolism. As discussed above, CR1 is also a complement regulatory protein. CR2 is structurally similar to CR1 (with 16 SCR domains; see Fig. 7), but recognizes the C3d fragment of C3b that is bound to antigen. CR2 is expressed on antigen-presenting cells such as follicular dendritic cells and B cells where it facilitates the process of antigen-immune complex-driven B-cell proliferation, providing a link between innate and adaptive immunity. CR3 represents another complement receptor that binds to iC3b, and β -glucan structures found on zymosan (yeast cell wall). Also, on activated monocytes, CR3 has been shown to bind fibrinogen and factor Xa (of the coagulation cascade). CR3 is a member of the β 2-integrin family of cell adhesion proteins that includes leukocyte functional antigen-1 (LFA-1) and CR4. LFA-1, CR3, and CR4 are routinely referred to as CD11a, CD11b, and CD11c, respectively. Each of these proteins associates with a molecule of CD18 to form a α - β heterodimer that is then transported and expressed on the cell surface. These proteins help mediate the cell-cell interactions necessary for such activities as chemotaxis and cytotoxic killing. A genetic deficiency in CR3/LFA proteins

leads to recurrent life-threatening infections. CR4 is found on neutrophils and platelets and binds C3d and iC3b. CR4 may facilitate the accumulation of neutrophils and platelets at sites of immune complex deposition.

In contrast to the ligands discussed earlier, which remain attached to activating surfaces, C3a, C4a, and C5a are small cationic polypeptides that diffuse into the surrounding medium to activate specific cells. These peptides are called anaphylatoxins because they stimulate histamine release from mast cells and cause smooth muscle contraction, which can produce increased vascular permeability and lead to a fatal form of shock called anaphylactic shock. These activities are lost when the peptides are converted to their des Arg analogs (i.e., with the loss of their carboxyl terminal arginine residue, referred to as C3a_{des Arg}, C5a_{des Arg}, etc.). This occurs rapidly *in vivo* and is catalyzed by serum carboxypeptidase N.

In addition to its anaphylatoxic properties, C5a and C5a_{des Arg} bind to specific receptors originally found on neutrophils and monocytes. Recently the receptors for both C5a and C3a have been cloned and sequenced. The C5aR (CD88) has been shown to be expressed on endothelial cells (EC), hepatocytes, epithelial cells (lung and kidney tubules), T cells, cells in the CNS as well as on the myeloid cell lines. In addition, expression levels of C5aRs are increased on EC and hepatocytes by exposure to LPS and IL-6. In myeloid cells (neutrophils and monocytes), the C5a-receptor interaction leads to a variety of responses, including chemotaxis of these cells into an inflammatory locus; activation of the cells to release the contents of several types of secretory vesicles and produce reactive oxygen species that mediate cell killing; increased expression of CR1, CR3, and LFA-1, resulting in cellular hyperadherence; and the production of other mediators such as various arachidonic acid metabolites and cytokines, e.g., IL-1, -6, and -8. Many of the adverse reactions seen during extracorporeal therapies, such as hemodialysis, are directly attributable to C5a production. C3aRs are expressed on a variety of cell types

TABLE 7 Clinical Settings Involving Complement

Hemodialysis and cardiopulmonary bypass
Kidney disease (especially glomerulonephritis)
Ischemia/reperfusion injury (e.g., angioplasty following heart attack)
Sepsis and adult respiratory distress syndrome
Recurrent infections
Transplantation
Rheumatoid arthritis
Systemic lupus erythematosus
Asthma
Alzheimer's disease
Hereditary angioedema

including eosinophils, neutrophils, monocytes, mast cells, and astrocytes (in the CNS), as well as γ -IFN-activated T cells. In eosinophils, C3a elicits responses similar to C5a, including intracellular calcium elevation, increases endothelial cell adhesion, and the generation of reactive oxygen intermediates.

CLINICAL CORRELATES

The normal function of complement is to mediate a localized inflammatory response to a foreign material. The complement system can become clinically relevant in situations where it fails to function or where it is activated inappropriately; some of these settings are shown in Table 7 (Lambris and Holers, 2000). In the first instance, a lack of activity due to a genetic deficiency in one or more complement proteins has been associated with increased incidence of recurrent infections (MBL deficiency in children), autoimmune disease (over 90% of C1-deficient patients develop SLE), and other pathologies (for example, a deficiency of C1 inhibitor is known to result in hereditary angioedema, where various soft tissues become extremely swollen because of overproduction of various vasoactive mediators). The second instance, inappropriate activation, also occurs in a variety of circumstances. It is now recognized that endothelial cells exposed to hypoxic conditions (ischemia due to angioplasty or a blocked artery due to atherosclerosis) activate complement following reperfusion of the blocked vessel. This results in further damage to the vessel wall and eventually to the surrounding tissue. Activation of the classical pathway by immune complexes occurs in various autoimmune diseases such as systemic lupus erythematosus and rheumatoid arthritis. Glomerular deposition of immune complexes results in local inflammation that can contribute to a type of kidney damage called glomerulonephritis (GN). Quite a number of experimental and clinical data have been accumulated demonstrating that complement directly contributes to the initiation and/or progression of GN (Table 8), resulting in the development of end-stage renal disease and the necessity of hemodialysis therapy.

TABLE 8 Types of Studies Demonstrating a Role for Complement in Kidney Disease

Deficiency or loss of complement regulatory activity results in tissue damage
Mechanistic and knockout studies implicate complement and C5 in particular
Ongoing glomerular disease is associated with various indices of complement activation
Inhibition of complement activation attenuates tissue damage in model systems

TABLE 9 Clinical Symptoms Associated with Cuprophan-Induced Biocompatibility Reactions

Cardiopulmonary:	Pulmonary hypertension
	Hypoxemia
	Respiratory distress (dyspnea)
	Neutropenia (pulmonary leukosequestration)
	Tachycardia
	Angina pectoris
	Cardiac arrest
Other:	Nausea, vomiting, diarrhea
	Fever, chills, malaise
	Urticaria, pruritus
	Headache

One of the major settings where complement has been implicated in adverse clinical reactions is during extracorporeal therapies such as hemodialysis, cardiopulmonary bypass, and apheresis therapy. The same nonspecific mechanism that permits the alternative pathway to recognize microbes results in complement activation by the various biomaterials found in different medical devices. The following discussion summarizes the clinical experience with hemodialysis and cardiopulmonary bypass, but many of the observations concerning complement activation and WBC activation are relevant to other medical biomaterial applications.

One of the most investigated materials (from the perspective of complement activation) is the cellulosic Cuprophan membrane used extensively for hemodialysis. Some of the adverse reactions that occur during clinical use of a Cuprophan dialyzer are listed in Table 9. In 1977, Craddock *et al.* showed that some of these same manifestations (neutropenia, leukosequestration, and pulmonary hypertension) could be reproduced in rabbits and sheep when the animals were infused with autologous plasma that had been incubated *in vitro* with either Cuprophan or zymosan. This effect could be abrogated by treatment of the plasma to inhibit complement activation (heating to 56°C or addition of EDTA), thus linking these effects with complement. The development and use of specific radioimmunoassays (RIAs) to measure C3a and C5a by Dennis Chenoweth (1984) led to the identification of these complement components in the plasma of patients during dialysis therapy. A typical patient response to a Cuprophan

FIG. 8. A typical response pattern to dialysis with a complement-activating hemodialysis membrane. Many investigators have noted that the extent of C3a production is directly proportional to the degree of neutropenia at the same time points.

membrane is shown schematically in Fig. 8. The C3a (and C5a) levels rise during the first 5–15 min, peaking between 10 and 20 min. For a Cuprophane membrane, typical peak C3a levels range from 4000 to 6000 ng/ml. During this period the white blood cells become hyperadherent and are trapped in the lung, resulting in a peripheral loss of these cells (neutropenia). As complement activation is controlled (e.g., by factor H), the C3a and C5a levels decrease to baseline levels and the WBCs return to the peripheral circulation, now in a more activated (primed) state. This is a very consistent response and many authors have noted a direct correlation between the extent of complement activation and the degree of neutropenia (as well as other responses such as CR3 expression) seen with various dialysis membranes.

Based on our understanding of the biochemistry of complement and its biological actions, the following scenario can be drawn (Fig. 9). Blood contact with the membrane results in initial protein deposition, including IgG, C3, and especially C3b, eventually leading to the formation of C3 and C5 convertase enzymes. Conversion of C5 results in C5a production, which leads to receptor-mediated neutrophil and monocyte activation. Production of C5b leads to MAC formation, which binds to bystander cells and results in subsequent activation of these cells through calcium-dependent mechanisms. Recognition of biomaterial-bound C3 and C4 fragments by WBC results in cell adherence and further activation of these cells. These various responses accounts for much of the pathophysiology seen clinically. The critical role of C5a in mediating many of these adverse reactions has been confirmed in experiments employing purified sheep C5a. Infusion of this isolated peptide into sheep, in a manner that would simulate exposure to this molecule during hemodialysis, produced dose-dependent responses identical to that seen when the sheep are subjected to dialysis (Johnson *et al.*, 1996). In addition, numerous *in vivo* and *in vitro* studies have documented the relationship between complement activation by biomaterials, the extent of WBC activation and the resulting inflammatory response illustrated

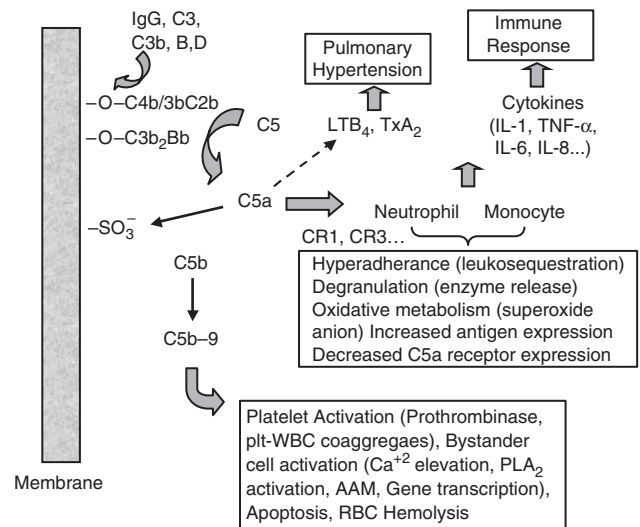

FIG. 9. The biochemical basis for complement-mediated adverse reactions during extracorporeal therapy. Production of C5a leads to receptor-dependent white blood cell activation. This results in profound neutropenia, increased concentrations of degradative enzymes, and reactive oxygen species that ultimately may lead to tissue damage and dysfunction of these important immune cells. Generation of secondary mediators, such as arachidonic acid metabolites (TxA₂, LTB₄) and cytokines, can have profound consequences on whole organ systems. Finally, formation of the MAC (C5b-9) has been linked with increased hemolysis during cardiopulmonary bypass and formation of microparticles and shown to increase platelet prothrombinase activity *in vitro*. This last observation suggests that surfaces that activate complement aggressively may be more thrombogenic.

in Fig. 9 (Tang *et al.*, 1998; Gemmell *et al.*, 1996; Larsson *et al.*, 1997; Lewis and Van Epps, 1987).

In the same time frame in which clinicians were linking complement with leukopenia in the hemodialysis setting, a number of cardiovascular scientists were demonstrating complement activation by the materials used to make cardiopulmonary bypass circuits. Typical levels of C3a produced in these procedures ranged from 300 to 2400 ng/ml. These investigations soon associated C3a and C5a production with a group of symptoms known as “postperfusion” or “postpump” syndrome (Table 10). Further analysis showed that complement was activated by the materials in the circuit (such as the polypropylene membranes and the nylon filters) but was also activated by during neutralization of the heparin anticoagulant with the protamine sulfate that was given to each patient at the end of the operation. This was further exacerbated by complement activation that occurred in the ischemic vascular bed upon reperfusion of the tissue that also occurred at the end of the procedure. The importance of complement activation, and C5 conversion in particular, to the clinical outcome of CPB patients was clearly demonstrated in a study by Fitch *et al.* (1999). Using a single chain anti-C5 antibody fragment that inhibited C5a and MAC generation during the procedure, these investigators showed that this antibody fragment lowered WBC activation, blood loss, cognitive deficits and myocardial injury. These results are consistent with other studies (Velthuis *et al.*, 1996; Hsu, 2001) using heparin-coated CPB circuits

TABLE 10 Postperfusion or Postpump Syndrome

Increased capillary permeability with accumulation of interstitial fluid
Blood loss requiring transfusions
Fever
Leukocytosis (increased WBC counts)
Organ dysfunction: heart, liver, kidney, brain and GI tract

that demonstrate lower inflammatory indices (complement, cytokine, and elastase levels) that are associated with improved clinical outcomes (decreased blood loss, length of ICU stays, and morbidity).

The CPB experience with heparin-coated devices demonstrates that modification of device materials (or the blood-contacting surfaces of those materials) can dramatically limit complement activation and the subsequent inflammatory response. Based in part on this and similar observations, hemodialyzer/membrane manufacturers began developing new membranes to produce more biocompatible (i.e., less complement-activating) devices. These new membranes tend to fall into two groups: moderately activating modified celluloses [such as cellulose acetate (CA), hemophane, and cellulose triacetate (CT)] and low activating synthetics [such as polyacrylonitrile (AN69), poly(methyl methacrylate) (PMMA), and polysulfone (PS)]. Moderately activating modified celluloses produce C3a levels and neutropenic responses that are about 50% of Cuprophan levels, while the synthetic materials display 0–20% activation compared to Cuprophan. Based on the known properties of complement and the structures of these membranes, the reasons for the improved biocompatibility can be rationalized as follows. Most of these materials have a diminished level of surface nucleophiles. In theory, this should result in lower deposition of C3b, and in fact this has been verified experimentally. The diminished capacity to bind C3b results in lower levels of C3 and C5 convertase activity and consequently an abated production of C3a and C5a. Patient exposure to C5a is reduced even further by materials that allow for transport through the membrane to the dialysate (for example, high-flux membranes such as polysulfone will do this) or by absorbing the peptide back onto the surface (the negatively charged AN69 has been shown to have a high capacity for binding cationic C5a). Thus, limiting C3b deposition and C5a exposure are two proven mechanisms of avoiding the clinical consequences of complement activation.

The same result can be also accomplished by facilitating the normal control of C3 convertase by factor H. Kazatchkine *et al.* (1979) have shown that heparin coupled to either zymosan or Sepharose limits the normal complement activation that occurs on these surfaces by augmenting C3b inactivation through factors H and I. Presumably, this accounts for the improved biocompatibility of heparin-coated circuits used in CPB described above. Mauzac *et al.* (1985) have prepared heparin-like dextran derivatives that are extensively modified with carboxymethyl and benzylamine sulfonate groups. These researchers have shown that these modifications diminish complement activation by the dextran substrate. A simple

modification of cellulose membranes (Cuprophan) with maleic anhydride has been shown to limit the complement-activating potential of these materials by over 90% (Johnson *et al.*, 1990). Again, increased binding of factor H to surface-bound C3b appears to account for the improved biocompatibility of maleated cellulose. Thus materials that limit complement activation through normal regulatory mechanisms are on hand and may prove to be the next generation of complement-compatible materials. In addition, as the studies of Fitch *et al.* have shown, pharmaceutical control of complement is possible with agents that are now in clinical development.

SUMMARY AND FUTURE DIRECTIONS

The immune response to a biomaterial involves both humoral and cellular components. Activation of the complement cascade by classical, lectin, or alternative pathways leads to the deposition of C4b and C3b proteins. Recognition of these molecules by receptors on granulocytes can cause activation of these cells, leading to the production of degradative enzymes and destructive oxygen metabolites. Recognition of C4b or C3b by other proteins in the cascade leads to enzyme formation (C3 and C5 convertases), which amplifies the response and can lead to the production of a potent inflammatory mediator, C5a. C5a binds to specific receptors found on PMNs and monocytes. The interaction of C5a with these cells elicits a variety of responses including hyperadherence, degranulation, superoxide production, chemotaxis, and cytokine production. Systemic exposure to C5a during extracorporeal therapies has been associated with neutropenia and cardiopulmonary manifestations (Tables 9 and 10) that can have pathologic consequences. The other portion of the C5 protein, C5b, leads to formation of a membrane attack complex that activates cells at sublytic levels and has cytotoxic potential if produced in large amounts. The control of these processes is understood well enough to begin designing materials that are more biocompatible. Limiting C3b deposition (nucleophilicity), adsorbing C5a to negatively charged surface groups, and facilitating the role of factors H and I are three approaches that have been shown to be effective. Translating the last mechanism into commercial materials is one of the major challenges facing the development of truly complement-compatible membranes.

4.5 SYSTEMIC TOXICITY AND HYPERSENSITIVITY

Arne Hensten-Pettersen and Nils Jacobsen

Artificial implant devices comprise a variety of metallic alloys, polymers, ceramics, hydrogels, or composites for a large number of purposes and with widely different properties. With the exception of drug delivery systems, sutures, and other degradable biomaterial systems (Chapter 2.7), the implant devices are intended to resist chemical and biochemical degradation and to have minimal leaching of structural components or additives. However, synthetic devices are influenced by chemical and in some cases enzymatic processes resulting in the release of biomaterials-associated components. Since there is no natural repair mechanisms parallel to natural tissues, degradation (biodegradation) is a “one-way” process that brings about microscopic and macroscopic surface and bulk changes of the devices, sometimes enhanced by the biomechanical and bioelectrical conditions that the devices are intended to resist. With the exception of pathologic calcification of certain polymer implants, the surface changes may not be significant for the mechanical strength of the implant, whereas in contrast the released substances very often have biological effects on the surrounding tissues or, possibly, at other remote locations. Inflammatory, foreign body, or other local host reactions and tumorigenesis are discussed in Chapters 4.2, 4.3, and 4.7. The following discussion is concerned with the possibility of systemic toxic reactions and/or hypersensitive reactions caused by biomaterials-derived xenobiotics.

KINETICS AND NATURE OF BIOMATERIALS COMPONENTS

Xenobiotic components derived from *in vivo* medical devices have parenteral contact with connective tissue or other specialized tissues such as bone, dentin, and vascular or ocular tissue, whereas leachables from skin- and mucosa-contacting devices have to pass the epithelial lining of the oral mucosa, the skin, the gastrointestinal tract, or—for volatiles—the lung alveoli to get “inside” the body. In either case, further distribution of foreign substances to other tissues and organs is dependent on membrane diffusion into blood capillaries and lymph vessels. The transport may be facilitated by reversible binding to plasma proteins, globulins (metal, metal compounds), and chylomicrons (lipophilic substances). Storage—and later release—may take place for certain components in tissues such as fat and bone.

In addition to particulate matter the released components consist of chemical substances of different atomic and molecular size, solubility, and other chemical characteristics depending on the mother material. Examples are metal ions such as cobalt, chromium, nickel, molybdenum, and titanium from metallic orthopedic implants or prosthodontic materials, or residual monomers, chemical initiators, inhibitors, plasticizers, antioxidants, etc., from polymer implants and dental materials. Other degradation products from inorganic, organic, and composite devices also "rub off" to the surrounding tissues. The kinetic mechanisms for biomaterials components are in part the same as those of xenobiotics introduced by food or environmental exposure, i.e., the released components are subject to oxidation, reduction, and hydrolysis followed by conjugation mechanisms. All metabolic changes are in their nature intended to eliminate them by way of the urine, bile, lungs, and to a certain degree in salivary, sweat, and mammary glands and hair (deBruin, 1981).

A key question is, do the released components or their metabolites have any systemic toxic effect on the host and/or could they induce unwanted immunological reactions?

TOXICODYNAMIC CONSIDERATIONS

Systemic toxicity depends on toxic substances hitting a target organ with high sensitivity to a specific toxicant. Target organs are the central nervous system, the hematopoietic system, the circulatory system, and visceral organs such as liver, kidney, and lungs, in that order. The toxicity is based on interference with key cell functions and depends on the dose and the duration of the exposure. Serious effects may be incompatible with continued life, but most effects are local and reversible cell damage. However, some sublethal effects may include somatic cell mutation expressed as carcinogenesis, or germinal cell mutation, resulting in reproductive toxicity.

The key word in the evaluation of general toxicity is the dose, defined as the amount of a substance an organism is exposed to, usually expressed as mg per kg body weight. Adverse effects of foreign substances are often the result of repeated, chronic exposure to small doses that over a prolonged period of time may have deleterious effects similar to one large, short time exposure, provided that the repeated doses exceed a certain threshold level. This level is determined by the capacity of metabolism and elimination. Another important factor is the possibility of synergistic potentiating effects when several toxicants are present simultaneously. Whatever mechanism is involved, the principle of systemic toxicity presupposes a dose-dependent reaction that may be measured and described, and that may be explained by specific reactions at distinct molecular sites (Eaton and Klaassen, 1996).

The components derived from biomaterials represent a large series of widely different foreign substances with few characteristics in common and with a largely unknown concentration. Most of them have to be characterized as toxic per se, with large variations regarding their place on a ranking list of potential toxicity. Metal ions and salts derived from biomaterials devices, such as mercury, nickel, and chromium, are classified

as toxicants. A similar statement could be made for components associated with polymeric materials. However, clinically relevant data on the concentration of degradation products are scarce, e.g., phthalate additives and degradation products from chemical additives derived from poly(methyl methacrylate) dental prostheses have been quantified in saliva (Lygre *et al.*, 1993). *In vitro* experiments have shown that chromium and nickel are released from base metal orthodontic appliances, although the amounts are not comparable with the amounts calculated in food intake (Park and Shearer, 1983). In addition, the proportion of uptake by mucosa is unknown. The presence of leachable substances has also been demonstrated in the surrounding tissues of implants, but quantification is difficult. Information is available on the release and uptake of mercury derived from dental amalgam. For example a series of studies has shown the presence mercury in plasma and urine after inhalation of metallic mercury released from dental amalgam (Mackert and Berglund, 1997). Accumulation of mercury in tissues belonging to the central nervous system has been shown after occupational exposure (Nylander *et al.*, 1989). Reproductive toxicity has been of specific concern. However, similar to other metals such as chromium and nickel, mercury exposure also takes place through food and through respiratory air. Careful scrutiny of the large number of partly controversial data by national and international scientific committees has not resulted in a consensus conclusion that the application of mercury amalgam should be discontinued as a dental biomaterial, although mercury is a significant environmental concern (The European Commission, 1998).

When occupational exposure is disregarded, the possibility of systemic toxicity or reproductive toxicity has not been seriously considered for other biomaterial components or metabolites, because of their low concentration as compared with their toxic potential. A fair conclusion at this point would be that there are no data indicating any systemic toxicity caused by biomaterials-derived xenobiotics. However, this field of interest is characterized by the increasing number of synthetic biomaterials on the market. Despite the premarketing testing programs it is difficult to predict single or synergistic toxic effects of leachable components and degradation products in the future.

ADVERSE EFFECTS OF DEFENSE MECHANISMS

The low probability of direct systemic adverse effects on target organs caused by biomaterial products does not rule out deleterious effects by other, dose-independent mechanisms. All substances not recognized as natural components of the tissues are subject to possible clearance by several mechanisms, e.g., phagocytic cells such as polymorphonuclear leukocytes, macrophages, and monocytes attempt to degrade and export the components. Larger foreign components are subject to more aggressive reactions by giant cells causing an inflammatory foreign-body reaction. Enzymes and other bioactive molecules associated with the phagocytosis and foreign-body reaction may cause severe local tissue damage. In addition, phagocytic cell contact and the contact with the circulatory

system of lymph and blood opens up another way of neutralizing foreign substances by way of the immune system, introducing a biologic memory of previously encountered foreign substances and an enhancement system for their neutralization.

HYPERSENSITIVITY AND IMMUNOTOXICITY

The immune system is an indispensable biologic mechanism to fight potentially adverse invaders, most commonly of microbial origin. However, the immune system occasionally strikes invading molecules—adverse or not—with an intensity that stands in contrast to the sometimes minute amounts of foreign substances, and with the ability to cause host tissue damage. This phenomenon is called hypersensitivity. The resulting injury is part of a group of adverse reactions classified as immunotoxic.

In principle, immunologic hypersensitivity comprises two different mechanisms: allergy and intolerance. Allergy is an acquired condition resulting in an overreaction upon contact with a foreign substance, given a genetic disposition and previous exposure to the substance. Allergic reactions may include asthma, rhinitis, urticaria, intraoral and systemic symptoms, and eczema. Intolerance is an inherited reaction that resembles allergy and has common mediators and potentiating factors, such as complement activation, and histamine release, but is not dependent on a previous sensitization process. The intolerance reactions have been associated with drugs such as acetylsalicylic acid, whereas intolerance to leachable biomaterial components such as benzoic acid is conceivable but not known.

ALLERGY AND BIOMATERIALS

A foreign substance able to induce an allergic reaction is called an allergen. There is no acceptable way of predicting whether a substance or a compound is potentially allergenic only on the basis of its chemical composition and/or structure. However, experimental evidence and years of empirical results after testing substances causing allergic reactions have given some leads, e.g., large foreign molecules such as proteins and nucleoproteins are strong allergens, whereas lipids are not. However, the strongest chemical allergens associated with biomaterials are often chemically active substances of low molecular weight, often less than 500 Da, such as lipid-soluble organic substances derived from polymer materials or metal ions and metal salts. These are called haptens, i.e., they become full allergens only after reaction or combination with proteins that may be present in macrophages and Langerhans cells of the host.

TYPES OF ALLERGIES

The allergies are most often categorized into four main groups (type I–IV) according to the reaction mechanisms. The types I to III are associated with humoral antibodies initiated by B-lymphocytes that develop to immunoglobulin-producing

plasma cells. The immunoglobulins are classified into five different classes, Ig E, A, D, G, and M, according to their basic structure and size. A variable portion of the immunoglobulin is specific for the antigen that induced its production (Roitt *et al.*, 1997). The type IV reaction is a cell-mediated reaction caused by T-lymphocytes. These interactions are also discussed in Chapter 4.3.

The types II and III allergies comprise antigen/antibody encounters including complement activation, cell lysis, release of vasoactive substances, inflammatory reaction, and tissue damage. Necrosis of periimplant tissue with histologic appearance and serum complement analyses consistent with Type III hypersensitivity has been observed in cases of atypical loosening of total hip prostheses (Hensten-Pettersen, 1993). However, an FDA document (Immunotoxicity Testing Guidance, 1999) omits the type II and III reactions for reasons of being “relatively rare and less likely to occur with medical devices/materials” leaving the types I and IV as relevant in the present context.

Type I Hypersensitivity

The type I reaction is based on an interaction between an intruding allergen and IgE immunoglobulins located in mast cells, basophils, eosinophils, and platelets, resulting in release of active mediators such as histamine and other vasoactive substances. The results are local or systemic reactions seen within a short time (minutes). The symptoms depend on the tissue or organ subject to sensitization, e.g., (1) inhaled allergens such as pollen or residual proteins associated with surgical latex gloves or other natural latex products that may result in asthmatic seizures, swelling of the mucosa of the throat, or worse; or (2) decreased blood pressure and anaphylactic shock. Food allergies may also give systemic symptoms. This type of host reaction is usually associated with full antigens. Since the potential allergens associated with biomaterials are small molecular haptens, the probability of IgE-based allergic reactions is low, although IgE antibodies to chromium and nickel have been reported (Hensten-Pettersen, 1993). Reports on adverse reactions to orthopedic devices describe patients with urticarial reactions. Contact urticaria is a wheal and flare response to compounds applied on intact skin. The role of immunological contact urticaria in relation to medical devices is not clear.

Type IV Hypersensitivity

The cell-mediated hypersensitivity is referred to as “delayed” because it takes more than 12 hours to develop, often 24–72 hours. Prolonged challenges of macrophage-resistant allergens, usually of microbial origin, may result in persistent immunological granuloma formation. The T-lymphocytes producing the response have been sensitized by a previous encounter with an allergen and act in concert with other lymphocytes and mononuclear phagocytes to create four histologically different types characterized by skin-related tissue reactions. The reactions are elicited by interaction of cells and mediators that comprise (1) swelling (the

Jones–Mote type); (2) induration (the granulomatous type); (3) swelling and induration and possibly fever (the tuberculin type); and (4) eczema (the contact type) (Roitt *et al.*, 1997). The latter form of delayed hypersensitivity has been of specific importance in relation to biomaterials. Most information on this reaction has been obtained by studying the reaction patterns following exposure to external environmental and occupation-related chemicals.

Allergic contact dermatitis is acquired through previous sensitization with a foreign substance. The hapten is absorbed by the skin or mucosa and binds to certain proteins associated with the Langerhans cells, forming a complete antigen. The antigen is brought in contact with the regional lymph nodes, resulting in the formation of activated, specialized T cells that are brought into circulation. Upon new exposure, the allergen may again be transported from the site of entrance. The new contact between the allergen and the activated, specialized T cells releases inflammatory mediators, resulting in further production and attraction of T cells causing tissue damage. The reactions are not necessarily limited to the exposure site.

The presence of allergic contact dermatitis is evaluated by allergologists or dermatologists by applying the suspected haptens using epidermal or intradermal skin tests and reading the dermal or epidermal reaction after specified amounts of time. Commercial test kits for epidermal testing are available for a series of chemical substances related to different occupations. A vast amount of information on the allergenic characteristics of biomaterials-related substances has been obtained in this way, especially as regards dental materials (Kanerva *et al.*, 1995).

Many biomaterials employed in dentistry such as metal alloys and resin-based materials have medical counterparts, and both categories of biomaterials have materials counterparts met with in everyday life. The sensitization process therefore often has taken place before the biomaterials contact.

ATOPY

Atopic individuals have a constitutional predisposition for IgE-based hypersensitive reactions caused by environmental and food allergens. The reactions include histamine-mediated hay fever, asthma, gastrointestinal symptoms, or skin rashes and are more pronounced at an early age. Atopics have an increased risk of acquiring irritant contact dermatitis to external biomaterial devices such as orthodontic appliances. The relation to allergic contact dermatitis is unclear (Lindsten and Kurol, 1997); so also is the relationship between atopy and allergens or haptens from biomaterials exposed parenterally.

IMMUNOLOGIC TOXICITY OF MEDICAL DEVICES

Immunologic toxicity to surface medical devices and external communicating devices (dialyzers, laparoscopes, etc.) may represent mechanisms of sensitization and hypersensitive reactions similar to those of orally exposed biomaterials. Hypersensitivity reactions to implants in clinically inobservable locations

are difficult to recognize unless they have dermal or systemic expressions. In addition, such reactions may be part of local toxic and/or mechanically induced inflammatory reactions using similar mediators for tissue response. For lack of more distinct descriptions, such reactions have been referred to as “deep tissue” reactions of type IV hypersensitivity.

A vast battery of *in vitro* and *in vivo* experimental studies have been performed to study potential adverse effects of biomaterial devices such as artificial joints, heart valves, and breast prostheses (Rodgers *et al.*, 1997). Aseptic loosening of metallic hip prostheses have been associated with “biologic” causes in addition to biomechanical factors and wear debris. However, it is currently unclear whether metal sensitivity is a contributing factor to implant failure (Hallab *et al.*, 2001). In fact, it is argued that the loosening process enhances the immunological sensitization, indicating that the cause/effect relation may be reversed (Milavec-Puretic *et al.*, 1998). What is clear is that local and general eczematous reactions have been observed following the insertion of metallic implants in patients subsequently shown to be allergic to cobalt, chromium, and nickel. Many case reports also describe the immediate healing of dermal reactions associated with metal implants (Al-Saffar and Revell, 1999). Metal allergy has also been discussed as a possible contributing factor in the development of in-stent coronary restenosis, although there is little evidence for this effect (Hillen *et al.*, 2002). However, established metal allergy in a patient does not as a rule seem to be accompanied by clinical reactions to implant alloys containing the metal. If this statement is true, it is in line with clinical observations made in surveys on the use of metallic alloys in prosthodontics and orthodontics. Inhomogeneity or mixture of alloys appear to determine the efflux of potentially hypersensitive metal ions, and hence increase the possibility of eliciting hypersensitive reactions (Grimsdottir *et al.*, 1992).

Methyl methacrylate bone cement is another potential allergenic factor in orthopedic surgery parallel with reactions in dentistry and cosmetics (Kaplan *et al.*, 2002), and immune-mediated disease and silicone based implants has been a matter of discussion for some time. However, a scientifically valid cause and effect relationship between immune based disease and silicone based implants has not been established (Rodgers *et al.*, 1997).

An extensive literature reflects clinical surveys and research activities related to natural latex used as barrier material by the health professions. It is accepted that residual latex proteins and chemicals associated with the production process may cause immediate and delayed reactions in patients and health personnel (Turjanmaa *et al.*, 1996).

OTHER INTERACTIONS

The FDA testing guidance referred to above also lists other interactions of medical devices, extracts of medical devices, or adjuvants with the immune system such as impairment of the normal immunologic protective mechanisms (immunosuppression), and long-term immunological activity (immunostimulation) that may lead to harmful autoimmune responses. The autoimmune reaction is explained by

the biomaterials-associated agent acting as an adjuvant that is stimulating to antibody/complement-based tissue damage by cross reactions with human protein. Chronic inflammatory, immune-related granuloma may take part in the development of autoimmune reactions.

CONCLUDING REMARKS

Biocompatibility issues related to medical devices form a multidimensional crossroad of technology and biology. One dimension is the various classes of biomaterials, such as plastics and other polymers, metals, ceramics, and glasses, depending on expert design to obtain maximal mechanical properties and minimal chemical dissolution. Another is the mode of application, ranging from skin and mucosal contact to totally submerged implants, with external communicating devices in between. A third dimension is the duration of contact, ranging from minutes to the expected lifetime, and the fourth, and decisive, is the biological reactions that can be expected. These circumstances prevent general statements on biomaterials. The present overview is aimed at students and limited to focus on collective mechanisms determining systemic toxicity and discuss hypersensitivity reactions documented by clinical reports.

4.6 BLOOD COAGULATION AND BLOOD-MATERIALS INTERACTIONS

Stephen R. Hanson

The hemostatic mechanism is designed to arrest bleeding from injured blood vessels. The same process may produce adverse consequences when artificial surfaces are placed in contact with blood. These events involve a complex set of interdependent reactions between (1) the surface, (2) platelets, and (3) coagulation proteins, resulting in the formation of a clot or thrombus that may subsequently undergo removal by (4) fibrinolysis. The process is localized at the surface by opposing activation and inhibition systems, which ensure that the fluidity of blood in the circulation is maintained. In this chapter, a brief overview of the hemostatic mechanism is presented. Although a great deal is known about blood responses to injured arteries and blood-contacting devices, important relationships remain to be defined in many instances. More detailed discussions of hemostasis and thrombosis have been provided elsewhere (Colman *et al.*, 2001; Esmon, 2003; Forbes and Courtney, 1987; Gresle *et al.*, 2002; Stamatoyannopoulos *et al.*, 1994).

PLATELETS

Platelets ("little plates") are nonnucleated, disk-shaped cells having a diameter of 3-4 μm and an average volume of $10 \times 10^{-9} \text{ mm}^3$. Platelets are produced in the bone marrow, circulate at an average concentration of about 250,000 cells per microliter of whole blood, and occupy approximately 0.3% of

FIG. 1. Platelet structure.

the total blood volume. In contrast, red cells typically circulate at 5×10^6 cells per microliter and may make up 40–50% of the total blood volume. As discussed later, platelet functions are designed to (1) initially arrest bleeding through formation of platelet plugs, and (2) stabilize the initial platelet plugs by catalyzing coagulation reactions leading to the formation of fibrin.

Platelet structure provides a basis for understanding platelet function. In the normal (nonstimulated) state, the platelet discoid shape is maintained by a circumferential bundle (cytoskeleton) of microtubules (Fig. 1). The external surface coat of the platelet contains membrane-bound receptors (e.g., glycoproteins Ib and IIb/IIIa) that mediate the contact reactions of adhesion (platelet–surface interactions) and aggregation (platelet–platelet interactions). The membrane also provides a phospholipid surface that accelerates important coagulation reactions (see below), and forms a spongy, canal-like (canalicular) open network that represents an expanded reactive surface to which plasma factors are selectively adsorbed. Platelets contain substantial quantities of muscle protein (e.g., actin, myosin) that allow for internal contraction when platelets are activated. Platelets also contain three types of cytoplasmic storage granules: (1) α -granules, which are numerous and contain the platelet-specific proteins platelet factor 4 (PF-4) and β -thromboglobulin (β -TG), and proteins found in plasma (including fibrinogen, albumin, fibronectin, and coagulation factors V and VIII); (2) dense granules that contain adenosine diphosphate (ADP), calcium ions (Ca^{2+}), and serotonin; and (3) lysosomal granules containing enzymes (acid hydrolases).

Platelets are extremely sensitive cells that may respond to minimal stimulation. Activation causes platelets to become sticky and change in shape to irregular spheres with spiny pseudopods. Activation is accompanied by internal contraction and extrusion of the storage granule contents into the extracellular environment. Secreted platelet products such as ADP stimulate other platelets, leading to irreversible platelet aggregation and the formation of a fused platelet thrombus (Fig. 2).

Platelet Adhesion

Platelets adhere to artificial surfaces and injured blood vessels. At sites of vessel injury, the adhesion process involves the interaction of platelet glycoprotein Ib (GP Ib) and connective tissue elements that become exposed (e.g., collagen) and requires plasma von Willebrand factor (vWF) as an

FIG. 2. Platelet reactions to artificial surfaces. Following protein adsorption to surfaces, platelets adhere and release α -granule contents, including platelet factor 4 (PF4) and β -thromboglobulin (β -TG), and dense granule contents, including ADP. Thrombin is generated locally through coagulation reactions catalyzed by procoagulant platelet surface phospholipids. Thromboxane A_2 (TxA_2) is synthesized. ADP, TxA_2 , and thrombin recruit additional circulating platelets into an enlarging platelet aggregate. Thrombin-generated fibrin stabilizes the platelet mass.

essential cofactor. GP Ib (about 25,000 molecules per platelet) acts as the surface receptor for vWF (Colman *et al.*, 2001). The hereditary absence of GP Ib or vWF results in defective platelet adhesion and serious abnormal bleeding.

Platelet adhesion to artificial surfaces may also be mediated through platelet glycoprotein IIb/IIIa (integrin $\alpha_{IIb}\beta_3$) as well as through the GP Ib–vWF interaction. GP IIb/IIIa (about 80,000 copies per resting platelet) is the platelet receptor for adhesive plasma proteins that support cell attachment, including fibrinogen, vWF, fibronectin, and vitronectin (Gresle *et al.*, 2002). Resting platelets do not bind these adhesive glycoproteins, events which normally occur only after platelet activation causes a conformational change in GP IIb/IIIa. Platelets that have become activated near artificial surfaces (for example, by exposure to factors released from already adherent cells) could adhere directly to surfaces through this mechanism (e.g., via GP IIb/IIIa binding to surface-adsorbed fibrinogen). Also, normally unactivated GP IIb/IIIa receptors could react with surface proteins that have undergone conformational changes as a result of the adsorption process (Chapter 3.2). The enhanced adhesiveness of platelets toward surfaces preadsorbed with fibrinogen supports this view. Following adhesion, activation, and release reactions, the expression of functionally competent GP IIb/IIIa receptors may also support tight binding and platelet spreading through multiple focal contacts with fibrinogen and other surface-adsorbed adhesive proteins.

Platelet Aggregation

Following platelet adhesion, a complex series of reactions is initiated involving (1) the release of dense granule ADP, (2) the formation of small amounts of thrombin (see later discussion), and (3) the activation of platelet biochemical processes leading to the generation of thromboxane A_2 . The release of ADP, thrombin formation, and generation of thromboxanes all act in

concert to recruit platelets into the growing platelet aggregate (Fig. 2). Platelet stimulation by these agonists causes the expression on the platelet surface of activated GP IIb/IIIa, which then binds plasma proteins that support platelet aggregation. In normal blood, fibrinogen, owing to its relatively high concentration (Table 1), is the most important protein supporting platelet aggregation. The platelet–platelet interaction involves Ca^{2+} -dependent bridging of adjacent platelets by fibrinogen molecules (platelets will not aggregate in the absence of fibrinogen, GP IIb/IIIa, or Ca^{2+}). Thrombin binds directly to platelet thrombin receptors and plays a key role in platelet aggregate formation by (1) activating platelets, which then catalyze the production of more thrombin; (2) stimulating ADP release and thromboxane A_2 formation; and (3) stimulating the formation of fibrin, which stabilizes the platelet thrombus.

Platelet Release Reaction

The release reaction is the secretory process by which substances stored in platelet granules are extruded from the platelet. ADP, collagen, epinephrine, and thrombin are physiologically important release-inducing agents and interact with the platelet through specific receptors on the platelet surface. Alpha-granule contents (PF-4, β -TG, and other proteins) are readily released by relatively weak agonists such as ADP. Release of the dense granule contents (ADP, Ca^{2+} , and serotonin) requires platelet stimulation by a stronger agonist such as thrombin. Agonist binding to platelets also initiates the formation of intermediates that cause activation of the contractile–secretory apparatus, production of thromboxane A_2 , and mobilization of calcium from intracellular storage sites. Elevated cytoplasmic calcium is probably the final mediator of platelet aggregation and release. As noted, substances that are released (ADP), synthesized (TxA_2), and generated (thrombin) as a result of platelet stimulation and release affect other platelets and actively promote their incorporation into growing platelet aggregates. *In vivo*, measurements of plasma levels of platelet-specific proteins (PF-4, β -TG) have been widely used as indirect measures of platelet activation and release.

Platelet Coagulant Activity

When platelets aggregate, platelet coagulant activity is produced, including expression of negatively charged membrane phospholipids (phosphatidylserine) that accelerate two critical steps of the blood coagulation sequence: factor X activation and the conversion of prothrombin to thrombin (see below). Platelets may also promote the proteolytic activation of factors XII and XI. The surface of the aggregated platelet mass thus serves as a site where thrombin can form rapidly in excess of the neutralizing capacity of blood anticoagulant mechanisms. Thrombin also activates platelets directly and generates polymerizing fibrin, which adheres to the surface of the platelet thrombus.

Platelet Consumption

In man, platelets labeled with radioisotopes are cleared from circulating blood in an approximately linear fashion over time

with an apparent life span of approximately 10 days. Platelet life span in experimental animals may be somewhat shorter. With ongoing or chronic thrombosis that may be produced by cardiovascular devices, platelets may be removed from circulating blood at a more rapid rate. Thus steady-state elevations in the rate of platelet destruction, as reflected in a shortening of platelet life span, have been used as a measure of the thrombogenicity of artificial surfaces and prosthetic devices (Hanson *et al.*, 1980, 1990).

COAGULATION

In the test tube, at least 12 plasma proteins interact in a series of reactions leading to blood clotting. Their designation as Roman numerals was made in order of discovery, often before their role in the clotting scheme was fully appreciated. Their biochemical properties are summarized in Table 1. Initiation of clotting occurs either intrinsically by surface-mediated reactions, or extrinsically through factors derived from tissues. The two systems converge upon a final common pathway that leads to the formation of thrombin, and an insoluble fibrin gel when thrombin acts on fibrinogen.

Coagulation proceeds through a “cascade” of reactions by which normally inactive factors (e.g., factor XII) become enzymatically active following surface contact, or after proteolytic cleavage by other enzymes (e.g., surface contact activates factor XII to factor XIIa). The newly activated enzymes in turn activate other normally inactive precursor molecules (e.g., factor XIIa converts factor XI to factor XIa). Because this sequence involves a series of steps, and because one enzyme molecule can activate many substrate molecules, the reactions are quickly amplified so that significant amounts of thrombin are produced, resulting in platelet activation, fibrin formation, and arrest of bleeding. The process is localized (i.e., widespread clotting does not occur) owing to dilution of activated factors by blood flow, the actions of inhibitors that are present or are generated in clotting blood, and because several reaction steps proceed at an effective rate only when catalyzed on the surface of activated platelets or at sites of tissue injury.

Figure 3 presents a scheme of the clotting factor interactions involved in both the intrinsic and extrinsic systems and their common path. Except for the contact phase, calcium is required for most reactions and is the reason why chelators of calcium (e.g., citrate) are effective anticoagulants. It is also clear that the *in vitro* interactions of clotting factors, i.e., clotting, is not identical with coagulation *in vivo*, which may be triggered by artificial surfaces and by exposure of the cell-associated protein, tissue factor. There are also interrelationships between the intrinsic and extrinsic systems, such that under some conditions “crossover” or reciprocal activation reactions may be important (Colman *et al.*, 2001; Bennett *et al.*, 1987).

MECHANISMS OF COAGULATION

In the intrinsic clotting system, contact activation refers to reactions following adsorption of contact factors onto a negatively charged surface. Involved are factors XII, XI,

TABLE 1 Properties of Human Clotting Factors

Clotting factor	Apparent molecular weight (number of chains)	Approximate normal plasma concentration ($\mu\text{g/ml}$)	Active Form
Intrinsic clotting system			
Prekallikrein	100,000 (1)	50	Serine protease
High molecular weight kininogen	120,000 (1)	80	Cofactor
Factor XII	80,000 (1)	30	Serine protease
Factor XI	143,000 (2)	3–6	Serine protease
Factor IX	57,000 (1)	3–5	Serine protease
Factor VIII ^a	330,000 (1)	0.2	Cofactor
Von Willebrand factor ^a	250,000 (1)	10	Cofactor for platelet adhesion
Extrinsic clotting system			
Tissue factor	44,000 (1)	0 ^b	Cofactor
Factor VII	50,000 (1)	1	Serine protease
Common pathway			
Factor X	59,000 (2)	5	Serine protease
Factor V	330,000 (1)	5–12	Cofactor
Prothrombin	72,000 (1)	140	Serine protease
Fibrinogen	340,000 (6)	2500	Fibrin polymer
Factor XIII	320,000 (4)	10	Transglutaminase

^a In plasma, factor VIII is complexed with von Willebrand factor which circulates as a series of multimers ranging in molecular weight from about 600,000 to 2×10^6 .

^b The tissue factor concentration in cell free plasma is low since tissue factor is an integral cell membrane-associated protein expressed by vascular and inflammatory cells, although a role in coagulation and thrombosis for a circulating form of soluble tissue factor has recently been postulated.

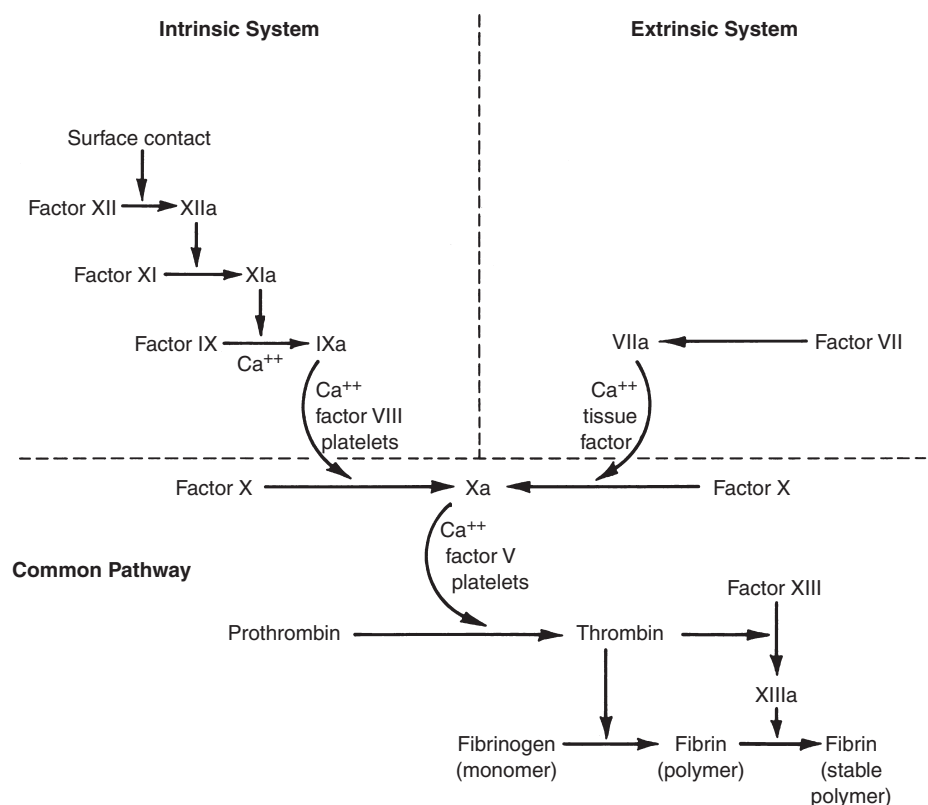

FIG. 3. Mechanisms of clotting factor interactions. Clotting is initiated by either an intrinsic or extrinsic pathway with subsequent factor interactions that converge upon a final, common path.

FIG. 4. Contact activation. The initial event *in vitro* is the adsorption of factor XII to a negatively charged surface (hatched, horizontal ovoid) where it is activated to form factor XIIa. Factor XIIa converts prekallikrein to kallikrein. Additional factor XIIa and kallikrein are then generated by reciprocal activation. Factor XIIa also activates factor XIa. Both prekallikrein and factor XI bind to a cofactor, high-molecular-weight kininogen (HMWK; dotted, vertical ovoid), which anchors them to the charged surface.

prekallikrein, and high-molecular-weight kininogen (HMWK) (Fig. 4). All contact reactions take place in the absence of calcium. Kallikrein also participates in fibrinolytic system reactions and inflammation (Bennett *et al.*, 1987). Although these reactions are well understood *in vitro*, their pathologic significance remains uncertain. For example, in hereditary disorders, factor XII deficiency is not associated with an increased bleeding tendency, and only a marked deficiency of factor XI produces abnormal bleeding.

A middle phase of intrinsic clotting begins with the first calcium-dependent step, the activation of factor IX by factor XIa. Factor IXa subsequently activates factor X. Factor VIII is an essential cofactor in the intrinsic activation of factor X, and factor VIII first requires modification by an enzyme, such as thrombin, to exert its cofactor activity. In the presence of calcium, factors IXa and VIIIa form a complex (the “tenase” complex) on phospholipid surfaces (expressed on the surface of activated platelets) to activate factor X. This reaction proceeds slowly in the absence of an appropriate phospholipid surface and serves to localize the clotting reactions to the surface (versus bulk fluid) phase. The extrinsic system is initiated by the activation of factor VII. When factor VII interacts with tissue factor, a cell membrane protein that may also circulate in a soluble form, factor VIIa becomes an active enzyme which is the extrinsic factor X activator. Tissue factor is present in many body tissues; is expressed by stimulated white cells and endothelial cells; and becomes available when underlying vascular structures are exposed to flowing blood upon vessel injury.

The common path begins when factor X is activated by either factor VIIa–tissue factor or by the factor IXa–VIIIa complex. After formation of factor Xa, the next step involves factor V, a cofactor, which (like factor VIII) has activity after modification by another enzyme such as thrombin. Factor Xa–Va, in the presence of calcium and platelet phospholipids,

forms a complex (“prothrombinase” complex) that converts prothrombin (factor II) to thrombin. Like the conversion of factor X, prothrombin activation is effectively surface catalyzed. The higher plasma concentration of prothrombin (Table 1), as well as the biologic amplification of the clotting system, allows a few molecules of activated initiator to generate a large burst of thrombin activity. Thrombin, in addition to its ability to modify factors V and VIII and activate platelets, acts on two substrates: fibrinogen and factor XIII. The action of thrombin on fibrinogen releases small peptides from fibrinogen (e.g., fibrinopeptide A) that can be assayed in plasma as evidence of thrombin activity. The fibrin monomers so formed polymerize to become a gel. Factor XIII is either trapped within the clot or provided by platelets and is activated directly by thrombin. A tough, insoluble fibrin polymer is formed by interaction of the fibrin polymer with factor XIIIa.

CONTROL MECHANISMS

Obviously, the blood and vasculature must have mechanisms for avoiding massive thrombus formation once coagulation is initiated. At least four types of mechanisms may be considered. First, blood flow may reduce the localized concentration of precursors and remove activated materials by dilution into a larger volume, with subsequent removal from the circulation following passage through the liver. Second, the rate of several clotting reactions is fast only when the reaction is catalyzed by a surface. These reactions include the contact reactions, the activation of factor X by factor VII–tissue factor at sites of tissue injury, and reactions that are accelerated by locally deposited platelet masses (activation of factor X and prothrombin). Third, there are naturally occurring inhibitors of coagulation enzymes, such as antithrombin III, which are potent inhibitors of thrombin and other coagulation enzymes (plasma levels of thrombin–antithrombin III complex can also be assayed as a measure of thrombin production *in vivo*). Another example of a naturally occurring inhibitor is tissue factor pathway inhibitor (TFPI), a protein that in association with factor Xa inhibits the tissue factor/factor VII complex. Fourth, during the process of coagulation, enzymes are generated that not only activate coagulation factors, but also degrade cofactors. For example, the fibrinolytic enzyme plasmin (see below) degrades fibrinogen and fibrin monomers and can inactivate cofactors V and VIII. Thrombin is also removed when it binds to thrombomodulin, a protein found on the surface of blood vessel endothelial cells. The thrombin–thrombomodulin complex then converts another plasma protein, protein C, to an active form that can also degrade factors V and VIII. *In vivo*, the protein C pathway is a key physiologic anticoagulant mechanism (Colman *et al.*, 2001; Esmon, 2003).

In summary, the platelet, coagulation, and endothelial systems interact in a number of ways that promote localized hemostasis while preventing generalized thrombosis. Figure 5 depicts some of the relationships and inhibitory pathways that apply to blood reactions following contact with both natural and artificial surfaces.

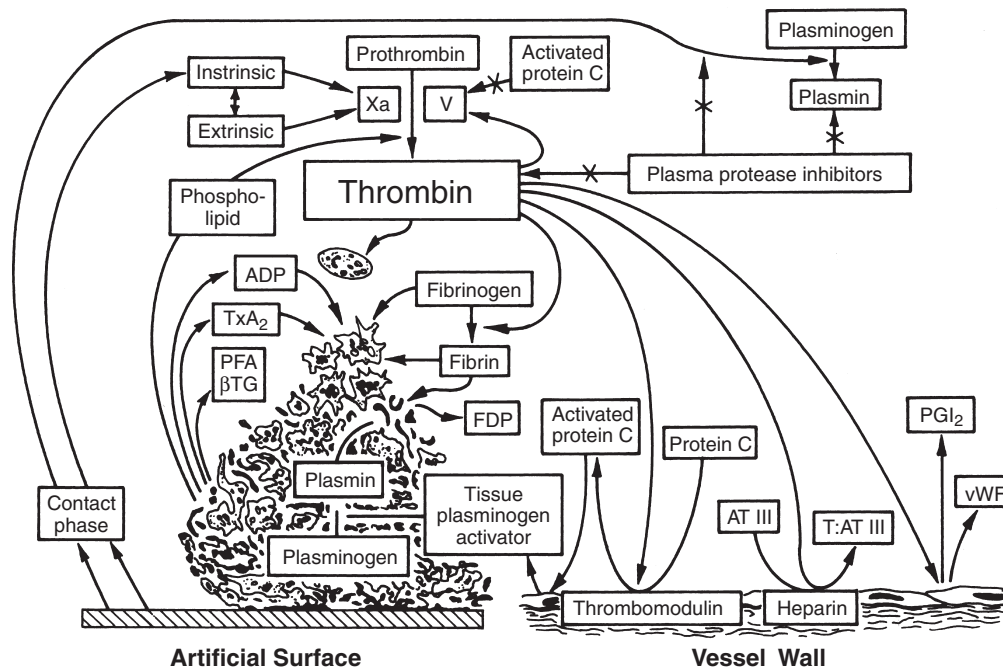

FIG. 5. Integrated hemostatic reactions between a foreign surface and platelets, coagulation factors, the vessel endothelium, and the fibrinolytic system.

Fibrinolysis

The fibrinolytic system removes unwanted fibrin deposits to improve blood flow following thrombus formation, and to facilitate the healing process after injury and inflammation. It is a multicomponent system composed of precursors, activators, cofactors and inhibitors, and has been studied extensively (Colman *et al.*, 2001; Forbes and Courtney, 1987). The fibrinolytic system also interacts with the coagulation system at the level of contact activation (Bennett *et al.*, 1987). A simplified scheme of the fibrinolytic pathway is shown in Fig. 6.

The most well-studied fibrinolytic enzyme is plasmin, which circulates in an inactive form as the protein plasminogen. Plasminogen adheres to a fibrin clot, being incorporated into the mesh during polymerization. Plasminogen is activated to plasmin by the actions of plasminogen activators that may be

FIG. 6. Fibrinolytic sequence. Plasminogen activators, such as tissue plasminogen activator (tPA) or urokinase, activate plasminogen to form plasmin. Plasmin enzymatically cleaves insoluble fibrin polymers into soluble degradation products (FDPs), thereby effecting the removal of unnecessary fibrin clot.

present in blood or released from tissues, or that may be administered therapeutically. Important plasminogen activators occurring naturally in man include tissue plasminogen activator (tPA) and urokinase. Following activation, plasmin digests the fibrin clot, releasing soluble fibrin–fibrinogen digestion products (FDP) into circulating blood, which may be assayed as markers of *in vivo* fibrinolysis (e.g., the fibrin D-D dimer fragment). Fibrinolysis is inhibited by plasminogen activator inhibitors (PAIs), and by a thrombin-activated fibrinolysis inhibitor (TAFI) that promotes the stabilization of fibrin and fibrin clots (Colman *et al.*, 2001).

Complement

As detailed in Chapter 4.4, the complement system is primarily designed to effect a biologic response to antigen–antibody reactions. Like the coagulation and fibrinolytic systems, complement proteins are activated enzymatically through a complex series of reaction steps (Bennett *et al.*, 1987). Several proteins in the complement cascade function as inflammatory mediators. The end result of these activation steps is the generation of an enzymatic complex that causes irreversible damage (by lytic mechanisms) to the membrane of the antigen-carrying cell (e.g., bacteria).

Since there are a number of interactions between the complement, coagulation, and fibrinolytic systems, there has been considerable interest in the problem of complement activation by artificial surfaces, prompted in part by observations that devices having large surface areas (e.g., hemodialyzers) may cause (1) reciprocal activation reactions between complement

enzymes and white cells, and (2) complement activation that may mediate both white-cell and platelet adhesion to artificial surfaces. Further observations regarding the complement activation pathways involved in blood-materials interactions are likely to be of interest.

Red Cells

Red cells are usually considered as passive participants in processes of hemostasis and thrombosis, although under some conditions (low shear or venous flows) red cells may form a large proportion of total thrombus mass. The concentration and motions of red cells have important mechanical effects on the diffusive transport of blood elements. For example, in flowing blood, red-cell motions may increase the effective diffusivity of platelets by several orders of magnitude. Under some conditions, red cells may also contribute chemical factors that influence platelet reactivity (Turitto and Weiss, 1980). The process of direct attachment of red cells to artificial surfaces has been considered to be of minor importance and has therefore received little attention in studies of blood-materials interactions.

White Cells

The various classes of white cells perform many functions in inflammation, infection, wound healing, and the blood response to foreign materials. White-cell interactions with artificial surfaces may proceed through as-yet poorly defined mechanisms related to activation of the complement, coagulation, fibrinolytic, and other enzyme systems, resulting in the expression by white cells of procoagulant, fibrinolytic, and inflammatory activities. For example, stimulated monocytes express tissue factor, which can initiate extrinsic coagulation. Neutrophils may contribute to clot dissolution by releasing potent fibrinolytic enzymes (e.g., neutrophil elastase). White cell interactions with devices having large surface areas may be extensive (especially with surfaces that activate complement), resulting in their marked depletion from circulating blood. Activated white cells, through their enzymatic and other activities, may produce organ dysfunction in other parts of the body. In general, the role of white-cell mechanisms of thrombosis and thrombolysis, in relation to other pathways, remains an area of considerable interest.

CONCLUSIONS

Interrelated blood systems respond to tissue injury in order to quickly minimize blood loss, and later to remove unneeded deposits after healing has occurred. When artificial surfaces are exposed, an imbalance between the processes of activation and inhibition of these systems can lead to excessive thrombus formation and an exaggerated inflammatory response. Whereas many of the key blood cells, proteins, and reaction steps have been identified, their reactions in association with artificial surfaces have not been well defined in many instances. Therefore, blood reactions that might cause thrombosis continue to limit the potential usefulness of many cardiovascular devices for

applications in man. Consequently, these devices commonly require the use of systemic anticoagulants, which present an inherent bleeding risk.

4.7 TUMORIGENESIS AND BIOMATERIALS

Frederick J. Schoen

The possibility that implant materials could cause tumors or promote tumor growth has long been a concern of surgeons and biomaterials researchers. This chapter describes general concepts in neoplasia, the association of tumors with implants in human and animals, and the pathobiology of tumor formation adjacent to biomaterials.

GENERAL CONCEPTS

Neoplasia, which literally means “new growth,” is the process of excessive and uncontrolled cell proliferation (Cotran *et al.*, 1999; Kumar *et al.*, 1997). The new growth is called

TABLE 1 Characteristics of Benign and Malignant Tumors

Characteristics	Benign	Malignant
Differentiation	Well defined; structure may be typical of tissue of origin	Less differentiated with bizarre (anaplastic) cells; often atypical structure
Rate of growth	Usually progressive and slow; may come to a standstill or regress; cells in mitosis are rare	Erratic and may be slow to rapid; mitoses may be absent to numerous and abnormal
Local invasion	Usually cohesive, expansile, well-demarcated masses that neither invade nor infiltrate the surrounding normal tissues	Locally invasive, infiltrating adjacent normal tissues
Metastasis	Absent	Frequently present; larger and more undifferentiated primary tumors are more likely to metastasize

a neoplasm or tumor (i.e., a swelling, since most neoplasms are expansile, solid masses of abnormal tissue). Tumors are either benign (when their pathologic characteristics and clinical behavior are relatively innocent) or malignant (harmful, often deadly). Malignant tumors are collectively referred to as cancers (derived from the Latin word for crab, to emphasize their obstinate ability to adhere to adjacent structures and spread in many directions simultaneously). The characteristics of benign and malignant tumors are summarized in Table 1. Benign tumors do not penetrate (invade) adjacent tissues, nor do they spread to distant sites. They remain localized and surgical excision can be curative in many cases. In contrast, malignant tumors have a propensity to invade contiguous tissues. Moreover, owing to their ability to gain entrance into blood and lymph vessels, cells from a malignant neoplasm can be transported to distant sites, where subpopulations of malignant cells take up residence, grow, and again invade as satellite tumors (called metastases).

The primary descriptor of any tumor is its cell or tissue of origin. Benign tumors are identified by the suffix “oma,” which is preceded by reference to the cell or tissue of origin (e.g., adenoma—from an endocrine gland; chondroma—from cartilage). The malignant counterparts of benign tumors carry similar names, except that the suffix “carcinoma” is applied to cancers derived from epithelium (e.g., squamous- or adeno-carcinoma, from protective and glandular epithelia, respectively) and “sarcoma” (e.g., osteo- or chondro-sarcoma, producing bone and cartilage, respective) to those of mesenchymal origin. Malignant neoplasms of the hematopoietic system, in which the cancerous cells circulate in blood, are called leukemias; solid tumors of lymphoid tissue are

called lymphomas. The major classes of malignant tumors are illustrated in Fig. 1.

Cancer cells express varying degrees of resemblance to the normal precursor cells from which they derive. Thus, neoplastic growth entails both abnormal cellular proliferation and modification of the structural and functional characteristics of the cell types involved. Malignant cells are generally less differentiated than normal cells. The structural similarity of cancer cells to those of the tissue of origin enables specific diagnosis (source organ and cell type); moreover, the degree of resemblance usually predicts prognosis of the patient (i.e., expected outcome based on biologic behavior of the cancer). Therefore, poorly differentiated tumors generally are more aggressive (i.e., display more malignant behavior) than those that are better differentiated. The degree to which a tumor mimics a normal cell or tissue type is called its grade of differentiation. The extent of spread and other effects on the patient determine its stage.

Neoplastic growth is unregulated. Neoplastic cell proliferation is therefore unrelated to the physiological requirements of the tissue and is unaffected by removal of the stimulus which initially caused it. These characteristics differentiate neoplasms from (1) normal proliferations of cells during fetal development or postnatal growth, (2) normal wound healing following an injury, and (3) hyperplastic growth that adapts to a physiological need, but that ceases when the stimulus is removed.

All tumors, benign and malignant, have two basic components: (1) proliferating neoplastic cells that constitute their parenchyma, and (2) supportive stroma made up of connective tissue and blood vessels. Although the parenchyma of neoplasms is characteristic of the specific cells of origin, the growth and evolution of neoplasms are critically dependent on the non-specific stroma, usually composed of blood vessels, connective tissue, and inflammatory cells.

ASSOCIATION OF IMPLANTS WITH HUMAN AND ANIMAL TUMORS

Neoplasms occurring at the site of implanted medical devices are unusual, despite the large numbers of implants used clinically over an extended period of time. Nevertheless, cases of both human and veterinary implant-related tumors have been reported (Black, 1988; Jennings *et al.*, 1988; Pedley *et al.*, 1981; Schoen, 1987). In all, more than 50 cases of tumors associated with foreign material have been reported, of which approximately half were adjacent to therapeutic implants. The remainder include tumors related to bullets, shrapnel, other metal fragments, sutures, bone wax, and surgical sponge. Implant-related tumors have been reported both short and long term following implantation. More than 25% of tumors associated with foreign bodies have developed within 15 years, and more than 50% within 25 years (Brand and Brand, 1980).

The vast majority of malignant neoplasms associated with clinical fracture fixation devices, total joint replacements, mechanical heart valves, and vascular grafts and experimental foreign bodies in both animals and humans are sarcomas. They comprise various histologic subtypes, including fibrosarcoma,

FIG. 1. Types of malignant tumors. (A) Carcinoma, exemplified by an adenocarcinoma (gland formation noted by arrow). (B) Sarcoma (composed of spindle cells). (C) Lymphoma (composed of malignant lymphocytes). All stained with hematoxylin and eosin; all $\times 310$.

osteosarcoma (osteogenic sarcoma), chondrosarcoma, and angiosarcoma, and are characterized by rapid and locally infiltrative growth. Carcinomas, reported far less frequently, have usually been restricted to situations where an implant has been placed in the lumen of an epithelium-lined organ. Illustrative reported cases are noted in Table 2; descriptions of others are available (Goodfellow, 1992; Jacobs *et al.*, 1992; Jennings *et al.*, 1988). Lymphomas have been reported in association with the capsules surrounding breast implants (Gaudet *et al.*, 2002; Keech and Creech, 1997; Sahoo *et al.*, 2003). A tumor forming adjacent to a clinical vascular graft is illustrated in Fig. 2. A non-implant-related primary tumor (gastric cancer) with a metastasis to a total knee replacement has also been reported (Kolstad and Hgstorp, 1990).

Whether there is a causal role for implanted medical devices in local or distant malignancy remains controversial. In an individual case, caution is necessary in implicating the implant

in the formation of a neoplasm; demonstration of a tumor occurring adjacent to an implant does not necessarily prove that the implant caused the tumor (Morgan and Elcock, 1995). Large-scale epidemiological studies and reviews of available data have concluded that there is no evidence in humans for tumorigenicity of non-metallic and metallic surgical implants (McGregor *et al.*, 2000). Indeed, the risk in populations must be low, as exemplified by recent cohorts of patients with both total hip replacement and breast implants who show no detectable increases in tumors at the implant site (Berkel *et al.*, 1992; Deapen and Brody, 1991; Mathiesen *et al.*, 1995; Brinton and Brown, 1997). A clinical and experimental study even suggested that the evidence of breast carcinoma may be decreased in women with breast implants (Su *et al.*, 1995). However, one study suggested a small increase in the number of lung and vulvar cancers in patients with breast implants (Deapen and Brody, 1991). Importantly, the presence of an implant does

not impair the diagnosis of breast cancer (Brinton and Brown, 1997).

Moreover, neoplasms are common in both humans and animals and can occur naturally at the sites at which biomaterials are implanted. Most clinical veterinary cases have been observed in dogs, a species with a relatively high natural frequency of osteosarcoma and other tumors at sites where orthopedic devices are implanted. Moreover, spontaneous human musculoskeletal tumors are not unusual. However, since sarcomas arising in the aorta and other large arteries are rare, the association of primary vascular malignancies with clinical polymeric grafts may be stronger than that with orthopedic devices.

Clinically benign but exuberant foreign-body reactions may simulate neoplasms. For example, fibrohistiocytic lesions resembling malignant tumors may occur as a reaction to silica, previously injected as a soft-tissue sclerosing agent (Weiss *et al.*, 1978). Moreover, regional lymphadenopathy (i.e., enlargement of lymph nodes) may result from an exuberant foreign-body reaction to material that has migrated from a prosthesis. This has been documented in cases of silicone emanating from both finger joints (Christie *et al.*, 1977) and breast prostheses (Hausner *et al.*, 1978), as well as in association with polymeric replacements of the temporomandibular joint, and with conventional metallic, ceramic, and polymeric total replacements of large joints (Jacobs *et al.*, 1995). A mass lesion caused by foreign-body granuloma in a lymph node can masquerade as a neoplasm on physical examination (sometimes called

a pseudotumor). Potentially, it could evolve into a lymphoma owing to chronic stimulation of the immune system.

PATHOBIOLOGY OF FOREIGN BODY TUMORIGENESIS

Considerable progress has been made over the past several decades in the understanding of the molecular basis of cancer (Cotran *et al.*, 1999; Kumar *et al.*, 1997). Four principles are fundamental and well accepted: (1) Neoplasia is associated with and often results from nonlethal genetic damage (or mutation), either inherited or acquired by the action of environmental agents such as physical effects (e.g., radiation, fibers or foreign bodies; Fry, 1989), chemicals or viruses. (2) The principal targets of the genetic damage are cellular regulatory genes (normally present and necessary for physiologic cell function, inducing cellular replication, growth and repair of damaged DNA). (3) The tumor mass evolves from the clonal expansion of a single progenitor cell that has incurred the genetic damage. (4) Tumorigenesis is a multistep process, generally owing to accumulation of successive genetic lesions. After a tumor has been initiated, the most important factors in its growth are the kinetics (i.e., balance of replication or loss) of cell number change and its blood supply. The formation of new vessels (angiogenesis) is essential for enlargement of tumors and for their access to the vasculature and, hence, metastasis (Carmeliet, 2003).

FIG. 2. Sarcoma arising 1 year following and in association with Dacron graft repair of abdominal aortic aneurysm. (A) and (B) Gross photographs (graft designated by arrow, surrounded by tumor mass). S. Maini, *Cancer* 46: 398-402, 1980.]

The pathogenesis of implant-induced tumors is not well understood, yet most experimental data indicate that physical effects rather than the chemical characteristics of the foreign body are the principal determinants of tumorigenicity (Brand *et al.*, 1975). Tumors are induced experimentally by a wide array of materials of diverse composition, including those that could be considered essentially nonreactive, such as certain glasses, gold or platinum, and other relatively pure metals and polymers. Indeed, one surgeon performed a much-maligned experiment in which dimes inserted in rats yielded a rate of 60% sarcomas in 16 months (prompting the suggestion that dimes and probably all metallic coins were carcinogenic and should be discontinued!) (Moore and Palmer, 1997). Solid materials implanted in a configuration with high surface area are most tumorigenic. Materials lose their tumorigenicity when implanted in pulverized, finely shredded or woven form, or when surface continuity is interrupted by multiple perforations. This trend is often called the Oppenheimer effect. Thus, foreign-body neoplasia is generally considered to be a transformation process mediated by the physical state of implants; it is largely independent of the composition of the materials, unless specific carcinogens are present.

Solid-state tumorigenesis depends on the development of a fibrous capsule around the implant. Tumorigenicity corresponds directly to the extent and maturity of tissue encapsulation of a foreign body and inversely with the degree of active cellular inflammation. Thus, an active, persistent inflammatory response inhibits tumor formation in experimental systems. Host (especially genetic) factors also affect the propensity to form tumors as a response to foreign bodies. Humans are less susceptible to foreign-body tumorigenesis than are rodents, the usual experimental model. In rodent systems, tumor frequency and latency depend on species, strain, sex, and age. Concern has recently been raised over the possibility that foreign-body neoplasia can be induced by the release of wear debris or needlelike elements from composites in a mechanism that is analogous to that of asbestos-related mesothelioma (Brown *et al.*, 1990; Jaurand, 1991). However, animal experiments suggest only particles with very high length-to-diameter ratios (>100) produce this effect. Particles with this high aspect ratio are highly unlikely to arise as wear debris from orthopedic implants.

Nevertheless, cancer at foreign-body sites may be mechanistically related to that which occurs in diseases in which tissue fibrosis is a prominent characteristic, including asbestosis (i.e., lung damage caused by chronic inhalation of asbestos), lung or liver scarring, or chronic bone infections (Brand, 1982). However, in contrast to the mesenchymal origin of most implant-related tumors, other cancers associated with scarring are generally derived from adjacent epithelial structures (e.g., mesothelioma with asbestos).

Chemical induction effects are also possible. With orthopedic implants, the stimulus for tumorigenesis could be metal particulates released by wear of the implant (Harris, 1994). Indeed, implants of chromium, nickel, cobalt, and some of their compounds, either as foils or debris, are carcinogenic in rodents (Swierzena *et al.*, 1987), and the clearly demonstrated widespread dissemination of metal debris from implants (to

lymph nodes, bone marrow, liver, and spleen, particularly in subjects with loose, worn joint prostheses) not only could cause damage to distant organs, but also could be associated with the induction of neoplasia (Case *et al.*, 1994). Although unequivocal cases of metal particles or elemental metals provoking the formation of malignant tumors are not available, continued vigilance and further study of the problem in animal models is warranted (Lewis and Sunderman, 1996).

“Nonbiodegradable” and “inert” implants have been shown to contain and/or release trace amounts of substances such as remnant monomers, catalysts, plasticizers, and antioxidants. Nevertheless, such substances injected in experimental animals at appropriate test sites (without implants), in quantities comparable to those found adjacent to implants, are generally not tumorigenic. Moreover, chemical carcinogens such as nitrosamines or those contained in tobacco smoke may potentiate scar-associated cancers.

A chemical effect has been considered in the potential carcinogenicity of polyurethane biomaterials (Pinchuk, 1994). Under certain conditions (i.e., high temperatures in the presence of strong bases), diamines called 2,4-toluene diamine (TDA) and 4,4'-methylene dianiline (MDA) can be produced from the aromatic isocyanates used in the synthesis of polyurethanes. TDA and MDA are carcinogenic in rodents. However, it is uncertain whether (1) TDA and MDA are formed *in vivo*, and (2) these compounds are indeed carcinogenic in humans, especially in the low dose rate provided by medical devices. Although attention has been focused on polyurethane foam-coated silicone gel-filled breast implants, one type of which contained the precursor to TDA, the risk is considered zero to negligible (Expert Panel, 1991).

Foreign-body tumorigenesis is characterized by a long latent period, during which the presence of the implant is required for tumor formation. Available data suggest the following sequence of essential developmental stages in foreign-body tumorigenesis (summarized in Table 3): (1) cellular proliferation in conjunction with tissue inflammation associated with the foreign-body reaction (specific susceptible preneoplastic cells may be present at this stage); (2) progressive formation of a well-demarcated fibrotic tissue capsule surrounding the implant; (3) quiescence of the tissue reaction (i.e., dormancy and phagocytic inactivity of macrophages attached to the foreign body), but direct contact of clonal preneoplastic cells with the foreign body surface; (4) final maturation of preneoplastic cells; and (5) sarcomatous proliferation. Support for this

multistep hypothesis for foreign body tumorigenesis comes from an experimental study by Kirkpatrick (2000) in which premalignant lesions were frequently found in implant capsules. A spectrum of lesions was observed, from proliferative lesions without atypical calls to atypical proliferation to incipient sarcoma.

The essential hypothesis is that initial acquisition of neoplastic potential and the determination of specific tumor characteristics does not depend on direct physical or chemical interaction between susceptible cells and the foreign body, and, thus, the foreign body per se probably does not initiate the tumor. However, although the critical initial event occurs early during the foreign-body reaction, the final step to neoplastic autonomy (presumably a genetic event) is accomplished only when preneoplastic cells attach themselves to the foreign-body surface. Subsequently, there is proliferation of abnormal mesenchymal cells in this relatively quiescent microenvironment, a situation not permitted with the prolonged active inflammation associated with less inert implants.

Thus, the critical factors in sarcomas induced by foreign bodies include implant configuration, fibrous capsule development and remodeling, and a period of latency long enough to allow progression to neoplasia in a susceptible host. The major role of the foreign body itself seems to be that of stimulating the formation of a fibrous capsule conducive to neoplastic cell maturation and proliferation. The rarity of human foreign body-associated tumors suggests that cancer-prone cells are infrequent in the foreign-body reactions to implanted human medical devices.

CONCLUSIONS

Neoplasms associated with therapeutic clinical implants in humans are rare; causality is difficult to demonstrate in any individual case. Experimental implant-related tumors are induced by a large spectrum of materials and biomaterials, dependent primarily on the physical and not the chemical configuration of the implant. The mechanism of experimental tumor formation, as yet incompletely understood, appears related to the implant fibrous capsule.

4.8 BIOFILMS, BIOMATERIALS, AND DEVICE-RELATED INFECTIONS

Bill Costerton, Guy Cook, Mark Shirtliff,
Paul Stoodley, and Mark Pasmore

INTRODUCTION

Tens of millions of medical devices are used each year and, in spite of many advances in biomaterials, a significant proportion of each type of device becomes colonized by bacteria and becomes the focus of a device-related infection. Topical devices (e.g., contact lenses) are colonized as soon as they are placed on tissue surfaces, transcutaneous devices (e.g., vascular catheters) are progressively colonized by skin organisms, and even surgically implanted devices regularly become foci of infection. Implanted devices may be colonized by bacteria at the time of surgery, or they may be colonized by organisms that gain access to their surfaces by a hematogenous route, from a distant source. The most significant factor in the development of device-related infections appears to be the skill of the surgical team, with prosthetic hips being infected in less than 0.2% of cases in large specialized clinics, and as many as 4% in less proficient facilities. Generally, large and complex medical devices that require long and complicated surgery for their placement are at high risk of bacterial infection, and transcutaneous devices in this category (e.g., the Jarvik heart) automatically become infected. In many areas of medicine, the risk of infection limits the use of devices that constitute the epitome of the engineer’s skill and imagination and incorporate the finest and most sophisticated biomaterials available in this fast-moving field.

As medical devices came into more regular use, the surgeons who placed them used their well-developed observation skills to define the “classic” device-related infection. These infections were often very slow to develop, with overt symptoms sometimes being seen almost immediately and sometimes being seen months or even years after the device was installed. Inflammation and pus formation were often local, especially in transcutaneous devices, but a certain proportion of patients with device-related infections suddenly developed acute disseminated infections caused by the same species that had colonized the device. These acute exacerbations of device-related infections responded well to antibiotic therapy. However, this treatment almost never reversed the local symptoms, and colonized devices often gave rise to a predictable series of acute exacerbations, so that good medical management usually dictated their removal. The bacteria that caused device-related infections were common skin biota (e.g., *Staphylococcus epidermidis*) and common environmental organisms (e.g., *Pseudomonas aeruginosa*), and certain species predominated in infections of certain devices. Because the infecting bacteria, and occasional fungi (e.g., *Candida albicans*), were so ubiquitous in the modern human environment, device recipients always had good immunity against these low-level pathogens, but these antibodies failed to prevent infection. It was the “front-line” medical specialists (e.g., orthopedic surgeons) who gradually persuaded medical microbiologists

and infectious disease specialists that device-related infections differed from acute bacterial infections in several important respects.

The biofilm concept was developed and articulated (Costerton *et al.*, 1978) in environmental microbiology, and it was introduced into medical microbiology when Tom Marrie *et al.* (1982) examined the surfaces of devices that had failed because of bacterial infection. This concept states that bacteria, in all but the most nutrient-deprived ecosystems, grow preferentially in matrix-enclosed communities attached to surfaces (Costerton *et al.*, 1987). Electron microscopy proved to be useful in the examination of the surfaces of failed medical devices, because both scanning (SEM) and transmission (TEM) electron microscopy involve dozens of washing steps that remove floating or loosely adherent bacteria. Therefore any bacterial or fungal cells that remained on the surfaces of the device, after processing, were *bona fide* biofilm organisms. With medical colleagues leading the search (Khoury *et al.*, 1992; Marrie and Costerton, 1984; Nickel *et al.*, 1985), our morphological team examined hundreds of types of failed medical devices and found biofilms on all of their surfaces. Biofilms were seen on the surfaces of contact lenses that had been worn by volunteers (McLaughlin-Borlace *et al.*, 1998), and very extensive sessile communities were seen on the surfaces of lenses that had been stored overnight in storage cases (Gray *et al.*, 1995; McLaughlin-Borlace *et al.*, 1998). Some of the most extensive biofilms we ever saw on a medical device were found on the surfaces of intrauterine contraceptive devices (Marrie *et al.*, 1982), and teeth and dental devices were equally heavily colonized. It was in this area of topical medical devices that the distinction was made between colonization, which is the simple presence of microbial biofilms on a surface, and the infections that occur when this presence of a biofilm elicits a pathogenic response.

The surface of skin is colonized by a wide variety of bacteria and fungi, most of which are removed or killed by surgical preparations, but the deeper layers are also colonized by bacteria (mostly *S. epidermidis*) that escape skin sterilants. This cutaneous biota rapidly colonizes the surfaces of any transcutaneous device, and the biofilm moves along any device that is placed in a subcutaneous "tunnel," until the entire surface of the device is colonized. In this manner a microbial biofilm is introduced into the normally sterile environment of the peritoneum, by the Techkhoff catheter (Dasgupta *et al.*, 1987), or into the normally sterile environment of the heart, by devices like the Hickman (Tenney *et al.*, 1986) and the Swan-Ganz (Mermel *et al.*, 1991) catheters. The inevitable colonization of transcutaneous devices, which is usually complete in 3–4 weeks, does not automatically lead to infection. All of the Hickman catheters in our National Cancer Institute study (Tenney *et al.*, 1986) were seen to be colonized, and one was even partially blocked by a very exuberant biofilm, but only four of the 81 patients experienced overt infection and bacteremia. Chronic ambulatory peritoneal dialysis (CAPD) patients all have well-developed biofilms on their Tenckhoff catheters, but many do not develop peritonitis if their humoral and cellular immune mechanisms can "keep up" (Dasgupta *et al.*, 1990) with the planktonic (floating) cells that are released from these sessile communities.

When implanted medical devices become colonized, the presence of these microbial biofilms always triggers pathogenic changes in the surrounding tissues, but symptoms are often slow to develop. Mechanical heart valves and vascular grafts can fail because biofilms on stitches that hold them in place cause inflammation, weaken the tissues involved, and lead to their detachment and displacement (Hyde *et al.*, 1998). Orthopedic devices may develop "aseptic loosening" in that the device is loosened by bone dissolution, but there are no signs of inflammation. The biofilms of the causative pathogens are so coherent that routine cultures of the device and the tissues are almost always negative. Biofilms elicit few symptoms, because their matrix-enclosed cells produce few toxins and stimulate only cursory immune responses and inflammation, but local symptoms will be produced when planktonic cells are released from these sessile communities.

The examination of failed medical devices frequently reveal microbial biofilms. Therefore, the unique characteristics of device-related infections can be explained in terms of the characteristics of biofilms (Costerton *et al.*, 1999). The slow development and asymptomatic nature of many device-related infections can be explained by the observation that biofilm bacteria produce few toxins and elicit little inflammatory response. Many device-related infections are negative in routine microbiological cultures because biofilms release a limited number of planktonic cells, large biofilm fragments grow up as a single colony on plates, and sessile cells do not grow well on agar surfaces. Common bacterial species predominate in device-related infections because they form biofilms very effectively in their natural environments (e.g., skin), and this biofilm mode of growth protects them from the immune responses that occur in all potential hosts. The biofilm mode of growth protects the causative agents of device-related infections from both humoral and cell-mediated immunity (see Chapter 4.3) (Leid *et al.*, 2002), so these infections occur in healthy individuals, and they are never resolved by even the most active host defense mechanisms. Exacerbations of device-related infections are caused by the release of planktonic cells, and antibiotics can kill these floating cells and reverse the symptoms of acute infection, but the infection persists because the causative biofilm is resistant to these antibacterial agents. Most, if not all, of the characteristics of device-related infections can be explained in terms of the characteristics of biofilms, so it may be useful to examine the burgeoning field of biofilm microbiology, as an early step in the search for new biomaterials that will control these infections.

BIOFILM MICROBIOLOGY

Many of the concepts and techniques that have served microbiologists well, in the virtual conquest of epidemic bacterial diseases caused by planktonic organisms, now serve us only poorly in the study of device-related and other chronic bacterial diseases. This section on biofilm microbiology will focus on the central fact that biofilm bacteria differ from their planktonic counterparts in so many ways that they are as different as spores are from vegetative bacteria, and it is imperative

that special biofilm methods be used in studies of the bacterial colonization of biomaterials.

Bacterial Adhesion to Surfaces

Often, the DLVO theory is applied to the study of bacterial adhesion to surfaces (van Loosdrecht *et al.*, 1990). This classic concept of colloid behavior visualizes a planktonic bacterial cell as a smooth colloid particle that interacts with the surface in a manner based on the charges on both surfaces, which overcome the basic repulsion of individual particles. Examinations of the surfaces of planktonic bacteria, using special preparations and electron microscopy, have clearly shown that these surfaces are not smooth. In addition to proteinaceous appendages (flagella and pili) that project 2–6 μm from the cell, the entire surfaces of planktonic cells of natural strains of bacteria are covered by a matrix of hydrophobic exopolysaccharide (EPS) fibers, and sometimes by a highly structured protein “coat.” The external EPS layer of planktonic cells is anchored to the polysaccharide O antigen fibers that project from the lipopolysaccharide (LPS) of the outer membrane of gram-negative cells, and to the polysaccharide teichoic acid fibers that project from the cell walls of gram-positive cells. Elegant freeze-substitution microscopy preparations have shown that the actual surface of planktonic bacterial cells that would be capable of interacting with the surface to be colonized is a 0.2 to 0.4- μm -thick forest of protein and polysaccharide fibers. The planktonic bacterial cell is not a smooth-surfaced colloid particle, and the actual interaction of these cells with surfaces is based on the bridging of bacterial fibers with fibers adsorbed to the surface being colonized. Thus, DLVO theory is of limited application in the study of bacterial adhesion.

Another conventional microbiology method, the reliance on pure cultures of bacteria isolated from the system of interest, but subcultured hundreds of times in rich media, also does not serve us well in biofilm studies relevant to medical devices. This method, which dates from Robert Koch in the 1850s, produces lab-adapted strains of bacteria that are selected in favor of planktonic growth, because the simple act of subculturing leaves adherent cells behind in the old culture and transfers only free-floating cells. These lab-adapted strains lack many surface structures that would be necessary for their survival in a hostile “wild” environment, but they are not challenged by antibacterial agents, so they survive in the test tube, but perish if they are released into natural ecosystems. When these lab-adapted strains are used in studies of bacterial adhesion to biomaterials, they come close to the smooth-surfaced colloidal particles visualized in the DLVO theory, and data that are misleading for the understanding of medical-device-centered infection are generated. Several companies have spent millions of dollars on novel biomaterials to which lab-adapted strains of bacteria would adhere to only very poorly, only to have these biomaterials heavily colonized by “wild” natural bacteria, and to find that they performed unsatisfactorily in clinical tests. Most microbiologists who focus on biofilms never do adhesion experiments on strains that are more than one transfer from an infected patient, if their objective is to assess the propensity of a biomaterial for colonization by a putative pathogen. Scientists

at the FDA and EPA are aware of this necessity to use “wild” bacteria in biomaterials testing.

When planktonic cells adhere to a surface, which they do with considerable avidity, they exhibit behaviors that have been divided into “reversible” and “irreversible” patterns (Marshall *et al.*, 1971). The most actively motile organisms (e.g., *P. aeruginosa*) may use their flagella as landing mechanisms, and then may use their type IV pili to produce a twitching motility that allows them to pile up into elaborate structures, some of which resemble the fruiting bodies of the myxobacteria. Other less mobile organisms produce “windrows” of cells (Korber *et al.*, 1995) following adhesion, while cells that have neither flagella nor pili simply stay in place if the location is favorable, and detach if it is not. Movies showing these post-adhesion behaviors of bacteria are available on the Center for Biofilm Engineering (CBE) Web site (www.erc.montana.edu). Biofilm engineers have generated surprising data (Stoodley *et al.*, 2001a, b) showing that many cells that adhere to surfaces also detach and leave the area, before they make the genetic switch to attach irreversibly and initiate the process of biofilm formation. Many people in the biomaterials field have speculated, intuitively, that key surface characteristics must favor (or inhibit) bacterial adhesion, and almost every possible combination of these characteristics has been tried in the search for colonization-resistant biomaterials. Wild bacteria adhere equally well to very hydrophobic (e.g., Teflon) and to very hydrophilic (e.g., PVC) surfaces, they colonize smooth surfaces as well as they adhere to rough surfaces (Marrie and Costerton, 1984; Sottile *et al.*, 1986), and they colonize smooth surfaces in very high shear flow systems (Characklis, 2003). Thus, we have no perfect biomaterial surface that resists bacterial colonization by virtue of its inherent surface properties, but nonfouling surfaces show limited potential for this application (Chapter 2.13).

Biofilm Formation on Surfaces

When a bacterial cell has “made the decision” to colonize a surface it sets in motion a pattern of gene expression that profoundly alters its previous planktonic phenotype, to produce a unique biofilm phenotype that may differ by as much as 70% in the proteins expressed (Sauer and Camper, 2001). Some of the first genes that are up-regulated in adherent cells are those involved in the production of the EPS material that will form the matrix of the biofilm and will also anchor the cell irreversibly to the surface. In *P. aeruginosa* the up-regulation of *algC*, which is a part of the alginate synthesis pathway, occurs within 18 minutes of initial cell adhesion (Davies and Geesey, 1995), and we see the secretion of matrix material by these cells within 30 minutes of adhesion. The genes that are up-regulated in the biofilm phenotype of many bacterial species are being analyzed by proteomics (Miller and Diaz-Torres, 1999; Oosthuizen *et al.*, 2002; Sauer and Camper, 2001; Sauer *et al.*, 2002; Svensater *et al.*, 2001; Tremoulet *et al.*, 2002a, b) and by microarray analysis (Schembri *et al.*, 2003; Schoolnik *et al.*, 2001; Stoodley *et al.*, 2002; Wagner *et al.*, 2003; Whiteley *et al.*, 2001), and individual genes involved in this profound phenotype shift are being identified daily. Sauer and her colleagues

have reported that the phenotype of planktonic cells of both *P. aeruginosa* and *P. putida* differ from that of their biofilm counterparts more than they differ from that of planktonic cells of other species in the same genus. The inherent resistance of biofilm bacteria to antibiotics, all of which were selected on the basis of their ability to kill planktonic cells, is now largely attributed to the altered gene expression pattern of the biofilm phenotype. Scientists at Microbia Ltd (Boston) have identified one specific gene (*fnt C*) that is responsible for this inherent antibiotic resistance in biofilms formed by all staphylococcal species, and the deletion or blockage of this gene produces biofilms that are susceptible to conventional antibiotics.

Once attached cells have triggered the conversion to the biofilm phenotype, the multicellular community on the colonized surface begins to accrete larger numbers of cells by binary fission and by further recruitment of planktonic cells from the bulk water phase. As they increase in numbers and produce large amounts of EPS matrix material, the attached cells form microcolonies in which they constitute approximately 15% of the volume and the matrix occupies approximately 85% of the volume. The microcolonies assume tower-like and mushroom-like shapes (Fig. 1) in most natural and cultured biofilms, but many other morphologies may be dictated by species characteristics and by nutrient availability. The microcolonies may occupy the colonized surface, as discrete entities separated by open water channels (Fig. 1), or they may pile up in several layers to form thick sessile communities, but they always maintain their structural integrity and move independently under shear stress. As the biofilm matures and undergoes more phenotypic changes (Stoodley *et al.*, 2002), the processes of cell division and recruitment come into balance with programmed detachment of planktonic cells from the sessile community and sloughing. Most natural biofilms reach a mature thickness and

FIG. 1. Diagrammatic representation of the tower-like and mushroom-like microcolonies that are the basic structural units of the biofilms on colonized surfaces. Note that the matrix material occupies $\pm 85\%$ of the mass of these structures (while the cells comprise $\pm 15\%$), that the microcolonies can be deformed into oscillating streamers by shear forces, and that water moves through these complex communities in a convective pattern. It was the complex differentiated structure of these microcolonies, and the maintenance of the open water channels, that stimulated speculation that some form of “hormone-like” cell–cell signaling must be involved in the formation of microbial biofilms.

a stable community structure within a week or two of their initiation of colonization, and many remain relatively stable for years. Stoodley *et al.* (2002) have concluded that the biofilm phenotype would favor bacterial survival in the harsh environment of the primitive earth, and they have suggested that the planktonic phenotype may have developed considerably later, as a mechanism for dissemination.

Natural Control of Biofilm Formation on Surfaces

The complex structure of biofilm communities (Fig. 1) stimulated a lively discussion of what signals (e.g., hormones or pheromones) must be operative to allow the development of shaped microcolonies and sustained water channels. In 1998 the first demonstration that biofilm development in *P. aeruginosa* is controlled by an acyl homoserine lactone (AHL) quorum-sensing signal was published (Davies *et al.*, 1998), and it has subsequently been reported that *agr*, *sar*, and *RAP* (Balaban *et al.*, 1998) signals control this same process in gram-positive organisms. Additionally, it was shown that the autoinducer II signal (furanone) controls biofilm formation, and many other processes, in virtually all bacterial species (Schauder *et al.*, 2001; Xavier and Bassler, 2003). Most biofilm specialists agree that these signals are simply the tip of the iceberg, that many more signals will be discovered, and that specific blockage of many of these simple chemical signals offers a practical way to control virtually any bacterial “behavior.” It has already been shown that specific signal inhibitors can block toxin production in *S. aureus*, and can even render specific bacteria essentially nonpathogenic in animal models (Balaban *et al.*, 2000).

The manipulation of biofilm formation is a very attractive target for new agents to prevent device-related infections. If bacteria that make contact with biomaterials were “locked” in the planktonic phenotype and were unable to assume the protected biofilm phenotype, they would be readily killed by host defense mechanisms and/or by antibiotic therapy. Several chemical analogs that block signal activity by interfering with the binding of the signal to its cognate receptor have been shown to be effective in inhibiting biofilm formation in specific pathogens (Balaban *et al.*, 1998). One such analog (RIP) prevents the binding of a biofilm control signal (RAP) to its receptor (TRAP). This signal blocker has been shown to prevent biofilm formation in an animal model of a device-related infection, and to allow complete eradication of the bacteria with conventional antibiotic therapy (Balaban *et al.*, 2003a, b). The researchers involved in the search for biofilm-control signal inhibitors are acutely aware of the subtle nature of the signal network in bacterial cells. It is highly unlikely that we will find a single ON/OFF switch for biofilm formation, and blockers that prevent biofilm formation may up-regulate invidious bacterial behaviors (e.g., toxin production), but we are encouraged by several observations made in natural ecosystems. Marine plants and animals control biofilm formation on their surfaces, presumably because biofilm/silt accretion would bury them and preclude photosynthesis in the plants, and at least one of the compounds that they use for this purpose is a signal inhibitor (de Nys *et al.*, 1995). In these natural systems, plant and animal surfaces are ideal locations for biofilm formation and growth,

but no bacterial mutant capable of thwarting the action of these natural biofilm control agents has emerged in millions of years of evolution.

Novel Engineering Approaches to Biofilm Control

The current therapy for device-related infections consists of trying to kill a biological entity (the bacteria) with a chemical (the antibiotic), with the only variable parameters being concentration and time of contact. Engineers have suggested that a number of physical forces could be harnessed to deliver higher concentrations of the antibiotic to the infecting organisms, or to compromise the bacteria in ways that make them more susceptible to the agents concerned. Two technologies that offer considerable promise involve the use of ultrasonic energy (Nelson *et al.*, 2002; Rediske *et al.*, 1998), and the imposition of a very weak sustained DC field (Costerton *et al.*, 1994) across the biofilm, and both have been shown to render sessile microbial populations susceptible to conventional antibiotics. Practical research is currently underway in the modification of biomaterials, and of device design, to harness the potential of these physical biofilm control technologies in our general strategies for the control of device-related infections.

BIOFILM-RESISTANT BIOMATERIALS

Biofilm-related complications have cost many lives in clinical settings. This unfortunate outcome may be reduced if the concepts and methods of modern biofilm microbiology can be inculcated into the development process for antibiofilm biomaterials. We will discuss some of the new agents that may give us effective control over the colonization of biomaterials and the incidence of device-related infections, and then we will discuss new methods for the release/delivery of these agents at the surfaces of biomaterials.

Testing for Antibacterial and Antibiofilm Properties of Biomaterials

There are serious concerns with the utility and information content of some of the methods used to assess the biofilm resistance of biomaterials. If a biomaterial gives a positive zone of inhibition test, what does it mean? It means that the biomaterial contained an antibacterial agent, which it released in the moist environment of the surface of an agar plate, and the agent killed the planktonic bacteria that had been deposited on this same surface to produce a “lawn.” The major parameter operative in the test is the diffusion of the antibacterial agent through the agar, or in the fluid on the agar surface, more than the effectiveness of the agent. A very effective agent would have a very small zone, if it moves slowly through agar, and a weak agent would have an enormous zone if it diffused well through agar, or if it diffused well through water and the plate was wet. The release kinetics of the agent from the biomaterial are those of a biomaterial on a moist agar surface, which is not a common use target for biomaterials. Flask tests, in which candidate biomaterials are suspended in a medium

that is simultaneously inoculated with planktonic bacteria, are equally naive. If the biomaterials release enough of an antibacterial agent in the first few minutes of the test, all of the planktonic cells will be killed, the medium will be sterile, and there will be no organisms to colonize the biomaterial. So an antibiotic-releasing biomaterial that “dumps” all of its antibacterial agents in a few minutes will emerge from this test with flying colors! If the bacteria used in these relatively crude tests are lab-adapted by repeated subculturing, and thus defective in both antibacterial resistance and adhesion to surfaces, the biomaterials will be seen as promising. Yet both these tests are inappropriate and tend to lead to biomaterials that fail in biofilm resistance in animal and clinical trials.

The most appropriate tests are ones that mimic the conditions in the systems in which the biomaterial is targeted for use. If the biomaterial will be subjected to flow, or even to fluid exchange, the test should include these parameters. If the biomaterial will be used in a body fluid, such as blood or urine, an accurate simulation of that fluid should be used in the test, and the bacteria supplying the challenge should be adapted to the fluid. Bacteria used to challenge the putative biomaterial should be “wild” strains, recently isolated from clinical sources, and the challenge should come from fast-growing exponential-phase cells supplied by a chemostat, and not from variable cells from a “batch” culture. All of these parameters are best delivered using a flow cell, fed by a chemostat, and one of the most popular designs for such a system is given in Stoodley *et al.* (2001a). The flow cell also allows direct observation of large areas of the surface of the biomaterial, especially if the flow cell is mounted on the stage of a confocal scanning laser microscope (CSLM), and surface colonization can be monitored continuously (Cook *et al.*, 2000). Because the confocal microscope can resolve bacteria on opaque surfaces, and because this microscope allows us to examine living hydrated preparations, we can actually see the first microbial cells that adhere to biomaterial surface (Fig. 2A). If the adherent cells survive, they will initiate biofilm formation, and the adherent cells will gradually form matrix-enclosed communities (Fig. 2B) within which the cells will be separated by 3–5 μm of slime-filled space. The formation of biofilms requires that the adherent cells must be alive, so the observation of structured biofilms (Fig. 2C) on a surface that makes antibacterial and antibiofilm claims could have unfortunate clinical consequences (Cook *et al.*, 2000).

The observation of cells on the surface of a biomaterial is not necessarily negative data, especially if the cells are not very numerous and have not formed biofilms, because some antibacterial agents kill “incoming” planktonic cells and the dead cells remain on the surface (Fig. 2D). Even though we prefer biomaterials whose active agents kill “incoming” bacteria and do not retain these dead cells on the surface, agents that kill and retain bacterial cells are of some interest. For this reason, one of several available live/dead probes to ascertain the viability of adherent bacterial cells on biomaterials can be used. All of these methods give “snapshot” data, in that they necessitate the termination of colonization and the removal of biomaterial from the test system, but they yield accurate and useful data. The BacLite Live/Dead probe (Cook *et al.*, 2000) distinguishes live cells on the basis of membrane integrity, and live cells stain green while dead cells stain red (Fig. 2B). Living cells can also

be distinguished from dead cells on the basis of their respiration using tetrazolium salts that produce an orange color when they are reduced by metabolically active organisms. In very practical terms, biomaterials set up in flow cells can be exposed to realistic flowing fluid containing active cells of a “wild” strain of potential pathogen, and the resultant colonization of its surface can be monitored by CSLM. When adherent bacterial cells are few and intermittent, live/dead data are not germane and the test can run for days without interruption. When the biomaterial becomes heavily colonized, by biofilm-forming bacteria that stain as living cells in the live/dead assay, the material is designated as having exceeded its period of colonization resistance. Because a layer of surviving cells provides

FIG. 2. These micrographs are confocal scanning laser microscope (CSLM) images of living unfixed biofilms formed on individual fibers of the clothlike material used to form the sewing cuffs of mechanical heart valves. (A–C) Images of biofilms formed when fibers of a silver-coated medical device were exposed to planktonic cells of *Staphylococcus epidermidis*, in a flow cell, as described in Cook *et al.* (2000). The biofilm seen in (A) was formed on the silver-coated fiber after 24 hours exposure, and special staining with the Live/Dead BacLite probe (B) showed that live cells (green) outnumbered dead cells (red) by a wide margin. When these same fibers were exposed to this planktonic challenge for 48 hours, as seen in (C), a mature biofilm had formed and individual bacterial cells were seen to be buried in large aggregates of matrix material. (D) Large numbers of dead cells (red) as seen in a Live/Dead stain of an effective antibacterial biomaterial that killed sessile cells of *S. epidermidis* as they attempted to colonize its surface. This putative biomaterial was, unfortunately, too toxic for clinical use.

FIG. 2.—continued

an optimum surface for further bacterial colonization, biomaterials that have exceeded their colonization-resistant period tend to accrete biofilms and fail very rapidly, as in the case of the materials seen in (Fig. 2A–C).

Although direct observations are obviously the “gold standard” in tests of the resistance of biomaterials to bacterial colonization, CSLM microscopes are complex and relatively expensive. Many groups, including the CBE, have struggled with the inherent difficulties of removing sessile biofilm bacteria from colonized surfaces, and of enumerating these cells by standard microbiological techniques. The technique usually used is called “scraping and plating,” and it involves breaking up the clumps of bacteria in the biofilm fragments and spreading these dispersed cells on the surface of an agar plate so that each cell gives rise to one colony when the plate is incubated. Many difficulties can contribute to the inaccuracy of this method, but all can be resolved or rationalized if all of the steps are monitored by microscopy. First, some cells may be left on the surface by the scraping method, which must be calibrated by microscopic examination of the scraped surface to see how many cells remain. Second, the scraped material must be homogenized or sonicated to break up clumps of bacteria in the scraped biofilm fragments to ensure that each living bacterium

gives rise to one colony on the agar plate. Sonication may kill some cells, so it is important to calibrate the sonication time for each type of biofilm, until microscopy shows that the resultant suspension is mostly single cells, and most of these cells are alive. Cells that have assumed the biofilm phenotype may not grow well on the surfaces of agar plates, when they have been removed from the sessile community and suspended in an unfamiliar milieu, so that “committed” biofilm cells may not grow well on plates. When scraping and plating are used without the calibrations discussed above, this method can yield data that are 4 log values lower than the bacterial numbers seen by direct microscopy. However, the scrape and plate method can yield accurate and consistent data when it is properly calibrated by microscopy, and the first biofilm method using this enumeration technique has now been accepted as ASTM Method E 2196-02.

Potential Agents for the Control of Microbial Colonization of Biomaterials

The continued search for biomaterials that resist microbial colonization by virtue of their inherent surface properties may still give us valuable information on minimizing adhesion, but we should use modern biofilm methods to conduct this research. The search may be somewhat quixotic, because the large sums of money spent to date have yielded only a handful of materials of questionable utility. Thus, candidate materials should be subjected to *sine qua non* testing in realistic systems early in their development cycles.

The strategy most commonly used in current antibacterial biomaterials is the incorporation of conventional antibiotics into the material, with the objective of killing incoming planktonic cells, before they can adhere and initiate biofilm formation. Although there are some successful applications of this basically sound approach, the problem lies in the typical release kinetics of such materials. Most of the agent is liberated in the first short time period, while the remainder is made available slowly and over a long period of time, thus exposing the bacteria to sublethal antibiotic concentrations that may stimulate the development of resistant strains. Antibiotics with very specific targets, such as penicillin (penicillin binding protein) and ciprofloxacin (DNA gyrase), may induce bacterial mutations that render the mutants dramatically more resistant to the agent in question. For this reason many biomaterial designers have chosen to use multitarget antimicrobial agents (e.g., chlorhexidine), because mutants are only marginally more resistant, but most of these nonspecific compounds are not approved for systemic use in humans.

This quandary of balancing efficacy against the danger of acquired bacterial resistance does not affect the large cohort of bacterial manipulation molecules that is currently moving briskly toward the biomaterials market. Some of these biofilm control molecules are specifically targeted on quorum-sensing mechanisms, such as RIP on the TRAP two-component system in gram-positives and the brominated furanones on the AHL systems of gram-negatives, but others are simply known to affect biofilm formation. It is now obvious that signal control of bacterial behavior is a subtle process, in which many factors

interact to control a network of activities, so we do not expect to find a simple ON/OFF switch that controls biofilm development. Nonetheless, we have found several signal blockers that inhibit biofilm formation and sharply reduce pathogenicity in animal models. The pivotal concept is that bacteria in contact with a biomaterial would be prevented from forming a biofilm on its surface, would be “locked” in the planktonic phenotype, and would be killed by host defenses (antibodies and activated leukocytes) and any antibiotics that might be present. Balaban *et al.* (2003b) have shown that the RIP analog of the RAP signal, which controls biofilm formation in all species of the *Staphylococcus* genus, prevents biofilm formation by these organisms on subcutaneous Dacron implants in rats. When specific antibiotics were administered to these test animals, while the challenging bacteria were locked in the planktonic phenotype, no live cells could be recovered from the biomaterial surfaces of the surrounding tissues. This approach to the control of device-related infections is rational and much more focused than conventional antibiotic therapy, and its proponents visualize a whole new series of species- and genus-specific agents that will control both biofilm formation and toxin production. Biofilm specialists take comfort from new observations that plants protect themselves from pathogenic biofilm colonization by the use of similar signals and signal blockers, and millions of years of coevolution have not produced resistant bacterial strains (Stoodley *et al.*, 2002).

Delivery of Biofilm Control Agents at Biomaterial Surfaces

The more candid among the surgeons who install medical devices have confided that some operations proceed perfectly, and the device slides into place rapidly and smoothly, while others take longer and “just don’t feel right.” It is these later cases that sometimes develop biofilms and device-related infections because the skin and environmental bacteria present near the biomaterial surfaces will have time to adhere and to initiate biofilm formation. Killing the planktonic bacteria before they have time to initiate biofilm formation is the objective of many programs in this area, and this can be accomplished by three general strategies:

1. Systemic antibiotic therapy that produces bactericidal concentrations in the body fluids in the operative field
2. Release of antibiotics and other bacterial manipulation molecules from the biomaterials to produce high and sustained concentrations of the agent in the immediate vicinity of the device
3. Irrigation and other techniques that deliver antibiotics to the biomaterial surface after the device is installed, before the operative wound is closed

Most surgeons use systemic antibiotic therapy in the perioperative time frame, and most also use this strategy in subsequent operations (including dental procedures) if a device has recently been installed and might not be fully epithelialized. The simplest manifestation of the antibiotic-releasing biomaterial strategy is a class of materials that can be “loaded,” like a sponge, by soaking them in a solution of the antibiotic in

question immediately before the device is installed. This tactic has backfired in many cases in which bacteria resistant to the antibiotic have started to grow in the fluids of the vessel in which the device is being soaked, have formed a biofilm on its surface, and have caused serious infections. We must be fastidious in the installation of medical devices, in that no preformed biofilms must ever be implanted, because preformed biofilms automatically give rise to biofilm infections (Ward *et al.*, 1992). It is equally important that the surfaces of biomaterials be absolutely clean, because any residue of dead biofilm or other organic accretion radically increases the colonization of that surface by planktonic bacteria and increases the chance of a biofilm infection. Also, some gram-negative bacterial cell-wall residues (endotoxin) can lead to inflammatory reactions.

The most commonly employed strategy in infection prevention is the impregnation of biomaterials with recognized antibacterial ions or molecules, with the intent of killing planktonic bacteria before they can colonize the material concerned. Whenever an ion or molecule is loaded into or onto a polymer, Fick's laws dictate that large amounts will be released in the early time frame, and that the release will taper off during the long period in which the concentration in this reservoir is being depleted (see Chapter 7.14). Many biomaterial designers have become adept at manipulating the initial concentration of the agent and the release rate, but we are always left with certain "spectra" of concentrations and polymer configurations that require choices of the "Hobson's" variety (that is, no real choice). If we put a large amount of ionic silver on a surface and release it quickly, we are flirting with silver toxicity. If we put a very stable form of silver on a surface and silver ions are released very slowly, bacteria will grow all over the silver coating (Fig. 2C) just as they colonize metallic copper (McLean *et al.*, 1993) if few copper ions are present. Westaim Biomedical, Inc., has introduced an exciting new silver coating for burn bandages that uses a galvanic combination of silver and copper and releases silver and copper ions at a steady rate that control bacterial colonization for a useful period of time. The galvanic potentials set up by these side-by-side "lakes" of copper and silver may also have an inhibitory effect on bacterial adhesion, biofilm formation, and the inherent resistance of biofilm bacteria to antibacterial agents.

Because many modern antibiotics are much less toxic than metal ions, the release patterns of these agents from biomaterials pose a different problem. We can obtain high and very effective concentrations of antibiotics, in the immediate vicinity of devices, for lengths of time that have already been found to be effective in certain clinical situations. These biomaterials are useful, but we cannot control the low-level release of the agent for months or years after this effective time frame. This produces a prolonged period in which the agent is present at a sublethal concentration, near the device and sometimes in the whole body, and raises the specter of the development of acquired antibiotic resistance in many potentially dangerous bacterial species. A new development at the University of Washington Engineered Biomaterials (UWEB) Engineering Research Center has addressed this problem. Biomaterials can be coated with a molecular "skin," a self-assembled surface layer, that completely contains molecules loaded into an

underlying plastic and can be temporarily deranged (by ultrasonic energy) to yield a controlled release of the molecule in question (Kwok *et al.*, 2001). This coating has been used to deliver insulin, in controlled pulses, and the UWEB and the CBE are currently adapting this ultrasonic-sensitive coating for the controlled release antibacterial agents (and bacterial manipulation agents) from implanted biomaterials. High concentrations of these agents could be released at the surfaces of medical devices, perioperatively or at any preliminary signs of device-related infection, and no further release would occur if the coating was not stimulated ultrasonically.

Many surgeons have expressed an interest in being able to sterilize a medical device *in situ*, after it has been installed and before the operative wound is closed. This strategy is rational, because the device is accessible, and any planktonic bacteria present in the operative field will initiate colonization of the surface of the device if they are not killed or manipulated to preclude biofilm formation. Irrigation with antibiotics is presently used, biofilm-inhibiting signals and signal blockers are being developed, and this *in situ* procedure may be the perfect opportunity for the use of ultrasonic energy and/or DC electric fields to enhance the killing of bacteria in nascent biofilms. We can readily contaminate sham animal operations with bacteria and determine the efficacy of several possible procedures for *in situ* sterilization by using the live/dead probe to examine the surfaces of devices recovered at intervals after the procedure. The final proof of the efficacy of the *in situ* sterilization of medical devices would be obtained in clinical tests, in which significant reductions in device-related infections could be documented.

SUMMARY

The concept that has been distilled from decades of clinical experience with device-related infections has now been fused with the biofilm concept, which states that bacteria live predominantly in matrix-enclosed protected communities. This fusion is reassuring, and intellectually satisfying, because it asserts that bacteria employ the same strategy for survival in the human body that they use in all other ecosystems. The mental image that is invoked is one in which a biofilm forms on the surface of a biomaterial, and that it has all of the properties of the sessile communities that predominate in industrial and environmental systems. Its cells express the distinct biofilm phenotype: They are resistant to antibacterial agents and to uptake by phagocytes, most of them grow slowly and adopt many different metabolic strategies, and they detach planktonic cells and biofilm fragments in a programmed manner. The clinical consequences of this mode of bacterial growth are that antibiotics are useful in treating acute planktonic exacerbations, but that these agents cannot clear the biofilm reservoir on the biomaterial, and the device must usually be removed to resolve the infection.

As we fuse the device-related infection concepts with biofilm concepts, we can discard several older methods that have been used to assess the efficacy of putative antibacterial biomaterials. New biofilm methods allow us to visualize bacteria on opaque surfaces, to determine the viability of these organisms, and even to identify the cells by genus and species. We realize that freshly

isolated “wild” bacteria adhere avidly to plastic and metal surfaces that have been “conditioned” by exposure to body fluids, and we are more sanguine about claims that biomaterials can resist colonization by virtue of their surface properties alone. New technologies that deliver antibiotics in controlled and effective doses, at the surfaces of novel biomaterials, offer a solution to the problem of bacterial resistance induced by sublethal concentrations of these agents from “exhausted” biomaterials. The discovery that cells in biofilms communicate with each other by means of chemical signals brings to the medical biomaterials area a whole set of new molecules that can manipulate bacterial behaviors, such as toxin production and biofilm formation. These bacterial manipulation agents, many of which control biofilms in natural environments, have already been shown to “lock” targeted bacteria in the planktonic phenotype and to make them susceptible to conventional antibiotics and host defense factors. Physical treatments (e.g., ultrasonic radiation and DC electric fields) that make biofilm cells susceptible to antibacterial agents are also made available for use in medical systems, because of the fusion of the biofilm field with the study of device-related infections. This synthesis of concepts may accelerate the development of biomaterials that truly resist bacterial colonization, and these materials may allow us to build medical devices that will be substantially less susceptible to device-related infections.

5.1 INTRODUCTION TO TESTING BIOMATERIALS

Buddy D. Ratner

How can biomaterials be evaluated to determine if they are biocompatible and will function in a biologically appropriate manner in the *in vivo* environment? Meaningful testing procedures are overviewed in the five chapters in this section. Chapter 9.4 offers further insights in correlating physical measurements with biological performance. This introduction is an aid in coalescing themes that are common to all biomaterials biological testing.

Evaluation under *in vitro* (literally “in glass”) conditions can provide rapid and inexpensive data on biological interaction (Chapter 5.2). However, the question must always be raised—will the *in vitro* test measure parameters relevant to what will occur in the much more complex *in vivo* environment? For example, tissue culture polystyrene, a surface modified polymer, will readily attach and grow most cells in culture. Untreated polystyrene will neither attach nor grow mammalian cells. Yet when implanted *in vivo*, both materials heal almost indistinguishably with a thin foreign body capsule. Thus, the results of the *in vitro* test do not provide information relevant to the implant situation. *In vitro* tests minimize the use of animals in research, a desirable goal. Also, *in vitro* testing is required by most regulatory agencies in the device approval process for clinical application. When appropriately used, *in vitro* testing provides useful insights that can dictate whether a device need be further evaluated in expensive *in vivo* experimental models.

Animals are used for testing biomaterials to model the environment that might be encountered in humans (Chapter 5.3). However, there is great range in animal anatomy, physiology, and biochemistry. Will the animal model provide data useful for predicting how a device performs in humans? Without validation to human clinical studies, it is often difficult to draw strong conclusions from performance in animals. The first step in designing animal testing procedures is to choose an animal model that offers a reasonable parallel anatomically or biochemically to the situation in humans. Experiments designed to minimize the number of animals needed, ensure that the

animals are treated humanely (e.g., NIH guidelines for the use of laboratory animals), and maximize the relevant information generated by the testing procedure are essential.

Some biomaterials fulfill their intended function in seconds. Others are implanted for a lifetime (10 years? 70 years?). Are 6-month implantation times useful to learn about a device intended for 3-minute insertion? Will six months implantation in a test model provide adequate information to draw conclusions about the performance of a device intended for lifetime implantation? These are not easy questions. However, they must be addressed and carefully considered in designing a biomaterials testing protocol.

This is a textbook on biomaterials with the special focus being materials. There are obviously important differences between implanting a sheet of cellulose (a material) in an animal and evaluating the performance and biological response of the same sheet of cellulose used as a dialysis membrane in an artificial kidney. The pros and cons of material testing (a relatively low cost procedure providing opportunities for carefully controlled experiments) versus evaluation in a device configuration (an expensive and difficult to control, but completely relevant situation) must always be weighed.

Experimental variability in the testing data is expected, particularly in tests in living systems. The more complex the system (e.g., a human in contrast to cells in culture), the larger the variability that might be expected. In order to draw defensible conclusions from expensive testing protocols, statistical methods assist us in ensuring that the results are meaningful within some probability range. Statistics should be used at two stages in testing biomaterials. Before an experiment is performed, statistical experimental design will indicate the minimum number of samples that must be evaluated to yield meaningful results. After the experiment is completed, statistics will help to extract the maximum amount of useful information from experiments.

Assistance in the design of many biomaterials tests is available through national and international standards-organizations. Thus, the American Society for Testing Materials (ASTM) and the International Standards Organization (ISO) can often provide detailed protocols for widely accepted, carefully thought out testing procedures (Chapter 10.2). Other testing protocols are available through government agencies (e.g., the FDA) and through commercial testing laboratories.

5.2 *IN VITRO* ASSESSMENT OF TISSUE COMPATIBILITY

Sharon J. Northup

The term “cytotoxicity” means to cause toxic effects (death, alterations in cellular membrane permeability, enzymatic inhibition, etc.) at the cellular level. It is distinctly different from physical factors that affect cellular adhesion (surface charge of a material, hydrophobicity, hydrophilicity, etc.). This chapter reviews the evaluation of biomaterials by methods that use isolated, adherent cells in culture to measure cytotoxicity and biological compatibility.

HISTORICAL OVERVIEW

Cell culture methods have been used to evaluate the biological compatibility of materials for more than two decades (Northup, 1986). Most often today the cells used for culture are from established cell lines purchased from biological suppliers or cell banks (e.g., the American Type Culture Collection, Manassas, VA). Primary cells (with the exception of erythrocytes in hemolysis assays) are seldom used because they have less assay repeatability, reproducibility, efficiency, and, in some cases, availability. Several methods have been validated for repeatability (comparable data within a given laboratory) and reproducibility (comparable data among laboratories). These methods have been incorporated into national and international standards used in the commercial development of new products. In addition, there are a wide variety of methods in the research literature that have been used in specialized applications and that are on the leading edge of scientific development. These are not discussed in this chapter. As the science of biomaterials evolves, some of these research methods may become incorporated into routine products.

BACKGROUND CONCEPTS

Toxicity

A toxic material is defined as a material that releases a chemical in sufficient quantities to kill cells either directly or indirectly through inhibition of key metabolic pathways. The number of cells that are affected is an indication of the dose and potency of the chemical. Although a variety of factors affect the toxicity of a chemical (e.g., compound, temperature, test system), the most important is the dose or amount of chemical delivered to the individual cell.

Delivered and Exposure Doses

The concept of delivered dose refers to the dose that is actually absorbed by the cell. It differs from the concept of exposure dose, which is the amount applied to a test system. For example, if an animal is exposed to an atmosphere containing a noxious substance (exposure dose), only a small portion of

the inhaled substance will be absorbed and delivered to the internal organs and cells (delivered dose). Because different cells have differing susceptibilities to the toxic effects of xenobiotics (foreign substances), the cells that are most sensitive are referred to as the target cells. Taken together, these two concepts mean that cell culture methods evaluate target cell toxicity by using delivered doses of the test substance. This distinguishes cell culture methods from whole-animal studies, which evaluate the exposure dose and do not determine the target cell dose of the test substance. This difference in dosage at the cellular level accounts for a significant portion of the difference in sensitivity (i.e., quantitation range) of cell culture methods compared with whole animal toxicity data. To properly compare the sensitivity of cell culture methods with *in vivo* studies, data from local toxicity models such as dermal irritation, implantation, and direct tissue exposure should be compared. These models reduce the uncertainties of delivered dose associated with absorption, distribution, and metabolism that are inherent in systemic exposure test models.

Safety Factors

A highly sensitive test system is desirable for evaluating the potential hazards of biomaterials because the inherent characteristics of the materials often do not allow the dose to be exaggerated. There is a great deal of uncertainty in extrapolating from one test system to another, such as from animals to humans. To allow for this, toxicologists have used the concept of safety factors to take into account intra- and interspecies variation. This practice requires being able to exaggerate the anticipated human clinical dosage in the nonhuman test system. In a local toxicity model in animals, there is ample opportunity for reducing the target cell dose by distribution, diffusion, metabolism, and changes in the number of exposed cells (because of the inflammatory response). On the other hand, in cell culture models, in which the variables of metabolism, distribution, and absorption are minimized, the dosage per cell is maximized to produce a highly sensitive test system.

Solubility Characteristics

The principal components in medical devices are water-insoluble materials (polymers, metals, and ceramics), meaning that less than one part of the material is soluble in 10,000 parts of water. Other components may be incorporated into the final product to obtain the desired physical, functional, manufacturing, and sterility properties. For example, plastics may contain plasticizers, slip agents, antioxidants, fillers, mold release agents, or other additives, either as components of the formulation or trace additives from the manufacturing process. The soluble components may be differentially extracted from the insoluble material. Till *et al.* (1982) have shown that the migration of chemicals from a solid plastic material into liquid solvents is controlled by diffusional resistance within the solid, chemical concentration, time, temperature, mass transfer resistance on the solvent side, fluid turbulence at the solid-solvent interface, and the partition coefficient of the chemical in the solvent. Because of these variables, the conditions for preparing

extractions of biomaterials have been carefully standardized to improve the reproducibility of the data.

Complete dissolution of biomaterials is an alternative approach for *in vitro* testing. Its main limitation is that it does not simulate the intended clinical application or may create degradation products that do not occur in the clinical application. Therefore, the actual clinical dosage or agent exposed to the cells in pharmacokinetic terms may be exaggerated because the rate of diffusion from the intact material or device may be very slow or different than that for complete dissolution.

ASSAY METHODS

Three primary cell culture assays are used for evaluating biocompatibility: direct contact, agar diffusion, and elution (also known as extract dilution). These are morphological assays, meaning that the outcome is measured by observations of changes in the morphology of the cells. The three assays differ in the manner in which the test material is exposed to the cells. As indicated by the nomenclature, the test material may be placed directly on the cells or extracted in an appropriate solution that is subsequently placed on the cells. The choice of method varies with the characteristics of the test material, the rationale for doing the test, and the application of the data for evaluating biocompatibility.

To standardize the methods and compare the results of these assays, the variables of number of cells, growth phase of the cells (period of frequent cell replication), cell type, duration of exposure, test sample size (e.g., geometry, density, shape, thickness), and surface area of test sample must be carefully controlled. This is particularly true when the amount of toxic extractables is at the threshold of detection where, for example, a small increase in sample size could change the outcome from nontoxic to moderate or severe toxicity. Below the threshold of detection, differences in these variables are not observable. Within the quantitation range of these assays, varying slopes of the dose-response curve or exposure-effect relationship (Klaassen, 1986) will occur with different toxic agents in a manner similar to that in animal bioassays.

In general, cell lines that have been developed for growth *in vitro* are preferred to primary cells that are freshly harvested from live organisms because the cell lines improve the reproducibility of the assays and reduce the variability among laboratories. That is, a cell line is the *in vitro* counterpart of inbred animal strains used for *in vivo* studies. Cell lines maintain their genetic and morphological characteristics throughout a long (sometimes called infinite) life span. This provides comparative data with the same cell line for the establishment of a database. The L-929 mouse fibroblast cell has been used most extensively for testing biomaterials. Initially, L-929 cells were selected because they were easy to maintain in culture and produced results that had a high correlation with specific animal bioassays (Northup, 1986). In addition, the fibroblast was specifically chosen for these assays because it is one of the early cells to populate a healing wound and is often the major cell in the tissues that attach to implanted medical devices. Cell lines from other tissues or species may also be used. Selection of a cell line is based upon the type of assay, the investigator's

experience, measurement endpoints (viability, enzymatic activity, species specific receptors, etc.), and various other factors. It is not necessary to use human cell lines for this testing because, by definition, these cells have undergone some dedifferentiation and lost receptors and metabolic pathways in the process of becoming cell lines.

Positive and negative controls are often included in the assays to ensure the operation and suitability of the test system. The negative control of choice is a high-density polyethylene material. Certified samples may be obtained from the U.S. Pharmacopeial Convention, Inc., Rockville, MD. Several materials have been proposed as candidates for positive controls. These are low-molecular-weight organotin-stabilized poly(vinyl chloride), gum rubber, and dilute solutions of toxic chemicals, such as phenol and benzalkonium chloride. All of the positive controls are commercially available except for the organotin-stabilized poly(vinyl chloride).

The methodologies for the three primary cell culture assays are described in the U.S. Pharmacopeia, and in standards published by the American Society for Testing and Materials (ASTM), the British Standards Institute (BSI), and the International Standards Organization (ISO). There are minor variations in the methods among these sources because of the evolving changes in methodology, the time when the standards were developed, and the individual experiences of those participating in standards development. Pharmacopeial assays are legally required by the respective ministries of health in the United States (Food and Drug Administration), Europe, Japan, Australia, and other countries. It is expected that the ISO methods will replace the individual national regulations in Europe, whereas the ASTM and BSI standards are voluntary, consensus standards. The basic methodologies, as described in the U.S. Pharmacopeia (2004), are described in the following paragraph.

Direct Contact Test

A near-confluent monolayer of L-929 mammalian fibroblast cells is prepared in a 35-mm-diameter cell culture plate. The culture medium is removed and replaced with 0.8 ml of fresh culture medium. Specimens of negative or positive controls and the test article are carefully placed in individually prepared cultures and incubated for 24 hr at $37 \pm 1^\circ\text{C}$ in a humidified incubator. The culture medium and specimens are removed and the cells are fixed and stained with a cytochemical stain such as hematoxylin blue. Dead cells lose their adherence to the culture plate and are lost during the fixation process. Live cells adhere to the culture plate and are stained by the cytochemical stain. Toxicity is evaluated by the absence of stained cells under and around the periphery of the specimen.

At the interface between the living and dead cells, microscopic evaluation will show an intermediate zone of damaged cells. The latter will have a morphological appearance that is abnormal. The change from normalcy will vary with the toxicant and may be evidenced as increased vacuolization, rounding due to decreased adherence to the culture plate, crenation, swelling, etc. For example, dying cells may round up and detach from the culture plate before they disintegrate. Crenation and swelling are often related to osmotic or oncotic

pressures. Vacuolization frequently occurs with basic substances and is due to lysosomal uptake of the toxicant and fluids. This interface area should be included in determining the toxicity rating.

Agar Diffusion Test

A near-confluent monolayer of L-929 is prepared in a 60-mm-diameter plate. The culture medium is removed and replaced with a culture medium containing 2% agar. After the agar has solidified, specimens of negative and positive controls and the test article are placed on the surface of the same prepared plate and the cultures incubated for at least 24 hours at $37 \pm 1^\circ\text{C}$ in a humidified incubator. This assay often includes neutral red vital stain in the agar mixture, which allows ready visualization of live cells. Vital stains, such as neutral red, are taken up and retained by healthy, viable cells. Dead or injured cells do not retain neutral red and remain colorless. Toxicity is evaluated by the loss of the vital stain under and around the periphery of the specimens. The interface area should be evaluated as described previously.

Selection of a proper agar for use in this assay continues to be a major problem. Agar is a generic name for a particular colloidal polymer derived from a red alga. There are many different grades of agar that are distinguished by their molecular weight and extent of cross-linking of the colloid. The mammalian tissue culture product called agar agar and agarose seem to work best. Agarose is a chemical derivative of agar that has a lower gelling temperature and is less likely to cause thermal shock. The thickness of the agar should be constant because the diffusion distance affects the cellular concentration of a toxicant. From a theoretical viewpoint, it could be expected that different chemicals will diffuse through the agar at different rates. This is true from a broad perspective, but because most toxicants are low molecular weight (less than 100 Da), the diffusion rate will not be sufficiently dissimilar within the 24-hour assay period.

Elution Test

An extract of the material is prepared by using (1) 0.9% sodium chloride or serum-free culture medium and a specified surface area of material per milliliter of extractant and (2) extraction conditions that are appropriate for the application and physical characteristics of the material. Alternatively, serum-containing culture media may be used with an extraction temperature of $37 \pm 1^\circ\text{C}$. The choice of extractant sets an upper limit on the quantitation range of the assay in that, without added nutrients, 0.9% sodium chloride will itself be toxic to the cells after a short incubation period. The extract is placed on a prepared, near-confluent monolayer of L-929 fibroblast cells and the toxicity is evaluated after 48 hours of incubation at $37 \pm 1^\circ\text{C}$ in a humidified incubator. Live or dead cells may be distinguished by the use of histochemical or vital stains as described earlier.

Interpretation of Results

Each assay is interpreted roughly on the basis of quartiles of affected cells. This corresponds to the customary

morphological and clinical rating scales of no, slight, moderate, and severe response grades. The terms used to describe these grades refer to the characteristics of the assays. In the direct-contact and agar-diffusion assays, one expects a concentration gradient of toxic chemicals, with the greatest amount appearing under the specimen and then diffusing outward in more or less concentric areas. Physical trauma from movement of the specimen in the direct-contact assay is evident by patches of missing cells interspersed with normal healthy cells. This is not a concern with the agar-diffusion assay because the agar cushions the cells from physical trauma. Interpretation of the elution test is based upon what happens to the total population of cells in the culture plate. That is, any toxic agent is evenly distributed in the culture plate and toxicity is evaluated on the basis of the percent of affected cells in the population. Generally, more experience in cell culture morphology is required to appropriately evaluate the elution test than is required for the other two techniques.

Table 1 lists the advantages and disadvantages of the three assays. The chief concern in each of the assays is the transfer or diffusion of some chemical(s) X from the test sample to the cells. This involves the total available amount of X in the material, the solubility limit of X in the solution phase, the equilibrium partitioning of X between the material surface and the solution, and the rate of migration of X through the bulk phase of the material to the material surface. If sufficient analytical data are available to verify that there is one and only one leachable chemical from a given material, then empirical toxicity testing *in vitro* or *in vivo* could be replaced with literature reviews and physiologically based pharmacokinetic modeling of hazard potential. Usually a mixture of chemicals migrate from materials and therefore, empirical testing of the biological effects of the mixture is necessary.

The direct-contact assay mimics the clinical use of a device in a fluid path, e.g., blood path, in which the material is placed directly in the culture medium and extraction occurs in the presence of serum-containing culture media at physiological temperatures. The presence of serum presumably aids in the solubilization of leachable substances through protein binding, the *in vivo* mechanism for transporting water-insoluble substances in the blood path. The direct contact assay may be used for testing samples with a specific geometry (for example $1 \times 1\text{-cm}^2$ squares using extruded sheeting or molded plaques of material) or with indeterminate geometries (molded parts). The major difficulty with this assay is the risk of physical trauma to the cells from either movement of the sample or crushing by the weight of a high-density sample. In most direct contact assays, there will be a zone of affected cells around the periphery of a toxic sample because of a slow leaching rate from the surface and bulk matrix of the material being tested. However, if the toxicant is water soluble, the rate of leaching may be sufficient to cause a decrease in the entire cell population in the culture plate rather than only those cells closest to the sample.

The disadvantages of the direct contact assay can be avoided by using the agar diffusion assay. The layer of agar between the test sample and the cells functions as a diffusion barrier to enhance the concentration gradient of leachable toxicants while also protecting the cells from physical trauma. The test sample itself may also be tested as a diffusion barrier to the migration of inks or labeling materials through the material

TABLE 1 Advantages and Disadvantages of Cell Culture Methods

	Direct contact	Agar diffusion	Elution
Advantages	Eliminate extraction preparation Zone of diffusion Target cell contact with material Mimic physiological conditions Standardize amount of test material or test indeterminate shapes Can extend exposure time by adding fresh media	Eliminate extraction preparation Zone of diffusion Better concentration gradient of toxicant Can test one side of a material Independent of material density Use filter paper disk to test liquids or extracts	Separate extraction from testing Dose response effect Extend exposure time Choice of extract conditions Choice of solvents
Disadvantages	Cellular trauma if material moves Cellular trauma with high density materials Decreased cell population with highly soluble toxicants	Requires flat surface Solubility of toxicant in agar Risk of thermal shock when preparing agar overlay Limited exposure time Risk of absorbing water from agar	Additional time and steps

matrix to the cellular side of the sample. Even contact between the test sample and the agar ensures diffusion from the material surface into the agar and cell layers. That is, diffusion at the material–solution interface is much greater than that at the material–air interface. Absorbant test samples, which could remove water from the agar layer, causing dehydration of the cells below, should be hydrated prior to testing in this assay.

The elution assay separates the extraction and biological testing phases into two separate processes. This could exploit the extraction to the extent of releasing the total available pool of chemical X from the material, especially if the extraction is done at elevated temperatures that presumably enhance the rate of migration and solubility limit of chemical X in a given solvent. However, when the extractant cools to room temperature, chemical X may precipitate out of solution or partition to the material surface. In addition, elevated extraction temperatures may foster chemical reactions and create leachable chemicals that would not occur in the absence of excessive heating. For example, the polymeric backbone of polyamides and polyurethanes may be hydrolyzed when these polymers are heated in aqueous solutions. Basically, these arguments lead back to a standardized choice of solvents and extraction conditions for all samples rather than optimized solvents for each material.

As with any biological or chemical assay, these assays occasionally are affected by interferences, false negatives, and false positives. For example, a fixative chemical such as formaldehyde or glutaraldehyde will give a false negative in the direct contact but not the agar diffusion assay, which uses a vital stain. A highly absorbent material could give a false positive in the agar diffusion assay because of dehydration of the agar. Severe changes in onconicity, osmolarity, or pH can also interfere with the assays. Likewise, a chelating agent that makes an essential element such as calcium unavailable to the cells could appear as a false positive result. Thus, a judicious evaluation of the test material and assay conditions is required for an appropriate interpretation of the results.

CLINICAL USE

The *in vitro* cytotoxicity assays are the primary biocompatibility screening tests for a wide variety of elastomeric, polymeric, and other materials used in medical devices. After the cytotoxicity profile of a material has been determined, then more application-specific tests are performed to assess the biocompatibility of the material. For example, a product which will be used for *in vitro* fertilization procedures would be tested initially for cytotoxicity and then application-specific tests for adverse effects on a very low cell population density would be evaluated. Similarly, a new material for use in culturing cells would be initially tested for cytotoxicity, followed by specific assays comparing the growth rates of cells in contact with the new material with those of currently marketed materials.

Current experience indicates that a material that is judged to be nontoxic *in vitro* will be nontoxic in *in vivo* assays. This does not necessarily mean that materials that are toxic *in vitro* could not be used in a given clinical application. The clinical acceptability of a material depends on many different factors, of which target cell toxicity is but one. For example, glutaraldehyde-fixed porcine valves produce adverse effects *in vitro* owing to low residues of glutaraldehyde; however, this material has the greatest clinical efficacy for its unique application.

In vitro assays are often criticized because they do not use cells with significant metabolic activity such as the P-450 drug-metabolizing enzymes. That is, the assays can only evaluate the innate toxicity of a chemical and do not test metabolic products that may have greater or lesser toxicity potential. In reality, biological effects of the actual leachable chemicals are the most relevant clinically because most medical devices are in contact with tissues having very low metabolic activity (e.g., skin, muscle, subcutaneous or epithelial tissues) or none. Metabolic products do not form at the implantation site, but rather, require transport of the leachable chemical to distant

tissues which are metabolically active. In the process, there is significant dilution of concentration in the blood, tissues, and total body water to the extent that the concentration falls below the threshold of biological activity.

NEW RESEARCH DIRECTIONS

The current interest in developing alternatives to animal testing has resulted in the development and refinement of a wide variety of *in vitro* assays. Cell cultures have been used for several decades for screening anticancer drugs and evaluating genotoxicity (irreversible interaction with the nucleic acids). Babich and Borenfreund (1987) have modified the elution assay for use with microtiter plates to evaluate the dose-response cytotoxicity potential of alcohols, phenolic derivatives, and chlorinated toluenes. This system has also been modified to include a microsomal (S-9) activating system to permit drug metabolism *in vitro* when evaluating pure chemicals such as chemotherapeutic and bacteriostatic agents (Borenfreund and Puerner, 1987). The microtiter methods are likely to have increased application because they provide reproducible, semiautomatic, quantitative, spectrophotometric analyses. The major hurdle will be in identifying the appropriate benchmark or quantitation range for interpreting the data for clinical risk assessment. In earlier quantitative methods for *in vitro* biocompatibility assays, statistical differences in biocompatibility, which are attainable with quantitative assays, were not found to be biologically different (Johnson *et al.*, 1985). That is, the objective data were biologically different only when they were separated into quartiles of response similar to the subjective data. Thus, the major direction of new research will be in defining the benchmarks for application of quantitative methodology.

5.3 IN VIVO ASSESSMENT OF TISSUE COMPATIBILITY

James M. Anderson and Frederick J. Schoen

INTRODUCTION

The goal of *in vivo* assessment of tissue compatibility of a biomaterial, prosthesis, or medical device is to determine the biocompatibility or safety of the biomaterial, prosthesis, or medical device in a biological environment. Biocompatibility has been defined as the ability of a medical device to perform with an appropriate host response in a specific application, and biocompatibility assessment is considered to be a measurement of the magnitude and duration of the adverse alterations in homeostatic mechanisms that determine the host response. In this chapter, the term “medical device” will be used to describe biomaterials, prostheses, artificial organs, and other medical devices, and the terms “tissue compatibility assessment,” “biocompatibility assessment,” and “safety assessment” will be considered to be synonymous.

From a practical perspective, the *in vivo* assessment of tissue compatibility of medical devices is carried out to determine that the device performs as intended and presents no significant harm to the patient or user. Thus, the goal of the *in vivo* assessment of tissue compatibility is to predict whether a medical device presents potential harm to the patient or user by evaluations under conditions simulating clinical use.

Recently, extensive efforts have been made by government agencies, i.e., FDA, and regulatory bodies, i.e., ASTM, ISO, and USP, to provide procedures, protocols, guidelines, and standards that may be used in the *in vivo* assessment of the tissue compatibility of medical devices. This chapter draws heavily on the ISO 10993 standard, Biological Evaluation of Medical Devices, in presenting a systematic approach to the *in vivo* assessment of tissue compatibility of medical devices.

In the selection of biomaterials to be used in device design and manufacture, the first consideration should be fitness for purpose with regard to characteristics and properties of the biomaterial(s). These include chemical, toxicological, physical, electrical, morphological, and mechanical properties. Relevant to the overall *in vivo* assessment of tissue compatibility of a biomaterial or device is knowledge of the chemical composition of the materials, including the conditions of tissue exposure as well as the nature, degree, frequency, and duration of exposure of the device and its constituents to the intended tissues

in which it will be utilized. Table 1 presents a list of biomaterial components and characteristics that may affect the overall biological responses of the medical device. Knowledge of these components in the medical device, i.e., final product, is necessary. The range of potential biological hazards is broad and may include short-term effects, long-term effects, or specific toxic effects, which should be considered for every material and medical device. However, this does not imply that testing for all potential hazards will be necessary or practical.

SELECTION OF *IN VIVO* TESTS ACCORDING TO INTENDED USE

In vivo tests for assessment of tissue compatibility are chosen to simulate end-use applications. To facilitate the selection of appropriate tests, medical devices with their component biomaterials can be categorized by the nature of body contact of the medical device and by the duration of contact of the medical device. Table 2 presents medical device categorization by body contact and contact duration. The tissue contact categories and subcategories as well as the contact duration categories have been derived from standards, protocols and guidelines utilized in the past for safety evaluation of medical devices. Certain devices may fall into more than one category, in which case testing appropriate to each category should be considered.

The ISO 10993 standard and the FDA guidance document (FDA blue book memorandum #G95-1) present a structured program for biocompatibility evaluation in which matrices are presented which indicate required tests according to specific types of tissue contact and contact duration. These matrices are not presented here but the *in vivo* tests are indicated in Table 3.

BIOMATERIAL AND DEVICE PERSPECTIVES IN *IN VIVO* TESTING

Two perspectives may be considered in the *in vivo* assessment of tissue compatibility of biomaterials and medical devices. The first perspective involves the utilization of *in vivo* tests to determine the general biocompatibility of newly developed biomaterials for which some knowledge of the tissue compatibility is necessary for further research and development. In this type of situation, manufacturing and other processes necessary to the development of a final product, i.e., the medical

device, have not been carried out. However, the *in vivo* assessment of tissue compatibility at this early stage of development can be used to evaluate the general tissue responses to the biomaterial as well as provide additional information relating to the proposed design criteria in the production of a medical device. While it is generally recommended that the identification and quantification of extractable chemical entities of a medical device should precede biological evaluation, it is quite common to carry out preliminary *in vivo* assessments to determine if there may be unknown chemical entities that produce adverse biological reactions. Utilized in this fashion, early *in vivo* assessment of the tissue compatibility of a biomaterial may provide insight into the biocompatibility of a material and may permit its further development into a medical device. Obviously, problems observed at this stage of development would require further efforts to improve the biocompatibility of the biomaterial and identify the agents responsible for the adverse reactions. As the *in vivo* assessment of tissue compatibility of a biomaterial or medical device is focused on the end-use application, it must be appreciated that a biomaterial considered compatible for one application may not be compatible for another application.

The second perspective regarding the *in vivo* assessment of tissue compatibility of medical devices focuses on the biocompatibility of the final product, that is, the medical device in

the condition in which it is to be implanted. Although medical devices in their final form and condition are commonly implanted in carefully selected animal models to determine function as well as biocompatibility, it may be not appropriate to carry out all of the recommended tests necessary for regulatory approval on the final device. In these situations, some tests may be carried out on biomaterial components of devices that have been prepared under the manufacturing and sterilization conditions and other processes utilized in the final product.

SPECIFIC BIOLOGICAL PROPERTIES ASSESSED BY IN VIVO TESTS

In this section, brief perspectives on the general types of *in vivo* tests are presented. Details regarding these tests are found in the references. ISO 10993 standards advise that the biological evaluation of all medical device materials include testing for cytotoxicity, sensitization, and irritation. (Cytotoxicity tests are *in vitro*.) Beyond these fundamentals, the selection of further tests for *in vivo* biocompatibility assessment is based on the characteristics and end-use application of the device or biomaterial under consideration.

Sensitization, Irritation, and Intracutaneous (Intradermal) Reactivity

Exposure to or contact with even minute amounts of potential leachables from medical devices or biomaterials can result in allergic or sensitization reactions. Sensitization tests estimate the potential for contact sensitization to medical devices, materials, and/or their extracts. Symptoms of sensitization are often seen in skin and tests are often carried out topically in guinea pigs. Test design should reflect the intended route (skin, eye, mucosa) and nature, degree, frequency, duration, and conditions of exposure of the biomaterial in its intended clinical use. While sensitization reactions are immune-system responses to contact with chemical substances, ISO guidelines suggest irritation to be a local tissue inflammation response to chemicals, without a systemic immunological component. The most severely irritating chemical leachables may be discovered prior to *in vivo* studies by careful material characterization and *in vitro* cytotoxicity tests. Irritant tests emphasize utilization of extracts of the biomaterials to determine the irritant effects of potential leachables. Intracutaneous (intradermal) reactivity tests determine the localized reaction of tissue to intracutaneous injection of extracts of medical devices, biomaterials, or prostheses in the final product form. Intracutaneous tests may be applicable where determination of irritation by dermal or mucosal tests are not appropriate. Albino rabbits are most commonly used.

Since these tests focus on determining the biological response of leachable constituents of biomaterials, their extracts in various solvents are utilized to prepare the injection solutions. Critical to the conduct of these tests is the preparation of the test material and/or extract solution and the choice of solvents which must have physiological relevance. Solvents

should be chosen to include testing for both water-soluble and fat-soluble leachables.

Systemic Toxicity Acute, Subacute, and Subchronic Toxicity

Systemic toxicity tests estimate the potential harmful effects *in vivo* on target tissues and organs away from the point of contact with either single or multiple exposure to medical devices, biomaterials, and/or their extracts. These tests evaluate the systemic toxicity potential of medical devices that release constituents into the body. These tests also include pyrogenicity testing, which assesses the induction of a systemic inflammatory response often measured as fever.

In tests using extracts, the form and area of the material, the thickness, and the surface area to extraction vehicle volume are critical considerations in the testing protocol. Appropriate extraction vehicles, i.e., solvents, should be chosen to yield a maximum extraction of leachable materials for use in the testing. Mice, rats, or rabbits are the usual animals of choice for the conduct of these tests and oral, dermal, inhalation, intravenous, intraperitoneal, or subcutaneous application of the test substance may be used, depending on the intended application of the biomaterial. Acute toxicity is considered to be the adverse effects that occur after administration of a single dose or multiple doses of a test sample given within 24 hours. Subacute toxicity (repeat-dose toxicity) focuses on adverse effects occurring after administration of a single dose or multiple doses of a test sample per day during a period of from 14 to 28 days. Subchronic toxicity is considered to be the adverse effects occurring after administration of a single dose or multiple doses of a test sample per day given during a part of the life span, usually 90 days but not exceeding 10% of the life span of the animal.

Pyrogenicity tests are also included in the systemic toxicity category to detect material-mediated fever-causing reactions to extracts of medical devices or materials. Although the rabbit pyrogen test has been the standard, the *Limulus* amoebocyte lysate (LAL) reagent test has been used increasingly in recent years. It is noteworthy that no single test can differentiate pyrogenic reactions that are material-mediated from those due to endotoxin contamination.

Genotoxicity

In vivo genotoxicity tests are carried out if indicated by the chemistry and/or composition of the biomaterial (see Table 1) or if *in vitro* test results indicate potential genotoxicity [changes in deoxyribonucleic acid (DNA)]. Initially, at least three *in vitro* assays should be used and two of these assays should utilize mammalian cells. The initial *in vitro* assays should cover the three levels of genotoxic effects: DNA destruction, gene mutations, and chromosomal aberrations (as assessed by cytogenetic analysis). *In vivo* genotoxicity tests include the micronucleus test, the *in vivo* mammalian bone marrow cytogenetic tests—chromosomal analysis, the rodent dominant lethal tests, the mammalian germ cell cytogenetic assay, the mouse spot test, and the mouse heritable translocation assay. Not all of the *in vivo* genotoxicity tests need be performed and the

most common test is the rodent micronucleus test. Genotoxicity tests are performed with appropriate extracts or dissolved materials using appropriate media as suggested by the known composition of the biomaterial.

Implantation

Implantation tests assess the local pathological effects on the structure and function of living tissue induced by a sample of a material or final product at the site where it is surgically implanted or placed into an implant site or tissue appropriate to the intended application of the biomaterial or medical device. The most basic evaluation of the local pathological effects is carried out at both the gross level and the microscopic level. Histological (microscopic) evaluation is used to characterize various biological response parameters (Table 4). To address specific questions, more sophisticated studies may need to be done. Examples include immunohistochemical staining of histological sections to determine the types of cells present, and studies of collagen formation and destruction. For short-term implantation evaluation out to 12 weeks, mice, rats, guinea pigs, or rabbits are the usual animals utilized in these studies. For longer-term testing in subcutaneous tissue, muscle, or bone, animals such as rats, guinea pigs, rabbits, dogs, sheep, goats, pigs, and other animals with relatively long life expectancy are suitable. If a complete medical device is to be evaluated, larger species may be utilized so that human-sized devices may be used in the site of intended application. For example, substitute heart valves are usually tested as heart valve replacements in sheep, whereas calves are usually the animal of choice for ventricular assist devices and total artificial hearts.

Hemocompatibility

Hemocompatibility tests evaluate effects on blood and/or blood components by blood-contacting medical devices or materials. *In vivo* hemocompatibility tests are usually designed to simulate the geometry, contact conditions, and flow dynamics of the device or material in its clinical application. From the ISO standards perspective, five test categories are indicated for hemocompatibility evaluation: thrombosis, coagulation, platelets, hematology, and immunology (complement and leukocytes). Two levels of evaluation are indicated: Level 1

TABLE 4 Biological Response Parameters as Determined by Histological Assessment of Implants

Number and distribution of inflammatory cells as a function of distance from the material/tissue interface
Thickness and vascularity of fibrous capsule
Quality and quantity of tissue ingrowth (for porous materials)
Degeneration as determined by changes in tissue morphology
Presence of necrosis
Other parameters such as material debris, fatty infiltration, granuloma, dystrophic, calcification, apoptosis, proliferation rate, biodegradation, thrombus formation, endothelialization, migration of biomaterials or degradation products

(required), and Level 2 (optional). Regardless of blood contact duration, hemocompatibility testing is indicated for external communicating devices—blood path indirect; external communicating devices—circulating blood; and blood-contacting implant devices. Chapter 5.4 gives further details on the testing of blood–material interactions.

Several issues are important in the selection of tests for hemocompatibility of medical devices or biomaterials. *In vivo* testing in animals may be convenient, but species' differences in blood reactivity must be considered and these may limit the predictability of any given test in the human clinical situation. While blood values and reactivity between humans and nonhuman primates are very similar, European community law prohibits the use of nonhuman primates for blood compatibility and medical device testing. Hemocompatibility evaluation in animals is complicated by the lack of appropriate and adequate test materials, for example, appropriate antibodies for immunoassays. Use of human blood in hemocompatibility evaluation implies *in vitro* testing, which usually requires the use of anticoagulants that are not usually present with the device in the clinical situation, except for perhaps the earliest implantation period. Although species differences may complicate hemocompatibility evaluation, the utilization of animals in short- and long-term testing is considered to be appropriate for evaluating thrombosis and tissue interaction.

Chronic Toxicity

Chronic toxicity tests determine the effects of either single or multiple exposures to medical devices, materials, and/or their extracts during a period of at least 10% of the lifespan of the test animal, e.g. over 90 days in rats. Chronic toxicity tests may be considered an extension of subchronic (subacute) toxicity testing and both may be evaluated in an appropriate experimental protocol or study.

Carcinogenicity

Carcinogenicity tests determine the tumorigenic potential of medical devices, materials, and/or their extracts from either single or multiple exposures or contacts over a period of the major portion of the lifespan of the test animal. Since tumors associated with medical devices have been rare (see Chapter 4.7) carcinogenicity tests should be conducted only if data from other sources suggest a tendency for tumor induction. In addition, both carcinogenicity (tumorigenicity) and chronic toxicity may be studied in a single experimental study. With biomaterials, these studies focus on the potential for solid-state carcinogenicity, i.e., the Oppenheimer effect (see Chapter 4.7). In carcinogenicity testing, controls of a comparable form and shape should be included; polyethylene implants are a commonly used control material. The use of appropriate controls is imperative as animals may spontaneously develop tumors and statistical comparison between the test biomaterial/device and the controls is necessary. To facilitate and reduce the time period for carcinogenicity testing of biomaterial, the FDA is exploring the use of transgenic mice carrying

the human prototype c-Ha-ras gene as a bioassay mode for rapid carcinogenicity testing.

Reproductive and Developmental Toxicity

These tests evaluate the potential effects of medical devices, materials, and/or their extracts on reproductive function, embryonic development (teratogenicity), and prenatal and early postnatal development. The application site of the device must be considered and tests and/or bioassays should only be conducted when the device has a potential impact on the reproductive potential of the subject.

Biodegradation

Biodegradation tests determine the effects of a biodegradable material and its biodegradation products on the tissue response. They focus on the amount of degradation during a given period of time (the kinetics of biodegradation), the nature of the degradation products, the origin of the degradation products (e.g., impurities, additives, corrosion products, bulk polymer), and the qualitative and quantitative assessment of degradation products and leachables in adjacent tissues and in distant organs. The biodegradation of biomaterials may occur through a wide variety of mechanisms, which in part are biomaterial dependent, and all pertinent mechanisms related to the device and the end-use application of the device must be considered. Test materials comparable to degradation products may be prepared and studied to determine the biological response of degradation products anticipated in long-term implants. An example of this approach is the study of metallic and polymeric wear particles that may be present with long-term orthopedic joint prostheses. Further insights on biodegradation are available in Chapters 6.2 and 6.3.

Immune Responses

Immune response evaluation is not a component of the standards currently available for *in vivo* tissue compatibility assessment. However, ASTM, ISO, and the FDA currently have working groups developing guidance documents for immune response evaluation where pertinent. Synthetic materials are not generally immunotoxic. However, immune response evaluation is necessary with modified natural tissue implants such as collagen, which has been utilized in a number of different types of implants and may elicit immunological responses. The Center for Devices and Radiological Health of the FDA has released a draft immunotoxicity testing guidance document whose purpose is to provide a systematic approach for evaluating potential adverse immunological effects of medical devices and constituent materials. Immunotoxicity is any adverse effect on the function or structure of the immune system or other systems as a result of an immune system dysfunction. Adverse or immunotoxic effects occur when humoral or cellular immunity needed by the host to defend itself against infections or neoplastic disease (immunosuppression) or unnecessary tissue damage (chronic inflammation, hypersensitivity, or autoimmunity) is compromised. Potential immunological effects and responses

TABLE 5 Potential Immunological Effects and Responses

Effects
Hypersensitivity
Type I—anaphylactic
Type II—cytotoxic
Type III—immune complex
Type IV—cell-mediated (delayed)
Chronic inflammation
Immunosuppression
Immunostimulation
Autoimmunity
Responses
Histopathological changes
Humoral responses
Host resistance
Clinical symptoms
Cellular responses
T cells
Natural killer cells
Macrophages
Granulocytes

that may be associated with one or more of these effects are presented in Table 5.

Representative tests for the evaluation of immune responses are given in Table 6. Table 6 is not all-inclusive and other tests that specifically consider possible immunotoxic effects potentially generated by a given device or its components may be applicable. Examples presented in Table 6 are only representative of the large number of tests that are currently available. However, direct and indirect markers of immune responses may be validated and their predictive value documented, thus providing new tests for immunotoxicity in the future. Direct measures of immune system activity by functional assays are the most important types of tests for immunotoxicity. Functional assays are generally more important than tests for soluble mediators, which are more important than phenotyping. Signs of illness may be important in *in vivo* experiments but symptoms may also have a significant role in studies of immune function in clinical trials and postmarket studies.

SELECTION OF ANIMAL MODELS FOR *IN VIVO* TESTS

Animal models are used to predict the clinical behavior, safety, and biocompatibility of medical devices in humans (Table 7). The selection of animal models for the *in vivo* assessment of tissue compatibility must consider the advantages and disadvantages of the animal model for human clinical application. Several examples follow, which exemplify the advantages and disadvantages of animal models in predicting clinical behavior in humans (also see Chapter 5.5).

As described earlier, sheep are commonly used for the evaluation of heart valves. This is based on size considerations and also the propensity to calcify tissue components of bioprosthetic heart valves and thereby be a sensitive model for this complication. Thus, the choice of this animal model for bioprosthetic heart valve evaluation is made on the basis of

TABLE 6 Representative Tests for the Evaluation of Immune Responses

Functional Assays	Phenotyping	Soluble Mediators	Signs of Illness
Skin testing	Cell surface markers	Antibodies	Allergy
Immunoassays (e.g., ELISA)	MHC markers	Complement	Skin rash
Lymphocyte proliferation		Immune complexes	Urticaria
Plaque-forming cells		Cytokine patterns (T-cell subsets)	Edema
Local lymph node assay		Cytokines (IL-1, IL-1ra, TNF α , IL-6, TGF- β , IL-4, IL-13)	Lymphadenopathy
Mixed lymphocyte reaction		Chemokines	
Tumor cytotoxicity		Basoactive amines	
Antigen presentation			
Phagocytosis			

ELISA, Enzyme-linked immunosorbent assay; IL, Interleukin; TNF, Tumor necrosis factor; TGF, Transforming growth factor; MHC, Major histocompatibility complex.

TABLE 7 Animal Models for the *In Vivo* Assessment of Medical Devices

Device Classification	Animal
Cardiovascular	
Heart valves	Sheep
Vascular grafts	Dog, pig
Stents	Pig, dog
Ventricular assist devices	Calf
Artificial hearts	Calf
<i>Ex-vivo</i> shunts	Baboon, dog
Orthopedic/bone	
Bone regeneration/substitutes	Rabbit, dog, pig, mouse, rat
Total joints—hips, knees	Dog, goat, nonhuman primate
Vertebral implants	Sheep, goat, baboon
Craniofacial implants	Rabbit, pig, dog, nonhuman primate
Cartilage	Rabbit, dog
Tendon and ligament substitutes	Dog, sheep
Neurological	
Peripheral nerve regeneration	Rat, cat, nonhuman primate
Electrical stimulation	Rat, cat, nonhuman primate
Ophthalmological	
Contact lens	Rabbit
Intraocular lens	Rabbit, monkey

accelerated calcification in rapidly growing animals, which has its clinical correlation in young and adolescent humans. Nevertheless, normal sheep may not provide a sensitive assessment of the propensity of a valve to thrombosis, which may be potentiated by the reduced flow seen in abnormal subjects but diminished by the specific coagulation profile of sheep.

The *in vivo* assessment of tissue responses to vascular graft materials is an example in which animal models present a particularly misleading picture of what generally occurs in humans. Virtually all animal models, including nonhuman primates, heal rapidly and completely with an endothelial blood-contacting surface. Humans, on the other hand, do not show extensive endothelialization of vascular graft materials and the resultant pseudointima from the healing response in humans

has potential thrombogenicity. Consequently, despite favorable results in animals, small-diameter vascular grafts (less than 4 mm in internal diameter) yield early thrombosis in humans, the major mechanism of failure, which is secondary to the lack of endothelialization in the luminal surface healing response.

The use of appropriate animal models is an important consideration in the safety evaluation of medical devices that may contain potential immunoreactive materials. The *in vivo* evaluation of recombinant human growth hormone in poly(lactic-co-glycolic acid)(PLGA) microspheres demonstrates the appropriate use of various animal models to evaluate biological responses and the potential for immunotoxicity. Utilizing biodegradable PLGA microspheres containing recombinant human growth hormone (rhGH), Cleland *et al.* used Rhesus monkeys, transgenic mice expressing hGH, and normal control (Balb/C) mice in their *in vivo* evaluation studies. Rhesus monkeys were utilized for serum assays in the pharmacokinetic studies of rhGH release as well as tissue responses to the injected microcapsule formulation. Placebo injection sites were also utilized and a comparison of the injection sites from rhGH PLGA microspheres and placebo PLGA microspheres demonstrated a normal inflammatory and wound-healing response with a normal focal foreign-body reaction. To further examine the tissue response, transgenic mice were utilized to assess the immunogenicity of the rhGH PLGA formulation. Transgenic mice expressing a heterologous protein have been previously used for assessing the immunogenicity of structural mutant proteins. With the transgenic animals, no detectable antibody response to rhGH was found. In contrast, the Balb/C control mice had a rapid onset of high-titer antibody response to the rhGH PLGA formulation. This study points out the appropriate utilization of animal models to not only evaluate biological responses but also one type of immunotoxicity (immunogenicity).

FUTURE PERSPECTIVES ON *IN VIVO* MEDICAL DEVICE TESTING

As presented earlier in this chapter, the *in vivo* assessment of tissue compatibility of biomaterials and medical devices is

dependent on the end-use application of the biomaterial or medical device. In this sense, the development and utilization of new biomaterials and medical devices will dictate the development of new test protocols and procedures for evaluating these new products. Furthermore, it must be understood that the *in vivo* assessment of tissue compatibility of biomaterials and medical devices is open-ended and new end-use applications will require new tests.

Over the past half-century, medical devices and biomaterials have generally been “passive” in their tissue interactions. That is, a mechanistic approach to biomaterials/tissue interactions has rarely been used in the development of biomaterials or medical devices. Heparinized biomaterials are an exception to this statement but considering the five subcategories of hemocompatibility, these approaches have minimal impact on the development of blood-compatible materials.

In the past decade, increased emphasis has been placed on bioactivity and tissue engineering in the development of biomaterials and medical devices for potential clinical application. Rather than a “passive” approach to tissue interactions, bioactive and tissue-engineered devices have focused on an “active” approach in which biological or tissue components, i.e., growth factors, cytokines, drugs, enzymes, proteins, extracellular matrix components, and cells that may or may not be genetically modified, are used in combinations with synthetic, i.e., passive, materials to produce devices that control or modulate a desired tissue response. Obviously, *in vivo* assessment of the targeted biological response of a tissue-engineered device will play a significant role in the research and development of that device as well as in its the safety assessment. It is clear that scientists working on the development of tissue-engineered devices will contribute significantly to the development of *in vivo* tests for biocompatibility assessment as these tests will also be utilized to study the targeted biological responses in the research phase of the device development.

Regarding tissue-engineered devices, it must be appreciated that biological components may induce varied effects upon tissue in the *in vivo* setting. For example, a simplistic view of the potentially complex problems that might result from a device releasing a growth factor to enhance cell proliferation is presented. Cell types in the implant site may react differently to the presence of an extrinsic growth factor. Autocrine, paracrine, and endocrine signaling may be different between the same cell types and different cell types in the implant site. Signal transduction systems may be variable depending on the different cells that are present within the implant site. The presence of a growth factor may result in markedly different cell proliferation, differentiation, protein synthesis, attachment, migration, shape change, etc., which would be cell type dependent. Thus, different cell type-dependent responses in an implant site, reacting to the presence of a single exogenous growth factor, may result in inappropriate, inadequate, or adverse tissue responses. These perspectives must be integrated into the planned program for *in vivo* assessment of tissue compatibility of tissue-engineered devices. Finally, a major challenge to the *in vivo* assessment of tissue compatibility of tissue-engineered devices is the use of animal tissue components in the early phase of device development, whereas the ultimate goal is the utilization of human tissue components in the final device

for end-use application. Novel and innovative approaches to the *in vivo* tissue compatibility of tissue-engineered devices must be developed to address these significant issues. Importantly, the development of clinically useful tissue-engineered devices will require enhanced understanding of the influence of the patient and biomechanical factors on the structure and function of healed and remodeled tissues. It will also require methodology that permits assessment of the dynamic progression of remodeling *in vivo*, perhaps through imaging of cellular gene expression and extracellular matrix remodeling noninvasively (Rabkin and Schoen, 2002). Careful studies of retrieved implants to establish biomarkers and mechanisms of structural evolution will be critical (see Chapter 9.5).

5.4 EVALUATION OF BLOOD–MATERIALS INTERACTIONS

Stephen R. Hanson and Buddy D. Ratner

Every day, thousands of devices made from synthetic materials or processed natural materials are interfaced with blood (see Chapters 7.2, 7.3, and 7.5). How can the biomaterials engineer know which materials might be best used in the fabrication of a blood-contacting device? This chapter will outline some methods and concerns in evaluating the blood compatibility of biomaterials, and the blood compatibility of medical devices. It does not automatically follow that if the materials comprising a device are blood compatible, a device fabricated from those materials will also be blood compatible. This important point should be clear upon completion of this chapter. Before considering the evaluation of materials and devices, the reader should be familiar with the protein and cellular reactions of blood coagulation, platelet responses, and fibrinolysis as discussed in Chapter 4.6. The history of methods

to assess blood compatibility is briefly addressed in Ratner (2000).

WHAT IS BLOOD COMPATIBILITY?

A discussion of the nature of blood compatibility would be straightforward if, following the introductory paragraph, there were a list of standard tests that might be performed to evaluate blood compatibility. By simply performing the tests outlined in such a list, a material could be rated “blood compatible” or “not blood compatible.” Unfortunately, no widely recognized, standard list of blood compatibility tests exists. Because of the complexity of blood–materials interactions (BMIs), there is a basic body of ideas that must be mastered in order to appreciate what blood interaction tests actually measure. This section introduces the rationale for BMI testing and addresses a few important measurement schemes.

“Blood compatibility” can be defined as the property of a material or device that permits it to function in contact with blood without inducing adverse reactions. Unfortunately, this simple definition offers little insight into what a blood-compatible material is. More useful definitions become increasingly complex. This is because there are many mechanisms that the body has available to respond to material intrusions into the blood. A material that will not trigger one response mechanism may be highly active in triggering another mechanism. The mechanisms by which blood responds to materials have been discussed in Chapter 4.6. A more recent definition of blood compatibility integrates a multiparameter assessment of BMI with some of the parameters defined quantitatively (Sefton *et al.*, 2000). This textbook chapter will discuss how one measures the blood compatibility of materials in light of these response mechanisms and definitions.

We can also view blood compatibility from a different perspective by considering a material that is *not* blood compatible, i.e., a thrombogenic material. Such a material would produce specific adverse reactions when placed in contact with blood: formation of clot or thrombus composed of various blood elements; shedding or nucleation of emboli (detached thrombus); the destruction of circulating blood components; and activation of the complement system and other immunologic pathways (Salzman and Merrill, 1987). Most often, in designing blood-contacting materials and devices our aim is to minimize these generally undesirable blood reactions. However, consider the case where our aim is to develop a hemostatic device to promote the rapid induction of clotting.

WHY MEASURE BLOOD COMPATIBILITY?

Many devices and materials are presently used in humans to treat, or to facilitate treatment of, various disease states. Such devices include the extracorporeal pump-oxygenator (heart–lung machine) used in many surgical procedures, hollow fiber hemodialyzers for treatment of kidney failure, catheters for blood access and blood vessel manipulation (e.g., angioplasty), heart assist devices, stents for lumenally supporting blood

vessels, and devices for the permanent replacement of diseased heart valves (prosthetic heart valves) and arteries (vascular grafts). Since these and other blood-contacting devices have been successfully used in patients for many years and are judged to be therapeutically beneficial, it is reasonable to ask: (1) is there a continued need for assessing BMI?, and (2) are there important problems that remain to be addressed? The answer in both cases is clearly "yes." For example, many existing devices are frequently modified by incorporation of new design features or synthetic materials primarily intended to improve durability, physical, and mechanical characteristics, i.e., devices may be modified to improve characteristics other than BMI. However, since these changes may also affect blood responses, and since BMIs are not entirely predictable based on knowledge of device composition and configuration, blood compatibility testing is nearly always required to document safety.

The performance of many existing devices is also less than optimal (Salzman and Merrill, 1987; Williams, 1987; McIntire *et al.*, 1985; Ratner, 2000). For example, prolonged cardiopulmonary bypass and membrane oxygenation can produce a severe bleeding tendency. Mechanical heart valves occasionally shed emboli to the brain producing stroke. Angiographic catheters can lead to strokes. Synthetic vascular grafts perform less well than grafts derived from natural arteries or veins; graft failure due to thrombosis can lead to ischemia (lack of oxygen) and death of downstream tissue beds; small-diameter vascular grafts (< 4 mm i.d.) cannot be made. Thus, while performance characteristics have been judged to be acceptable in many instances (i.e., the benefit/risk ratio is high), certain existing devices could be improved to extend their period of safe operation (e.g., oxygenators), and to reduce adverse BMI long-term (e.g., heart valves). Further, many devices are only "safe" when anticoagulating drugs are used (e.g., oxygenators, mechanical heart valves, hemodialyzers). Device improvements that would reduce adverse BMI and thereby eliminate the need for anticoagulant therapy would have important implications both for health (fewer bleeding complications due to drug effects) and cost (complications can be expensive to treat). The reusability of devices that can undergo repeated blood exposure in individual patients (e.g., dialyzers) is also an important economic consideration.

For certain applications there are no devices presently available that perform adequately (due to adverse BMIs) even when antithrombotic drugs are used. Thus, there is a need for devices that could provide long-term oxygenation for respiratory failure, cardiac support (total artificial heart), and intravascular measurement of physiologic parameters (O_2 , CO_2 , pH), as well as for small-diameter vascular grafts (<5 mm internal diameter) and other conduits (e.g., stents) for reconstruction of diseased arteries and veins. Overall, there is a compelling need for continued and improved methods for evaluating BMI.

WHAT IS THROMBOGENICITY?

The thrombogenic responses induced by a material or device can be phenomenologically categorized into two groups.

First, as the term implies, a thrombogenic device may cause the accumulation of various blood elements that are preferentially concentrated locally relative to their concentrations in circulating blood (thrombus formation). Cardiovascular devices may also exhibit regions of disturbed flow or stasis that lead to the formation of blood clots (coagulated whole blood). These *local* effects may compromise device functions such as the delivery of blood through artificial blood vessels, the mechanical motions of heart valves, gas exchange through oxygenators, and the removal of metabolic waste products through dialysis membranes. These local blood reactions may also produce effects in other parts of the host organism, i.e., *systemic* effects. Thus thrombi may detach from a surface (embolize) and be carried downstream, eventually occluding a blood vessel of comparable size and impairing blood flow distal to the site of occlusion. Chronic devices may produce steady-state destruction or "consumption" of circulating blood elements, thereby lowering their concentration in blood (e.g., mechanical destruction of red cells by heart prostheses producing anemia, or removal of platelets due to ongoing thrombus formation), with a concomitant rise in plasma levels of factors released from those blood elements (e.g., plasma hemoglobin, platelet factor 4). Mediators of inflammatory responses and vessel tone may also be produced or released from cells (e.g., platelets, white cells, the complement pathway) following blood-surface interactions that can affect hemodynamics and organ functions at other sites. Thus "thrombogenicity" may be broadly defined as the extent to which a device, when employed in its intended use configuration, induces the adverse responses outlined above. Although all artificial surfaces interact with blood, an acceptably non-thrombogenic device can be defined as one that would produce neither local nor systemic effects of health consequence to the host organism.

With "thrombogenicity" now defined in a global manner in terms of adverse outcome events associated with device usage, the obvious goal is to design and improve devices using materials that are blood compatible (nonthrombogenic) for specific applications. Ideally, the biomaterials engineer would like to consult a handbook for a list of materials useful in the fabrication of a device. Unfortunately, there is little consensus as to what materials are blood compatible. Because of this lack of consensus, there is no "official" list of blood-compatible materials. As a result, an individual interested in learning which materials might be suitable for construction of a new blood-contacting device generally consults published studies, or directly performs studies on candidate materials.

Despite intensive efforts, the blood compatibility of specific materials for particular device applications is not well established because (1) the types of devices used are numerous, (2) they may exhibit complex flow geometries, (3) they are continuously being improved, (4) the possible blood responses are numerous, complex, dynamic, and not fully understood, and (5) it is difficult and expensive to measure device thrombogenicity (clinically significant local thrombosis or systemic effects) in a systematic way in either experimental animals or humans (Williams, 1987). Most tests purported to measure blood

FIG. 1. Possible scenarios for blood-materials interactions, and limitations of evaluating only local thrombus formation at fixed time points. (A) Device remains free of thrombus. (B) Large thrombus forms and remains attached. (C) Large thrombus forms but detaches (embolizes). (D) Surface is highly reactive toward blood but deposited material is quickly removed through microembolism and or lysis. Inspection of devices C and D could lead to the incorrect conclusion that these surfaces are blood compatible.

compatibility really evaluate certain blood-material interactions, which are the events that occur (and observations that are made) when blood contacts a material. Figure 1 illustrates how alternate interpretations can be applied to data from “blood compatibility” tests. This concept is further expanded upon in Fig. 2. These alternative interpretations often invalidate or modify conclusions one would like to draw from such tests. For accuracy, the term “BMI assessment” will be used for the remainder of this chapter instead of “blood compatibility test.” Based upon the characteristics of the evaluation method (i.e., what is really being measured) the biomaterials scientist must relate the significance of the events being observed (the BMIs) to the blood compatibility of the material or device. A solid understanding of the physical and biological mechanisms of blood-materials interactions is required to make this connection in a rational way.

In more specific terms, BMIs are the interactions (reversible and irreversible) between surfaces and blood solutes, proteins, and cells (adsorption, absorption, adhesion, denaturation, activation, spreading) that occur under defined conditions of exposure time, blood composition, and blood flow. Since each of these variables influence BMIs, we generally cannot (1) extrapolate results obtained under one set of test conditions to another set of conditions, (2) use short-term testing to predict long-term results, and (3) predict *in vivo* device performance based on BMIs testing of materials per se in idealized flow geometries. Nonetheless, such tests have provided important insights into the mechanisms of thrombus formation in general,

and the relationships between BMIs and blood compatibility. These studies also permit some general guidelines for device construction and, to a limited extent, may allow prediction of device performance in humans. These points are addressed in subsequent sections of this chapter.

The foregoing considerations suggest that no material may be simply “blood compatible” or “nonthrombogenic” since this assessment will depend strongly on details of the test system or usage configuration. In fact, under conditions of sluggish (low shear) blood flow or stasis, most if not all polymeric materials may become associated with localized blood clotting and thus be considered “thrombogenic.” This is because synthetic materials, unlike the vascular endothelium (the perfect “blood-compatible material” that lines all blood vessels), cannot actively inhibit thrombosis and clotting by directly producing and releasing inhibitors or by inactivating procoagulant substances. The possibility that there may be no “biomaterials solution” to certain problems, or that device performance could be improved by emulating strategies found in nature, has led some investigators to consider coating devices with endothelial cells, antithrombotic drugs, or anticoagulating enzymes. Although there is no evidence that these methods have solved the problem of biomaterial thrombogenicity for any device, the approaches appear promising and are being widely explored. As for conventional synthetic materials and devices, establishing the usefulness of biologic surfaces and drug delivery devices requires appropriate methods for evaluating their blood interactions.

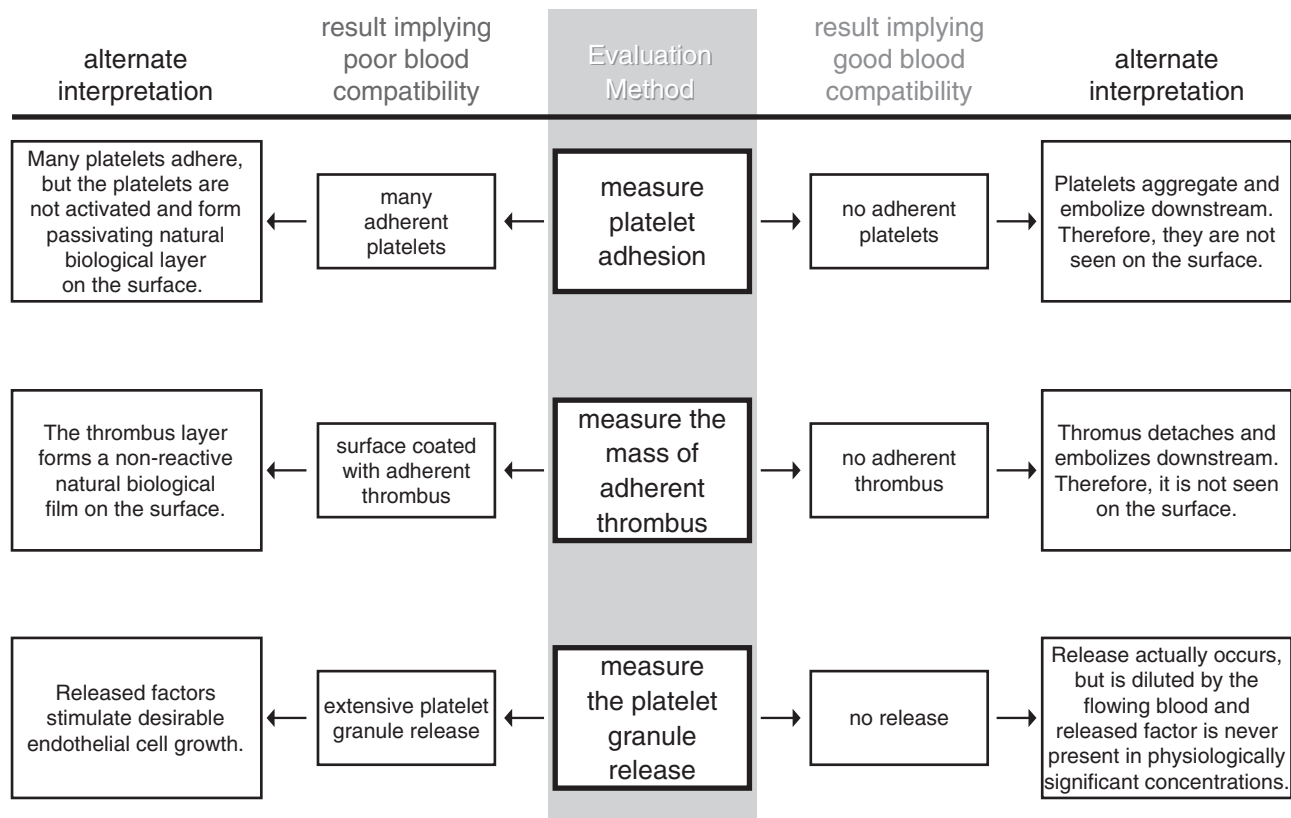

FIG. 2. Alternative scenarios that can be applied for interpreting results of blood–material interaction assays.

KEY CONSIDERATIONS FOR BMI ASSESSMENT

In 1856 Rudolph Virchow proposed that the three factors that contribute to the coagulation of blood are the blood chemistry, the blood-contacting surface, and the flow regime (commonly referred to as Virchow’s triad).

This assessment is still valid and provides a framework for more formally introducing the variables important in any system intended to evaluate BMIs. Also, the interaction time of blood with materials (ranging from seconds to years) has an influence on the three components of the triad. As described later, these variables may each profoundly influence the results and interpretation of BMI testing, and the ranking of blood compatibility of materials according to that test. It is assumed

that the reader has reviewed the mechanisms of blood response to artificial surfaces as outlined in Chapter 4.6.

Blood: Factors Affecting Its Properties

The source and methods for handling blood can have important effects on BMI. Blood obtained from humans and various animal species has been employed *in vitro* and *in vivo*, in both the presence and absence of anticoagulants. Blood reactivity is also influenced by the extent and period of manipulation *in vitro*, the surface-to-volume ratio of blood placed in extracorporeal circuits, and the use of pumps for blood recirculation. These aspects are discussed next and summarized in Table 1.

The blood chemistry of each animal species is different. In particular, blood may vary with respect to the concentrations and functions of blood proteins and cells that participate in coagulation, thrombosis, and fibrinolysis (Chapter 4.6). The size of blood-formed elements may also differ. A comparison of blood chemistry between man and the more commonly used animal species has been published (McIntire et al., 1985). While human blood is obviously preferable for BMI, it is often impossible to use human blood in certain experiments. In addition there are significant health concerns in experimenting with human blood, and animals are commonly used for both *in vitro* and *in vivo* studies. Unfortunately, most investigations have employed a single animal species or blood source. There

TABLE 1 Factors Important in the Acquisition and Handling of Blood for BMI Experiments

Species of the blood donor
Health, gender, and age of the blood donor
Blood reactivity of the donor (individual physiological differences)
Time interval between blood draw and BMI experiment
Care with which the puncture for the blood draw was made
Temperature (for blood storage and testing)
Anticoagulation
Drugs and anesthetics present in the blood
Blood damage due to centrifugation and separation operations
Blood damage due to contact with foreign surfaces prior to the BMI experiment
(syringe, needle, blood bag, bottles, tubing, etc.)
Blood damage due to the air-blood interface
Blood damage due to pumping and recirculation

have been few comparisons between human and animal blood responses for evaluating BMI in any particular test situation (also see Chapter 5.5). In many instances differences between human and animal blood responses are likely to be large and must be borne in mind when interpreting experimental results. For example, the initial adhesiveness of blood platelets for artificial surfaces appears to be low in man and some primates, and high in the dog, rat, and rabbit (Grabaowski *et al.*, 1976). Following the implantation of chronic blood-contacting devices (e.g., vascular grafts) there may be large differences between man and all other animal species in terms of device healing and incorporation of surrounding tissues, which will be reflected as differences in the *time course* of BMIs. Further, although laboratory animals serving as blood donors for BMI experiments may represent a relatively homogeneous population in terms of age, health status, blood responses, etc., the human recipients of blood-contacting devices may vary considerably in terms of these parameters. Thus the results obtained with any animal species must be viewed with great caution if conclusions are to be drawn as to the significance of the results for humans.

Despite these limitations, animal testing has been particularly helpful in defining *mechanisms* of BMI and thrombus formation, and the interdependence of blood biochemical pathways, the nature of the surface, and the blood flow regime. In addition, while results of animal testing may not quantitatively predict results in man, in many cases results are likely to be qualitatively similar. These aspects are discussed further hereafter. In general, studies in lower animal species such as the rabbit, rat, and guinea pig may be useful to screen for profound differences between materials, for example, by incorporation of an antithrombotic drug delivery system into an otherwise thrombogenic device. Short-term screening to identify markedly reactive materials, and longer-term studies to evaluate the effects of healing phenomena on BMI, can also be performed in other species such as the dog and pig. When differences in BMI are likely to be modest (for example, as a consequence of subtle changes in surface chemistry or device configuration) the ranking of materials based on tests with lower animal species may be unrelated to results that would be obtained in man; studies with primates, which are

hematologically similar to man, are more likely to provide results that are clinically relevant. However, the relationships between human and primate BMI are also not well established in many models and applications, and should therefore be interpreted with caution.

In vitro testing generally requires anticoagulation of the blood that can have a profound effect on BMI. *In vivo* testing and the use of extracorporeal circuits are also commonly performed with anticoagulants. Two anticoagulants are most frequently used: sodium citrate, a chelator for calcium ions that are required for certain reactions of platelets and coagulation proteins, and heparin, a natural polysaccharide used to block the action of the coagulation protease thrombin (Chapter 4.6). Both can markedly affect BMI. In particular, the removal of calcium ions may profoundly depress platelet-surface reactions and the capacity of platelets to form aggregates and thrombi. Thus the relationship between BMI in the presence of citrate anticoagulant, and “thrombogenicity” in the absence of anticoagulant, is questionable. Similar concerns apply to heparin anticoagulation. Although this agent is less likely to interfere with the earliest platelet reactions, platelet thrombus formation may be impaired by inhibition of thrombin activity. The use of heparin is appropriate for evaluation of devices whose use normally requires heparinization *in vivo* (e.g., oxygenators, dialyzers). In general, results with anticoagulated systems cannot be used to predict performance in the absence of anticoagulants. A discussion of anticoagulants in the context of BMI has been presented (McIntire *et al.*, 1985).

Blood is a fragile tissue that begins to change from the moment it is removed from the body. It may become more active (activated) or less active (refractory) in several ways, even with effective anticoagulation. Thus, BMI evaluations with blood aged more than a few hours are questionable. If purified blood components or cells are used (e.g., platelets, fibrinogen), studies must be performed to insure that they remain functionally normal. In most cases the volume of blood used, relative to test surface area, should be large. Similarly, the area of non-test surfaces, including exposure to air interfaces, should be minimized. Changes in blood or test surface temperature, or exposure to intense light sources (Haycox *et al.*, 1991), can also produce artifactual results. When blood is pumped, the recirculation rate (fraction of total blood volume pumped per unit time) should be minimized since blood pumping alone can induce platelet and red cell damage, platelet release reactions, and platelet refractoriness (Haycox and Ratner, 1993).

Flow: How It Affects Blood Interactions

Blood flow controls the rate of transport (by diffusion and convection) of cells and proteins in the vicinity of artificial surfaces and thrombi. This subject has been reviewed (Leonard, 1987; Turitto and Baumgartner, 1987; Chapter 3.5). Although physiologically encountered blood shear forces probably do not damage or activate platelets directly, such forces can dislodge platelet aggregates and thrombi that may attach farther downstream or are carried away (embolize) to distal circulatory beds. Platelet diffusion in flowing blood, and early platelet attachment to surfaces, may be increased 50- to 100-fold by the

presence of red blood cells that greatly enhance the movement of platelets across parallel streamlines. At higher shear forces, red cells may also contribute chemical factors that enhance platelet reactivity (Turitto and Baumgartner, 1987).

A number of studies using well-characterized flow geometries have suggested that the initial attachment of platelets to artificial surfaces increases with increasing blood flow, or, more specifically, with increasing wall shear rate (the slope of the velocity profile at the surface). Under conditions of low wall shear rate flow (less than $\sim 1000 \text{ sec}^{-1}$) early platelet adhesion (over the first minutes of exposure) may depend more upon the platelet arrival rate (i.e., platelet availability) than on substrate surface properties (Friedman *et al.*, 1970). Under these conditions the platelet-surface reaction rate is said to be *diffusion controlled*. At higher shear rates, platelet adhesion may depend upon both the rate of platelet transport as well as surface properties (Schaub *et al.*, 2000); thus, studies designed to assess the role of surface properties are best performed under flow conditions where platelet transport is not limiting. Following initial platelet adhesion, subsequent processes of platelet aggregation and *in vivo* thrombus formation (over minutes to hours) may be partly *reaction controlled*. For example, platelet accumulation on highly thrombogenic artificial surfaces (e.g., fabric vascular grafts) or biologic surfaces (e.g., collagen) may be quite rapid and depends on both the substrate reactivity and factors influencing platelet availability (shear rate, hematocrit, and the platelet content of blood) (Harker *et al.*, 1991). Under other circumstances, the rate of platelet-surface interactions may be almost entirely reaction controlled. For example, with smooth-walled artificial surfaces that cause repeated embolization of small platelet aggregates continuously over days, the overall rate of platelet destruction depends strongly on material properties but not on blood flow rate or circulating platelet numbers over wide ranges of these variables (Hanson *et al.*, 1980). These concepts of diffusion and reaction control are further explained in Fig. 3.

It has been observed that under arterial flow conditions (high wall shear rate), thrombus that forms *in vivo* may be largely composed of platelets ("white thrombus"), whereas thrombus that forms under venous flow conditions (low shear rate) may contain mostly red cells entrapped in a fibrin mesh ("red thrombus"). The process of platelet thrombus formation may not be affected by administration of heparin in normal anticoagulating amounts (i.e., arterial thrombosis may be heparin-resistant), while venous thrombosis is effectively treated with heparin. This lack of effect against platelet reactions is somewhat surprising since the procoagulant enzyme thrombin, one of the most potent activators of platelets, is strongly inhibited by heparin. These observations have been incorrectly interpreted to mean that arterial and venous thrombosis are separable processes, with the former depending only on platelet reactions and the latter depending only on coagulation-related events. However, while platelet-dependent (arterial) thrombosis may be little affected by heparin, it is blocked quite effectively by other inhibitors of thrombin (Hanson and Harker, 1988; Wagner and Hubbell, 1990), indicating that heparin is limited in its capacity to block the thrombin enzyme when thrombin is produced locally in high concentrations through reactions that may be catalyzed on the platelet

FIG. 3. The effects of flow and material surface properties on platelet transport to, and reaction with, surfaces. One can define two rate processes, r_1 , the rate of platelet transport from blood to the surface (higher in rapidly flowing blood), and r_2 , the rate of reaction of a platelet with the surface. (A) In low wall shear rate blood flow, platelets can be slow to reach the surface and r_1 dominates the kinetics of the reaction—for reactive surfaces, the surface can be “starved” of platelets for reaction. (B) In high wall shear rate blood flow, platelets are transported to the surface much more rapidly than they can react with the surface, and the intrinsic reactivity of the surface, r_2 , can be observed.

surface (Chapter 4.6). The formation of fibrin, due to the action of thrombin on fibrinogen, is also important for thrombus formation and stabilization since (1) fibrinolytic enzymes can reduce platelet thrombus formation, and (2) arterial thrombi are often composed of alternating layers of platelets and fibrin. Thus, in most circumstances, thrombin is a key promoter of *local* platelet and fibrin accumulation (on surfaces), under both high-shear and low-shear conditions. Thrombi may differ in appearance because under high-flow conditions, thrombin and precursor procoagulant enzymes (e.g., factor Xa) may be diluted sufficiently to prevent *bulk phase* clotting and trapping of red cells. These ideas have been addressed quantitatively (Basmadjian *et al.*, 1997). Also, flow effects on surface-induced thrombosis have been reviewed and the importance of pharmacological interventions on modulating this process have been described (Hanson and Sakariassen, 1998). Thus, the shear dependency of surface thrombosis depends on the surfaces' chemical composition. For example, anticoagulation effects may be more pronounced on a tissue factor-rich surface than on a collagen surface, particularly at low wall shear rates. Further, some platelet inhibitors such as aspirin are shear dependent while others seem not to be.

In summary, thrombus formation requires the transport by flow of platelets and coagulation proteins to surfaces. Fibrin polymerization, as well as local platelet activation and recruitment into growing thrombi, requires conversion of prothrombin to thrombin, the end product of a sequential series of coagulation reactions that are also catalyzed by platelets, and may be amplified or inhibited by various feedback mechanisms (Chapter 4.6). Blood flow regulates each reaction step such that under low (venous) flow conditions fibrin formation is abundant; thrombi may resemble coagulated whole blood with many entrapped red cells. Under high (arterial) flows platelets, stabilized by much smaller amounts of fibrin, may comprise the greater proportion of total thrombus mass.

Surfaces: The Properties of Biomaterials and Devices and Their Relationship to Blood Interactions

Many different artificial surfaces, in various device applications, are used in contact with blood. As discussed subsequently, tests designed to assess certain blood-materials interactions have shown that the surface physicochemical properties of materials and devices can have important effects on early events, for example, on protein adsorption and platelet adhesion, yet how these effects relate to subsequent thrombus formation remains uncertain.

When placed in contact with blood, most, if not all, artificial surfaces first acquire a layer of adsorbed blood proteins whose composition and mass may vary with time in a complex manner depending on substrate surface type (Chapter 3.2). This layer mediates the subsequent attachment of platelets and other blood cells that can lead to the development of platelet aggregates and thrombi. The relationship between material properties, the protein layer, and the propensity of a material or device to accumulate thrombus is not well understood because (1) protein-surface reactions involve complex, dynamic processes of competitive adsorption, denaturation, and activation; (2) cell-surface interactions may modify the protein layer, i.e., cells may deposit lipid and protein "footprints" derived from the cell membrane; (3) the importance of specific adsorbed proteins for subsequent cell interactions is not well defined; and (4) there have been few relevant tests in which both protein adsorption and later thrombus formation have been assessed. Under conditions of low blood shear, the capacity of negatively charged surfaces (such as glass) to activate intrinsic coagulation (via factor XII) can lead to thrombin production with subsequent platelet deposition and fibrin clot formation. Under other circumstances the availability on surfaces of adhesive plasma proteins, such as fibrinogen, may be important for regulating cell attachment (Horbett *et al.*, 1986).

With anticoagulated blood, initial platelet attachment to a variety of surfaces may be comparable and limited to a partial platelet monolayer, suggesting that surface properties may be "inconsequential" for early platelet adhesion, especially where platelet transport to the surface may be rate-limiting (Friedman *et al.*, 1970). In the absence of anticoagulants, initial platelet attachment may vary, but no general relationship to substrate surface properties has been demonstrated. In attempts to establish such relationships, thrombus formation has been studied using devices implanted in animals and composed of various materials including polymers, metals, carbons, charged surfaces, and hydrogels. Correlations have been sought between the blood response and surface properties such as charge (anionic-cationic), hydrophilicity, hydrophobicity, polarity, contact angle, wettability, and critical surface tension (Salzman and Merrill, 1987; Williams, 1987; McIntire *et al.*, 1985). These parameters have not proven satisfactory for predicting device performance even in idealized test situations, reflecting the complexity of the phenomena being investigated, the limitations of animal modeling (e.g., Fig. 1), and, in some cases, inadequate characterization of material surface properties (see Chapters 1.4 and 9.4 and Ratner, 1993a).

In many cases, material properties are constrained by the intended device application. For example, vascular grafts and

the sewing rings of prosthetic heart valves are composed of fabric or porous materials to permit healing and tissue anchoring. Other materials must be permeable to blood solutes and gases (dialysis and oxygenator membranes) or distensible (pump ventricles, balloon catheters) and may necessarily exhibit complex flow geometries. In general, devices with flow geometries that cause regions of flow recirculation and stasis tend to produce localized clotting in the absence of heparin anticoagulation. On a microscopic scale, surface imperfections, cracks, and trapped air bubbles may serve as a focus to initiate thrombus formation. Although surface smoothness is usually desirable, many devices having a fabric or microporous surface (e.g., vascular grafts) function well if the layer of thrombus that forms is not thick enough to interfere with device function (Salzman and Merrill, 1987).

The complexity of understanding blood interactions with materials, as illustrated by the lack of consensus on what materials are or are not blood compatible, was pointed out many years ago (Ratner, 1984). The difficulty in assigning a label of "blood compatible" or ranking materials as to their suitability for use in blood still persists as is illustrated in two studies. One study, using a number of different screening assays, questioned the effects of surface properties on blood interactions since trends from each of the assays could not be correlated with each other (Sefton *et al.*, 2001). Another study, using fluorescent fiber optic microscopy to observe platelet deposition, ranked materials as to the magnitude of their interaction with blood (Schaub *et al.*, 2000). Both studies were of high quality and offered insights into testing blood interactions and measuring BMI. Yet, taken as a set, they offer little insight that will allow us to conclude exactly which surface properties will yield the most blood-compatible material.

Blood Interaction Times with Materials and Devices

Different events may occur at short and long BMI times. A test performed where blood contacts a device for seconds or minutes may yield a result that will have no meaning for devices used for hours or days, or which may be implanted chronically. Thus, measurements of protein adsorption may not predict levels of platelet adhesion. Platelet adhesion alone is not an adequate measure of thrombogenicity and does not predict local or systemic thrombogenic effects that could be harmful to the host organism. However, several studies indicate that an early maximum in platelet thrombus accumulation may be seen within hours of device exposure and this can be sufficient to produce device failure (e.g., small-diameter vascular graft occlusion) (Harker *et al.*, 1991). Therefore, short-term testing (over hours) may be appropriate for predicting the clinical usefulness of devices that can produce an acute, severe thrombotic response. In general, the nature and extent of BMIs may change continuously over the entire period of device exposure. An exception to this rule may be chronic implants that do not undergo tissue coverage (e.g., heart valve struts, arteriovenous shunts) and that may interact with blood elements at a constant rate as shown, for example, by steady-state increases in rates of platelet consumption (Hanson *et al.*, 1980).

EVALUATION OF BMIs

In this section we provide a general summary and interpretation of more commonly used *in vitro* and *in vivo* animal testing procedures to evaluate BMIs. It is emphasized that a thorough characterization of material properties is critical for the interpretation of these tests (Chapters 1.2 and 1.4 and Ratner, 1993a). A few specific tests that have been historically influential, and tests that are used today are summarized in Table 2.

BMIs can be evaluated *in vitro* and *in vivo*. Also, we can look at the BMIs of either biomaterials in a test configuration or the blood interactions of real devices. There are typically unique systems, apparatus and geometries for *in vitro*, *in vivo*, and device-based assays. However, there are commonalities in the measurements of blood parameters. For example, blood can be circulated through a tube *in vitro*, circulated through a biomaterial shunt *in vivo*, or circulated through a hemodialyzer (*in vivo*, or *in vitro*). In all cases, the blood emerging from the test system might be assessed by a partial thromboplastin time (PPT) test, a laser scattering assay of emboli produced, or a flow

cytometric analysis of activated platelets. Thus, the methods for contacting blood with biomaterials and the methods for assessing blood change can often be considered separately.

In Vitro Tests of BMIs

In vitro BMI tests involve placing blood or plasma in a container composed of a test material, or recirculating blood through a flow chamber in which test materials contact blood under well-defined flow regimes that simulate physiologic flow conditions. Many flow geometries have been studied including tubes, parallel plates, packed beds, annular flows, rotating probes, and spinning disks. The older literature on these test methods has been reviewed (McIntyre *et al.*, 1985; Turitto and Baumgartner, 1987), and has yielded considerable insight into how proteins and platelets are transported to, and react with, artificial surfaces. Such studies provided a wealth of morphologic information at the cellular level regarding details of platelet–surface and platelet–platelet interactions (Sakariassen *et al.*, 1989). However, as discussed earlier, these tests are usually of short duration and are strongly influenced by the

TABLE 2 A Few Tests for Assessing Blood–Materials Interactions

Test name	Parameter(s) measured	Literature reference
<i>Historical</i>		
Vena cava ring test	Thrombus in a test ring in the vena cava	<i>Bull. N. Y. Acad. Med.</i> 48(2): 482 (1972).

blood source, handling methods, and the use of anticoagulants. Thus, *in vitro* test results generally cannot be used to predict longer-term BMI and *in vivo* outcomes and can provide only the most general guidelines for the selection of materials for particular devices.

However, *in vitro* tests may be useful for screening materials that are highly reactive toward blood. Tests of the whole-blood clotting time and variations thereof involve placing non-anticoagulated whole blood (or blood anticoagulated with sodium citrate that is then recalcified) into containers of test material and measuring the time for a visible clot to form. Materials that quickly activate intrinsic coagulation and cause blood to clot within a few minutes (such as negatively charged glass) are probably unsuitable for use in devices with low shear blood flow, or in the absence of anticoagulants.

Recirculation of heparinized blood or citrated blood through tubular devices and materials may lead to platelet deposition onto highly thrombogenic materials with the appearance in plasma of proteins released from platelets (Kottke-Marchant *et al.*, 1985; Haycox and Ratner, 1993). Thus, these and similar methods may identify materials that might cause rapid platelet accumulation *in vivo* over short time periods, and therefore be unsuitable for certain applications such as small diameter vascular grafts or blood conduits. Both recirculation tests and *in vitro* clotting assays can be considered for preliminary screening and identification of materials that could be highly thrombogenic. Most artificial surfaces in common use would probably “pass” these tests. Since small differences in test results are likely to be meaningless for predicting material performance in actual use applications, these tests are not appropriate for optimizing or refining material properties. *In vivo* testing is therefore required.

Contemporary methods for evaluating damage to blood in *in vitro* test systems may expand the significance of these methods. For example, platelet-derived microparticles in blood have been used as a marker of blood damage induced by biomaterial surfaces (Gemmell, 2000).

In Vivo Tests of BMIs

Many studies have been performed in which test materials, in the form of rings, tubes, and patches, are inserted for short or long time periods into the arteries or veins of experimental animals (Salzman and Merrill, 1987; Williams, 1987; McIntire *et al.*, 1985). For the following reasons, most of these tests are of questionable relevance to the use of biomaterials in man: (1) The timing and type of measurements may be such that important blood responses are unrecognized. In particular, the measurement of gross thrombus formation at a single point in time may lead to incorrect conclusions about local thrombus formation (e.g., Fig. 1) and does not provide assessment of systemic effects of thrombosis such as embolization and blood element consumption. (2) With more commonly used animal species (e.g., dogs), blood responses may differ from those in humans both quantitatively and qualitatively. (3) The hemodynamics (blood flow conditions) of the model may not be controlled or measured. (4) There may be variable blood vessel trauma and tissue injury that can cause local thrombus

formation through the extrinsic pathway of blood coagulation (Chapter 4.6). Thus, *in vivo* testing of materials in idealized flow geometries (rather than actual device configurations) may provide few insights into selection of materials for use in man.

Evaluations of BMI may be performed in animals having arteriovenous (A-V) or arterioarterial (A-A) shunts, i.e., tubular blood conduits placed between an artery and vein, or between an artery and artery. A-V shunts have been studied in a variety of animals including baboons, dogs, pigs, and rabbits (McIntyre *et al.*, 1985). Qualitatively similar results have been obtained with shunts in dogs and baboons (Sefton *et al.*, 2000). An A-V shunt system is illustrated in Fig. 4. Once established, shunts may remain patent (not occluded) for long periods of time (months) without the use of anticoagulants. Test materials or devices are simply inserted as extension segments or between inlet and outlet portions of the chronic shunt. These systems have the advantages that (1) blood flow is easily controlled and measured, (2) native or anticoagulated blood can be employed, (3) the animal’s physiology removes damaged blood elements and makes new blood with each circulation through the body, and (4) both short-term and long-term BMIs, including both local and systemic effects, can be evaluated. The downsides of these tests are complex surgery, the high expense, and ethical issues associated with working with larger animals.

As an example, consider the A-V shunt model in baboons—baboons are used because they are hematologically similar to man. The blood responses to tubular biomaterials and vascular grafts have been quantitatively compared with respect to (1) localized thrombus accumulation, (2) consumption of circulating platelets and fibrinogen, (3) plasma levels of factors released by platelets and coagulation proteins during thrombosis, and (4) embolization of microthrombi to downstream circulatory beds (Harker *et al.*, 1991). These studies in primates are consistent with observations in man that certain commonly used polymers [e.g., polytetrafluoroethylene,

FIG. 4. Illustration of an arteriovenous (A-V) shunt placed between the femoral artery and vein (in the leg) of an experimental animal. Materials to be tested (in this case a tubular device) are interposed between inlet and outlet segments of the shunt.

TABLE 3 Blood–Materials Responses and Their Evaluation

Blood Components	Blood Response	Assessment ^a
Thrombus	Clot	Direct visual and histologic evaluation; noninvasive imaging (angiography, ultrasound, radioisotope, magnetic resonance); evidence of device dysfunction.
	Thromboembolism	Emboli detection (ultrasound, laser); evidence of organ/limb ischemia, stroke.
Platelets	Consumption	Increased removal of radioisotopically labeled cells; reduced blood platelet count.
	Dysfunction ^b	Reduced platelet aggregation <i>in vitro</i> ; prolonged bleeding time.
	Activation	Increased plasma levels of platelet factor 4 and B-thromboglobulin; platelet membrane alterations (e.g., by flow cytometry).
Red cells ^b	Destruction	Decreased red cell count; increased plasma hemoglobin.
White cells ^b	Consumption/activation	Decreased counts of white cell populations; increased white cell plasma enzymes (e.g., neutrophil elastase).
Coagulation factors	Consumption ^b	Reduced plasma fibrinogen, factor V, factor VIII.
	Thrombin generation	Increased plasma levels of prothrombin fragment 1.2 and thrombin : antithrombin III complex.
	Fibrin formation	Increased plasma level of fibrinopeptide A.
Fibrinolytic proteins	Dysfunction ^b	Prolonged plasma clotting times.
	Consumption ^b	Reduced plasma plasminogen level.
	Plasmin generation	Increased plasma level of plasmin : antiplasmin complex.
	Fibrinolysis	Increased plasma level of fibrin D-dimer fragment.
Complement proteins ^b	Activation	Increased plasma levels of complement proteins C3a, C3b, C5a, C5b-9.

^aRadioimmunoassays (RIA) and enzyme-linked immunoassays (ELISA) may not be available for detection of nonhuman proteins.

^bTests which may be particularly important with long-term and/or large surface area devices.

polyethylene, plasticized poly(vinyl chloride), silicone rubbers] and some vascular grafts (e.g., polytetrafluoroethylene) are relatively nonthrombogenic in extracorporeal circuits and arteries. Thus, results with shunt models, particularly in higher animal species, may predict BMI in humans when employed under comparable flow conditions (laminar unidirectional flow with arterial shear rates). Since extracorporeal shunts exclude modulating effects of blood vessel cells and tissue injury, results with these models may be less relevant to the behavior of devices that are placed surgically or whose responses may be mediated by interactions with the vessel wall as well as the blood (e.g., heart valves, grafts, indwelling catheters, and sensors).

***In Vivo* Evaluation of Devices**

Since the blood response to devices is complex and not well predicted by testing of materials per se in idealized configurations, animal testing, and ultimately clinical testing, of functioning devices is required to establish safety and efficacy. Broad guidelines, based on the type of device being considered, are given next and apply to both animal and clinical testing. A summary of *in vivo* blood responses to devices, and of commonly used methods which have proven useful for evaluating those responses, is given in Table 3. Table 4, based upon one paper, lists the wide range of screens that have been used in one group over a decade to understand blood interaction with devices, specifically ventricular assist devices (Wagner *et al.*, 2000).

platelet factor 4 (PF4), beta thromboglobulin (BTG), flow cytometric detection of p-selectin expression, platelet deposition

Complement

C3a, C5b-9

Leukocyte activation

flow cytometric detection of monocyte tissue factor expression, monocyte–platelet microaggregates, granulocyte–platelet microaggregates

[based upon Wagner, *et al.* (2000)]

Devices that have relatively small surface areas and are exposed for short periods of time (hours to days) include catheters, guidewires, sensors, and some components of

extracorporeal circuits. With these devices the primary concern is the formation of significant thrombus that could interfere with device function (e.g., cause blood sensor malfunction), produce vessel occlusion (catheters), and either embolize spontaneously or be stripped from the device surface when it is removed from the body (e.g., during catheter withdrawal through a vessel insertion site), producing occlusion of distal vessels and tissue ischemia. Devices exposed for short periods that have large surface areas (dialyzers) and complex circuitries (pump-oxygenators) may, in addition, produce (1) a marked depletion of circulating blood cells and proteins (e.g., platelets and coagulation factors), (2) an immune/inflammatory response through activation of complement proteins and white cells, and (3) organ dysfunction mediated by hemodynamic, hematologic, and inflammatory reactions. Mechanical devices that are used for long periods of time (heart assist devices, extracorporeal membrane oxygenators) may produce profound systemic effects and organ dysfunction such that their use in man remains problematic. Other long-term implants (grafts, heart valves, stents) might be further improved by extending their period of safe operation and patency, and by reducing the frequency of embolic phenomena (e.g., stroke) and requirements for the concurrent use of antithrombotic drugs.

With both long-term and short-term device applications, thrombus formation can be assessed directly and indirectly. Important indirect assessments include depletion of circulating blood cells and proteins consumed in the process of thrombus formation, and the appearance in plasma of proteins generated in the process of thrombus formation (e.g., fibrinopeptide A, platelet factor 4). Direct assessment of blood flow rate, flow geometry, and extent of flow channel occlusion can in many cases be achieved using sophisticated methods including angiography, ultrasound imaging, and magnetic resonance imaging. Devices that are removed from the circulation should be visually inspected to assess whether thrombus has formed at particular sites or on certain materials. Emboli in flowing blood may be detected using ultrasound and laser-based techniques, although these methods are not used widely at present. Thrombus formation and rates of platelet destruction by both acutely placed and chronically implanted devices can be determined quantitatively by measurements of platelet lifespan and scintillation camera imaging of radioisotopically labeled blood elements (McIntire *et al.*, 1985; Hanson *et al.*, 1990).

In one study, a circulating loop system to assess materials under well controlled conditions was directly compared to results obtained on an actual device in flowing blood (Münch *et al.*, 2000). A Chandler loop was used as the well-defined test system. A cardiopulmonary bypass (CPB) device was used to observe blood reaction in a device. Both the recirculating loop system and the CPB device were surface treated with two types of heparin coatings. The parameters measured after blood flow were thrombin-antithrombin III (TAT) complex, platelet count, red blood cell count, white blood cell count, polymorphonuclear leukocyte elastase, and complement C3 activation. There were many observations reported including some tests that showed no significant difference between the two surfaces in the loop model and statistically significant

differences in the CPB model, and vice versa. The authors concluded:

In the more complex and realistic simulated CPB model, experimental design and cost factors prevented easy/optimum manipulation of critical variables such as blood donor (use of paired samples) and heparin level. Testing in the simpler loop model, on the other hand, readily offered manipulation of these variables, and produced endings which overlapped with observations from the more complex CPB model. Thus, the models described here complimented.

Finally, it is important to emphasize that thrombosis occurs dynamically, such that thrombi continuously undergo processes of both formation and dissolution. Device failure represents the imbalance of these processes. Older thrombi may also be reorganized considerably by the enzymatic and lytic mechanisms of white cells. While the initial consequences of surgical device placement include tissue injury, thrombosis due to tissue injury, and foreign-body reactions, the flow surface of long-term implants may become covered with a stable lining of cells (e.g., ingrowth of vascular wall endothelial and smooth muscle cells onto and into vascular grafts) or blood-derived materials (e.g., compacted fibrin). Certain reactions of blood elements (e.g., platelets, thrombin) may also stimulate the healing response. Ultimately, long-term devices such as the small-caliber graft may fail because of excessive tissue ingrowth that could be largely unrelated to biomaterials properties, or may be stimulated by the biomaterials.

We summarize this section on device testing recognizing that many device applications described earlier, as well as laboratory and clinical methods for evaluating their biologic responses, will be unfamiliar to the bioengineer. However, it is important to appreciate that (1) each device may elicit a unique set of blood responses, both short-term and long-term, (2) methods are available to assess systemic changes in the blood and host organism that indirectly reflect thrombus formation, and (3) localized thrombus formation can usually be measured directly and quantitatively. Whenever possible, serial and dynamic studies should be performed to establish the time course of ongoing thrombus formation and dissolution. These measurements will ultimately predict device performance and allow for the rational selection of biomaterials that will minimize adverse blood-device interactions.

CONTEMPORARY CONCEPTS IN BMI EVALUATION

A few trends are noted in the recent literature that describe powerful methods to assess BMI. Two of these trends will be highlighted here: flow cytometry and emboli detection.

The use of flow cytometry to analyze activation of blood elements can be an effective method of measuring blood cell reaction and isolating specific pools of cells that have or have not undergone reaction. The basic technology behind flow cytometry (sometimes called fluorescence activated cell sorting, FACS) involves the laser separation of fluorescently labeled cells from a narrow flow stream of cells. The fluorescently labeled cells can be diverted from the flow stream to another flow channel where they are counted and harvested. One of

the earliest studies using flow cytometry for blood compatibility studies showed that in contact with blood-activating synthetic materials, thrombotic membrane fragments called microparticles are released (Gemmell *et al.*, 1995). Since that important study, flow cytometry has been used to look at the up-regulation of platelet P-selectin (CD62), a consequence of α -granule release, monocyte and neutrophil CD11b (Mac-1 receptor) up-regulation (Gemmell, 2000), platelet activation by annexin V binding to the negative phospholipid found on activated platelets (Wagner *et al.*, 2000) and a number of other biospecific factors relating to platelet activation, white cell activation and platelet aggregate formation. The power of the flow cytometry method resides in its ability to pinpoint an event in a large pool of cells that can be identified by a fluorescent tag. The method is applicable to blood that has been contacted with synthetic materials *in vitro* or *in vivo*.

The ability to go beyond measurements of adhesive phenomena in blood (accumulating thrombus or platelets) and to expand studies to nonadhesive encounters leading to blood activation and damage represents an important growth area for BMI evaluation. Cytometric studies allow us to do systemic measurements rather than just local assessment. Methods to study embolus production in real time permit a key, clinically relevant parameter to be measured and quantified. Doppler ultrasound seems to have potential to do this, though the instrumentation is expensive. Other alternatives to study microemboli in blood include use of the Coulter counter on sampled blood and filtration pressure methods. However, a method that seems to have excellent potential to advance our understanding of how surfaces induce embolus formation is laser light scattering. Initial developments making this method suitable for embolus analysis in whole blood were published over 20 years ago (Reynolds and Simon, 1980) and then used for the assessment of BMI in conjunction with a baboon shunt model (Garfinkle *et al.*, 1984). New developments in light scattering instrumentation and data analysis should make laser microembolus detection a key tool for studying biomaterial reactions with blood (Solen *et al.*, 2003).

CONCLUSIONS

The most blood compatible material known is the natural, healthy, living lining of our blood vessels. This "material" functions well by a combination of appropriate surface chemistries, good blood flow characteristics, and active biochemical processes involving removal of prothrombotic substances and secretion of natural anticoagulants. It seems unlikely that we will ever match this performance in a synthetic material or device, although attempts to imitate aspects of the natural system represent a promising strategy for developing a new generation of blood-compatible devices (Chapters 2.14, 2.16, 3.4, and 7.18). At present, however, synthetic materials that perform less well than the vessel wall, but still satisfactorily, will be needed. This chapter provides only a brief outline of the issues involved in evaluating materials and devices to find those that are minimally damaging or activating towards blood. The subject of blood compatibility testing is complex, and advanced study of the subject is required before considering experiments

intended to elucidate basic mechanisms or improve human health. Further discussion elaborating upon the complexity of the issues involved in BMI testing can be found in Ratner, 1984, 1993b, 2000. Detailed discussion on the characterization of materials for biomaterials application and on BMI testing can also be found in a recent publication coordinated by the Device and Technology Branch of the National Heart, Lung and Blood Institute, NIH (Harker *et al.*, 1993).

5.5 LARGE ANIMAL MODELS IN CARDIAC AND VASCULAR BIOMATERIALS RESEARCH AND TESTING

Richard W. Bianco, John F. Grehan, Brian C. Grubbs, John P. Mrachek, Erik L. Schroeder, Clark W. Schumacher, Charles A. Svendsen, and Matt Lahti

INTRODUCTION

The purpose of using animal models in biomaterials research is to examine biomechanical systems as they exist in one species (the model) and apply that knowledge to human physiologic systems. Such an approach has long been employed and has resulted in improved health and increased longevity for humankind. The importance of this approach has been realized by many great investigators including Charles Darwin, who poignantly describes this link and its importance in a letter to a Swedish professor of physiology in 1881: “I know that physiology cannot possibly progress except by means of experiments on living animals, and I feel the deepest conviction that he who retards the progress of physiology commits a crime against mankind.”

The development of new technologies, including *in vitro* methods and computer modeling, that has occurred in the last few decades has enhanced the approach to the study of physiology. In spite of all this progress, however, the use of *in vivo* models still remains a necessity in investigations into certain physiologic phenomena, especially those related to the pathophysiological mechanisms of disease. Traditional mammalian models in biomedical research, such as rats, mice, guinea pigs, hamsters, and rabbits, have provided the scientific community with voluminous amounts of information about human disease and basic biological processes. For the evaluation of cardiac and vascular biomaterials, however, investigations using larger domestic animals have proven to be more valuable because these models portray anatomical and physiological characteristics that more closely resemble those observed in humans. This similarity allows creation of models that are capable of providing more accurate predictions of a bioprosthetic device’s or a biomaterial’s future clinical performance.

This chapter will focus on three commonly used animal models for *in vivo* biomaterials research and testing in cardiac and vascular surgery: dogs, pigs, and sheep. The chapter will begin with a short discussion on responsible use of animals

in biomaterials research and testing, followed by specific considerations and examples of existing animal models for each species. Finally, current standards and testing requirements for *in vivo* preclinical evaluation of cardiac and vascular devices, as well as proposed future requirements, will be discussed.

RESPONSIBLE USE OF ANIMALS

Introduction

There are two basic principles governing the use of animals in research, education, and testing: (1) scientific reliance on the use of live animals should be minimized; (2) pain, distress, and other harm to laboratory animals should be reduced to the minimum necessary to obtain valid scientific data. Strict adherence to these basic ethical principles will not only enhance the quality of each *in vivo* preclinical evaluation but will also ensure that current and future generations of scientists will be able to employ all valid tools available to predict clinical safety of new or modified medical devices and other technology designed to improve human health.

Investigator and Institutional Responsibilities

When considering animal models for biomaterials research the investigator and sponsoring institution should first assess their responsibilities with respect to federal, state, and local laws and regulations. Additionally, given the growing public and political sensitivity to the use of research animals, all laboratories using animals must ensure that their programs recognize and comply with current definitions of humane animal care and use. The importance of this issue is reflected in a resolution adopted by the American Association for the Advancement of Science, February 19, 1990. This section briefly presents legal obligations and provides practical guidelines for responsible use of laboratory animals.

The Animal Welfare Act (Public Law 89-544, as amended) provides federal regulations that cover laboratory animal care and use. The regulations [Title 9 of the Code of Federal Regulations (CFR), Chapter 1, subchapter A—Animal Welfare, Parts 1, 2, 3] are enforced by the Animal and Plant Health Inspection Service (APHIS), U.S. Department of Agriculture. The Act covers dogs, cats, nonhuman primates, guinea pigs, hamsters, rabbits, and “any other warm-blooded animal, which is used or is intended for use in research, teaching, testing, experimentation . . .” (9 CFR subchapter A, Part 1, Section 1.1). Species specifically exempt from the Act include birds, rats, and mice bred for use in research, and horses and livestock species used in agricultural research. Institutions using those species covered by the Act must be registered by APHIS. Continued registration is dependent on submission of annual reports to APHIS by the institution, as well as satisfactory inspection of the institution’s animal facility during unannounced site visits by APHIS inspectors. The Act provides specifications for animal procurement (i.e., from licensed suppliers), husbandry, and veterinary care that are used to determine compliance with the Act. An annual report must be supplied to APHIS and should contain a

list of all species and the numbers of animals used by the institution in the previous year. The animals listed in the annual report must be categorized by the level of discomfort or pain they were thought to experience in the course of the research, education, or testing process they were used for.

In 1985 amendments were made to the Act (7 U.S.C. 2131, et seq.) and were implemented on October 30, 1989, August 15, 1990, and March 18, 1991. These amendments extended the Act to cover the institution’s administrative review and control of its animal research program (Federal Register, Vol. 54, No. 168, pp. 36112–36163; Vol. 55, No. 36, pp. 28879–28881; Vol. 56, No. 32, pp. 6426–6505). Specifically, the new regulation requires that all animal research protocols be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) before they are initiated. Furthermore, the submitted protocols must state in writing that less harmful alternatives were considered but are not available, and that the proposed research is not unnecessarily duplicative. Additional requirements increase the scope of husbandry requirements for laboratory dogs and nonhuman primates.

The other relevant federal body is the National Institutes of Health (NIH). The Health Research Extension Act of 1985 (Public Law 99-158) required the director of NIH to establish guidelines for the proper care of laboratory animals and IACUC oversight of that care. Broad policy is described in the Public Health Service Policy on Humane Care and Use of Laboratory Animals (NIH, 1986), which identifies the Guide for the Care and Use of Laboratory Animals (NIH, 1985a) as the reference document for compliance. This policy applies to all activities involving animals either conducted by or supported by the U.S. Public Health Service (PHS). Before an institution can receive animal research funding from NIH or any other PHS agency, that institution must file a statement of assurance with the PHS Office for Protection from Research Risks (OPRR) that it is complying with these guidelines.

As required by the Animal Welfare Act, the PHS policy mandates that an annual update on animal research use and IACUC review of animal protocols and facilities be submitted. Unlike the Animal Welfare Act, however, the PHS policy covers all vertebrate species, does not include an enforcement arm for routine inspections (but does provide for inspection in cases of alleged misconduct), and penalizes noncompliant institutions by withdrawing funding support.

State and local laws and regulations may also affect animal research programs. These mainly involve restrictions on the availability of cats and dogs from municipal shelters. Within the past decade several states have also enacted registration and inspection statutes similar to the Animal Welfare Act. In several states, court rulings have required IACUC reports and deliberations at state-supported institutions to be conducted in public (e.g., Florida, Massachusetts, North Carolina, Washington).

Housing and Handling

The physical and psychological well-being of laboratory animals is determined in large part by their environment. Thus, careful attention must be paid to both the housing and handling of any investigational animal as improper handling or care may result in undue stress. The Institute of Laboratory

Animal Resources of the National Academy of Sciences publishes a detailed guide with specific recommendations for the housing of many laboratory animal species (Guide for the Care and Use of Laboratory Animals, 1996). Adequate assessment of available facilities and their compliance with these regulations must be considered conducting any animal investigation. This assessment should be done not only for regulatory affairs compliance, but also for scientific accuracy as data obtained from subjects that are not cared for properly may be inaccurate.

Euthanasia

In addition to housing and handling issues, investigators must become familiar with the issues pertaining to the appropriate practice of euthanasia. Study protocol completion or undue suffering of an individual study subject are both inviolable indications for euthanasia. Cachexia, anorexia, and a moribund state are also indications for euthanasia. In this phase of the investigation, as in all other phases of an animal investigation, great care should be taken to avoid any undue stress to the animal. To facilitate this, euthanasia techniques used should result in rapid unconsciousness followed by cardiac and respiratory arrest. The 1993 Report of the American Veterinary Medical Association (AVMA, 1993) provides multiple acceptable techniques for euthanasia and is an invaluable resource for investigators in the process of designing a study.

ANIMAL MODELS AND SPECIES CONSIDERATION

Canine

Introduction

The history of the use of canines in experimental surgery is extensive. Early experimental surgery required an animal model that was inexpensive, readily available, and easily managed. The solution to this problem came in the form of mongrel dogs. These animals could be obtained from pounds inexpensively and were often familiar with humans. Today, the emotional content of using canines for research has prohibitively increased the cost of these animals, and society no longer deems them appropriate for chronic studies. Although some acute studies may involve the use of pound animals, the majority of biomaterials research and testing involving canines requires the additional expense of using purpose-bred animals and has forced many researchers to look for alternative animal models. Despite this controversy, the canine model has been and still is considered the gold standard for many investigations.

Comparative Anatomy and Physiology

The canine cardiovascular physiology is similar to that of humans (Table 1). This homology, along with ease of vascular access and low body fat, make canines an ideal model for cardiac and peripheral vascular studies. A thoracotomy performed through the left fourth intercostal space will generally provide adequate access to the canine cardiovascular and pulmonary systems. There are only three significant anatomic

variants to be aware of in canine surgery. First, the long thoracic nerve must be preserved because it innervates the serratus ventralis muscle, which is extremely important for ambulation in quadrupeds. As its course takes it along the dorsal aspect of the more cranial ribs, it can be easily transected while making the thoracotomy incision. The second important feature of canine anatomy is the drainage pattern of the right azygous vein. This vein empties into the superior vena cava (SVC) just proximal to where the SVC enters the right atrium. Care must be taken when encircling the SVC to avoid disruption of the azygous drainage. Last, the canine coronary vasculature is a highly collateralized system, which makes the canine model less desirable for regional ischemia/reperfusion investigations.

Canines show remarkable hematologic and metabolic similarity to humans as well (Table 2). Notable differences include a higher hemoglobin (range 14–19 g/dl) and white blood cell (WBC) numbers (range 6–16 thousand per cubic millimeter). The WBC differential and platelet counts are nearly identical to those in humans. Serum chemistries and liver functions also show remarkable similarities with the exception of serum amylase levels, which can be up to five times those in humans. Blood typing within the canine model is of arguable importance. Numerous canine blood groups have been described but only eight dog erythrocyte antigen (DEA) systems are currently recognized by international standards (Hale, 1995). Universal donor animals can be used if necessary; however, transfusion of typed and cross-matched blood is recommended as it reduces the risk of a transfusion reaction.

Perioperative Care

Anesthesia Dogs should be fasted for 12 hours prior to their operation to reduce the risk of aspiration during anesthetic induction and endotracheal intubation. Preparation of the animal involves administration of a mild intramuscular (IM) sedative such as acepromazine, a phenothiazine tranquilizer. Peripheral intravenous (IV) accesses can then be established. Prior to intubation, 0.05 mg/kg of atropine, an anticholinergic, may be administered to reduce the amount of oral secretions and ease endotracheal (ET) intubation. Once a secure airway has been obtained, anesthesia can be fully induced with a barbiturate such as thiopental sodium (12.5 mg/kg IV). Table 3 lists several of the recommended drugs and doses for sedation and anesthesia in dogs.

General anesthesia is maintained intraoperatively with an inhalation anesthetic such as isoflurane, with close monitoring of the physiological states of relaxation, oxygenation, and circulation. Periodic arterial blood gas analysis allows the adjustment of mechanical ventilation. Noninvasive blood pressure analysis may be sufficient for shorter peripheral vascular cases; however, invasive arterial blood pressure analysis should be instituted for all cases involving cardiopulmonary bypass. Peripheral arteries, such as the femoral or carotid arteries, or a more central artery such as the internal mammary artery, are equally sufficient for the placement of pressure monitoring cannulae. Core temperature analysis and continuous EKG monitoring are also essential elements of any operative procedure.

TABLE 1 Hemodynamic Values of Species Used to Evaluate Cardiac and Vascular Bioprostheses

Hemodynamic values	Dog	Pig	Sheep	Human
Heart rate (beats/min)	98 ± 17.9	105 ± 10	95 ± 24.2	70 ± 14
Mean arterial pressure (mm Hg)	96 ± 6.7	102 ± 9	70 ± 24	95 ± 11
Systolic pressure (mm Hg)	126 ± 23	127 ± 8	85 ± 3	126 ± 14
Diastolic pressure (mm Hg)	90 ± 20	86 ± 7	58 ± 15	79 ± 10
Stroke volume (ml/beat/kg)	2.0 ± 0.4	1.34 ± 0.26	1.03 ± 0.78	1.14 ± 0.31

Analgesia Postoperatively, assessment of pain and discomfort may be based on a number of criteria. Canines will often display an abnormal posture, due to muscle flaccidity or rigidity when experiencing discomfort. Additionally, when approached, they may exhibit markedly different responses to their caretaker than observed preoperatively

such as abnormal aggressiveness, withdrawal to touch, or increased vocalizations. As with all pain management, less medication is required if it is administered in a scheduled manner. This laboratory has had good results using a narcotic agonist/antagonist combination (e.g., buprenorphine) delivered through either a subcutaneous injection or intravenously.

TABLE 3 Anesthetics and Sedatives Acceptable for Use in Species Used to Evaluate Cardiac and Vascular Biomaterials

Drug name	Dose/kg			Route of delivery				
	Dog	Pig	Sheep	PO	SQ	IM	IP	IV
Preanesthetic anticholinergics								
Atropine	0.05 mg	0.05–0.5 mg	0.05 mg		X	X		X
Glycopyrrolate	0.011 mg	0.011 mg				X		
Phenothiazine/buterothiopyridone sedatives

Table 4 lists several commonly used analgesics and their doses for use in dogs.

Existing Models

Cardiac Devices Availability, familiarity, ease of housing, and anatomical similarities made canines the natural choice for early cardiac studies. Cardiopulmonary bypass, coronary artery bypass, and early valve studies were all developed primarily with canine models. An experimental protocol for coronary artery bypass grafting in canines was first documented in 1968 (Green *et al.*, 1968). Wakabayashi (Wakabayashi and Connolly, 1968) developed the technique in 1967 in an animal model and the Cleveland Clinic Group (Favaloro, 1969) independently developed and performed the technique in humans at approximately the same time. The concurrent development and improvement of cardiopulmonary bypass machines along with a safe technique for aortic cross-clamping (Wakabayashi *et al.*, 1971) made surgical revascularization possible. Further refinements such as internal mammary artery

use and radial artery grafts were also developed using the canine model (Rossiter *et al.*, 1974).

The canine model is suitable for testing both synthetic and biosynthetic vascular grafts used for coronary artery bypass, and still represents the gold standard for animal models of coronary artery bypass. This laboratory and others (Tomizawa *et al.*, 1994) have used the canine model for biosynthetic graft evaluations. In this model, a coronary artery bypass is performed using aortic cross-clamping and standard cardiopulmonary bypass with cooling. The left anterior descending artery is dissected free, ligated proximally, and looped just distal to the circumflex bifurcation. The distal anastomosis is sewn just past the origin of the first diagonal coronary artery. The aortic cross-clamp is then removed to reestablish distal blood flow. The proximal anastomosis is sewn into the aorta, with the aid of a partially occluding clamp for hemostasis. Important technical considerations for this model include perioperative antibiotics and anticoagulation with aspirin (325 mg/day) postoperatively.

The canine model offers several advantages for these studies. There is a large historical database for comparison, canines

tolerate bypass well, and the availability of autologous saphenous vein for grafting allows researchers to perform positive controls. Additionally, canines have multiple sites for vascular access, which facilitates repeated angiographic evaluation of the conduit being studied. Although dogs tend to be more hypercoagulable than humans, patency in a canine model portends long-term patency in humans. Perhaps the most important aspect of this model is that it evaluates the new device/biomaterial in its intended clinical position.

Coronary artery stent placement is one of the newer techniques available to interventional cardiologists. Because of the recent shift away from the canine as a model for chronic device evaluation, only a few of the early studies (Schatz *et al.*, 1987; Roubin *et al.*, 1990) were performed in a canine model; the current standard uses a swine model (see later discussion). Nevertheless, a few recent reports have been published in which a canine model is used to study stent thrombogenesis (Santos *et al.*, 1998; Ueda *et al.*, 1999).

The evaluation of artificial heart valves began in the 1950s, using a canine model and valves created from materials such as polyurethane (Akutsu *et al.*, 1959; Doumanian and Ellis, 1961). Because early studies with artificial valves were hampered by short survival times secondary to thrombosis, anticoagulation was introduced in 1961 (Doumanian and Ellis, 1961) and led to a significant increase in survival. This advancement was followed by the rapid introduction of prosthetic cardiac valves into clinical use (Starr and Edwards, 1961). It was noted that although anticoagulation was used, humans tended to be less thrombogenic than dogs, a fact that would hinder more extensive use of the canine model for years to come. A relationship was also found to exist between bacteremia and postoperative thrombus formation. The combination of preoperative antibiotics, short bypass times, postoperative

anticoagulation, and aseptic blood sampling techniques was eventually found to have a significant impact on survival of canines with artificial valves (Bianco *et al.*, 1986). Table 5 lists various antibiotics used in cardiovascular animal research models and their recommended dosing regimens.

The use of preoperative antibiotics, short cardiopulmonary bypass runs, and postoperative anticoagulation also validated the canine model for chronic studies involving artificial valves. At the time, a canine model represented a cost-effective alternative to other more expensive large animal models. Later studies, however, questioned the accuracy of biosynthetic valve calcification data derived from the canine model (Chanda *et al.*, 1997). Indeed, variation in the rate of calcification was recognized and eventually the FDA endorsed the juvenile sheep model for chronic bioprosthetic valve studies. The juvenile sheep model remains the model of choice for chronic evaluation of bioprosthetic valve; however, the canine remains an excellent model for chronic or acute hemodynamic testing.

Vascular Devices The canine model also has a long history in the research and testing of peripheral vascular biomaterials and devices. Early studies utilized large vessels such as the abdominal or thoracic aorta. However, expansion into other vascular beds began in the late 1960s and early 1970s with the use of the carotid artery to test small vascular prosthetics (Sharp, 1970). Ease of access to the carotid artery, along with its high flow rate and high pressure, led to investigations with multiple graft materials. In these investigations it was quickly discovered that graft diameter had a significant impact on thrombogenesis. Polytetrafluoroethylene (PTFE) grafts (Kelly and Eisemen, 1982) were developed with the help of a canine model, and again, it was recognized that this model represents a more thrombogenic environment than the human.

TABLE 5 Antibiotics Acceptable for Use in Large Animal Models

Drug name	Dose/kg			Frequency ^a	Route of delivery ^b			
	Dog	Pig	Sheep		PO	SQ	IM	IV
Pencillins

Intimal hyperplasia of PTFE grafts was noted in these early canine studies and subsequently led to further research into this important complication. As in humans, long vascular grafts were shown to develop intimal hyperplasia at the anastomotic sites but poor endothelialization of the midportion of the grafts (Brophy *et al.*, 1991). More recently, however, swine have replaced the canine model for studies of these phenomena. Interestingly, the observations made in these early canine studies using PTFE grafts led investigators to develop clinical protocols to improve their long-term patency. In fact, one of these canine protocols, systemic aspirin therapy, is now recognized as the therapy of choice in improving graft patency (Curl *et al.*, 1986). Aspirin administration reduces thromboxane B2 levels and prevents platelet aggregation. In this laboratory,

aspirin (325 mg/day) is used routinely as postoperative therapy (beginning the first post-operative day) in investigations involving peripheral vascular prostheses.

Despite the cost, the canine model has several advantages that still make it the model of choice for many peripheral vascular studies. Ease of repeated vascular access, good long-term patency, and physiologic conditions similar to humans have all been cited for promulgation of the model. The increased thrombogenicity of smaller grafts can also be thought of as an advantage in that long-term patency represents success under rigorous conditions, thereby implying an increased potential for success in clinical trials. Physical durability, patency, and biomaterial–host interactions can all be tested (at the site of intended clinical use) within the same model.

Overall, the canine animal model has provided a long history of significant contributions to our understanding of cardiovascular physiology and to the development and testing of cardiovascular biomaterials and devices. In more recent times, there has been a shift away from the dog for many studies because of public concerns and rising animal cost. As a result other large domestic animals have become useful models for ongoing biomaterials research.

Swine

Introduction

It is believed that the majority of the breeds of swine we now know are descended from the Eurasian wild boar (*Sus scrofa*). Archaeological evidence from the Middle East indicates domestication of the pig occurred as early as 9000 years ago, with some evidence for domestication even earlier in China. From here the pig spread across Asia, Europe, Africa, and ultimately North America (Towne and Wentworth, 1950; Mellen, 1952; Clutton-Brock, 1999b). Today, swine serve many purposes in society from food source and pets to biomedical research subjects. In this latter role, swine have proven useful during the past four decades in studying a variety of human ailments including cardiovascular (Ramo *et al.*, 1970; Cevallos *et al.*, 1979), gastrointestinal (Kerzner *et al.*, 1977; Leary and Lecce, 1978; Pinches *et al.*, 1993), and hepatic (Mersmann *et al.*, 1972; Soini *et al.*, 1992; Sielaff *et al.*, 1997) diseases. Studies in swine have also provided extensive information in the areas of organ transplantation (Calne *et al.*, 1974; Marino and De Luca, 1985; Grant *et al.*, 1988; Al-Dossari *et al.*, 1994; Granger *et al.*, 1994).

Multiple authors have reported advantages to using swine as models in biomedical research including, but not limited to, anatomic and physiologic similarities to humans, low cost, availability, and the ability of swine to produce large litters of hearty newborns (Stanton and Mersmann, 1986; Swindle, 1992; Tumbleson and Schook, 1996). In addition, naturally occurring models of human disease (e.g., atherosclerosis) can be found in various strains of swine, making them ideal candidates for the study of these disease processes. Also helpful to investigators using swine is a large body of agricultural literature in the areas of swine nutrition, reproduction, and behavior that may have application in biomedical research. For all these reasons swine have become increasingly popular in the biomedical research laboratory.

Comparative Anatomy and Physiology

Swine are the one readily available species in which cardiovascular anatomy and physiology most closely resembles those in humans, likely because of a similar phylogenetic development that led to an omnivorous species with a cardiovascular system that has accommodated to a relative lack of exercise (McKenzie, 1996). The heart of an adult swine weighs 250–500 grams and comprises approximately 0.25% of the body weight (Ghoshal and Nanda, 1975), similar to that of humans. The coronary vasculature of a pig heart is nearly identical to that of humans in anatomic distribution, reactivity, and paucity of collateral flow (Hughes, 1986). The right and left coronary

arteries are similar in size to each other. The left coronary supplies the greater part of the wall of the left ventricle and auricle, including the interventricular septum, by means of its circumflex and paraconal interventricular branches. The right coronary supplies the wall of the right ventricle and the auricle via its circumflex and subsinuosal branches (Ghoshal and Nanda, 1975). These similarities make swine ideal for the study of ischemia/reperfusion and coronary stent technology.

There are certain cardiovascular anatomic differences between swine and humans that must be considered when using swine as investigational subjects. First, the left azygous vein drains directly into the right atrium in swine compared to drainage into the brachiocephalic vein in humans (Ghoshal and Nanda, 1975). Second, there are only two arch vessels coming off of the aorta in swine. The most proximal of these is the brachiocephalic trunk, which gives rise to the right subclavian and a common carotid trunk that bifurcates into right and left carotid arteries. The second arch vessel is the left subclavian artery (Ghoshal and Nanda, 1975).

Electrophysiologic parameters of pigs more closely resemble those of man than any nonprimate animal. These parameters include similar P and R-wave amplitudes, P-R intervals of 70–113 msec (longer in older animals), mean QRS duration of 39 msec, a Q-T interval of 148–257 (again longer in older animals), as well as ventriculoatrial (V-A) conduction when the right ventricular endocardium is stimulated faster than normal sinus rate (Hughes, 1986). These similarities make the pig a good model for studying pacemakers. Some investigators have found swine to be highly susceptible to ventricular arrhythmias, often requiring prophylactic pharmacologic protection (i.e., lidocaine, flecainide, or bretylium). Alternatively, other investigators have exploited this ventricular instability to study “induced” tachyarrhythmias, and the pharmacologic agents and/or electrical interventions to manage them (Hughes, 1986).

Physiologically, swine have hemodynamic and metabolic values that are similar to those of humans (Tables 1 and 2). They also share similar pulmonary function parameters such as respiratory rate and tidal volumes (Willette *et al.*, 1996). Although they have lower levels of hemoglobin, circulating red cell volume, arterial oxygen saturation, and markedly lower venous oxygen saturations, they have similar platelet function, and lipoprotein patterns. Other physiologic characteristics that may play a role in experimentation include a higher core body temperature, a contractile spleen that sequesters 20–25% of the total red cell mass, very fragile arteries and veins, a higher plasma pH, and a higher plasma bicarbonate level. Swine also have 50% more functional extracellular space than humans and a slightly increased volume of total body water (Hannon *et al.*, 1990; Swindle *et al.*, 1986).

Perioperative Care

Anesthesia Swine should be fasted at least 12 hours prior to the induction of anesthesia, longer if one desires the large bowel to be empty prior to surgery. Unless gastric surgery is to be performed, the animals may be given water without restriction. It is common to administer an IM preanesthetic agent followed by an IV anesthetic agent after IV access has

been obtained. IM injections can safely be administered in the neck just behind the ear, in the triceps muscle of the forelimb, or in the semimembranosus–semitendinosus muscles of the hindlimb. IV access is most commonly obtained in the lateral auricular veins (Riebold and Thurmon, 1985; Swindle and Smith, 1994; Swindle, 1994). The preanesthetic/anesthetic protocol used in this laboratory involves the administration of an IM injection of a combination drug (Telazole) consisting of a dissociative anesthetic and a tranquilizer (tiletamine and zolazepam) at a dose of 2–4 mg/kg for sedation. Following this IV thiopental sodium (6–25 mg/kg) is administered if necessary. ET intubation follows and anesthesia is maintained via inhaled isoflurane (1–2 vol%). Commonly used anesthetics, doses, and routes of delivery are given in Table 3.

Analgesia Postoperative analgesia is a very important component of any animal experiment. Appropriate use of postoperative analgesia involves rapid recognition of discomfort and appropriate therapy. When in pain or distress swine will demonstrate changes in social behavior, gait, posture, and a lack of bed-making. Most swine will become very reluctant to move when in pain, and if forced to move will vocalize with even greater enthusiasm than they generally display (Gross, 1994). Buprenorphine is currently the analgesic of choice used in swine (Swindle and Smith, 1994; Swindle, 1994); we have found it to be very effective, and it can be administered at 0.05–0.1 mg/kg every 8–12 hours. Standard narcotics such as morphine and fentanyl are effective pain relievers but have a very short half-life in swine. Additional analgesic agents are listed in Table 4.

Existing Models

Cardiac Devices Orthotopic valve replacement in large animals is an important component of preclinical prosthetic valve assessment for the initial evaluation of surgical handling characteristics, hemodynamic performance, and valve-related pathology. Early investigators using swine for cardiovascular research described difficulties with venous access (Swan and Piermattei, 1971), anesthesia (Piermattei and Swan, 1970), cardiopulmonary bypass (Swan and Meagher, 1971), and several anatomic peculiarities (Swan and Piermattei, 1971). Subsequently, cardiovascular surgical procedures using swine have become technically feasible, and several investigators have conducted acute and chronic studies for the assessment of hemodynamic profiles of cardiac prostheses (Hasenkam *et al.*, 1988a,b, 1989; Hazekamp *et al.*, 1993). However, only a few long-term swine studies have been performed to examine the potential of prosthetic heart valve implants for thrombogenicity (Gross *et al.*, 1997; Henneman *et al.*, 1998; Grehan *et al.*, 2000).

It has been reported that heart valve replacement in swine requires certain measures not needed with other species. These include the use of a crystalloid prime without plasma volume expanders (especially starch based), prophylactic administration of pharmacological protection against ventricular arrhythmias, insurance of adequate hypothermic cardioprotection during the time of cross-clamp, administration of “shock” doses of corticosteroid just prior to reperfusion, and the use of inotropic support during bypass weaning (Gross *et al.*, 1997).

In our experience, (see later discussion) however, we have found some of these precautions unnecessary for the successful use of the pig in the evaluation of cardiac prosthesis.

In our investigation, 22 swine underwent mitral valve replacement with no operative deaths. All animals were weaned from cardiopulmonary bypass without inotropic assistance. No cardioplegic protection was used, and only mild total body hypothermia was instituted. Pathologic analysis of valves explanted from animals surviving more than 30 days demonstrated extensive fibrous sheath formation leading to valve orifice obstruction and restriction of leaflet motion in a significant number of animals. The extensive fibrous sheath formation (and subsequent valvular dysfunction) represents a chronic tissue response observed in many species following mitral valve replacement. This chronic tissue response, however, was noted to have developed sooner in swine than in our previous studies involving prosthetic valve implantation into other species (i.e., sheep). Additionally, we did not find this model to be useful in predicting device-related thrombogenicity, as there were no clinical or pathologic differences observed among the valve designs studied (Grehan *et al.*, 2000). The utility of swine in predicting the thrombogenic potential of cardiac valvular prostheses is therefore limited.

Improved biotechnology has brought left ventricular assist devices (LVAD) into the clinical arena as bridge to transplantation therapy for patients with end-stage cardiac disease or those suffering from acute myocardial infarction (Frazier *et al.*, 1992; Oz *et al.*, 1997; Park *et al.*, 2000). Clinical observations of patients who have received LVAD have revealed that these patients have a propensity for developing right ventricular dysfunction. To study this phenomenon, a model of iatrogenic congestive heart failure (CHF) using 7 days of rapid pacing to induce cardiomyopathy has been developed in swine (Chow and Farrar, 1992). This model has been used to investigate the hemodynamics and septal positioning of the assist devices that may contribute to right ventricular dysfunction (Chow and Farrar, 1992; Hendry *et al.*, 1994).

Vascular Devices Initially, the pig was developed as a model to study solid organ transplantation. However, more recently its use has made an impact on the study of vascular disease. The pig is currently the species of choice for *in vivo* evaluation of vascular stents, restenosis biology, and balloon injury. The advantages of using swine include (1) easy access to coronary arteries with present catheterization and angioplasty techniques; (2) coronary arteries of sufficient size for catheters used in adult humans; (3) balanced coronary circulation that is anatomically similar to humans; (4) spontaneous development of atherosclerosis; and (5) comparable coagulation and fibrinolytic systems and lipid metabolism to humans (Fritz *et al.*, 1980; White *et al.*, 1989; Karas *et al.*, 1992; Willette *et al.*, 1996).

Numerous *in vitro* studies indicate that the coagulation and fibrinolytic systems in swine closely resemble those of humans (Wilbourn *et al.*, 1993; Karges *et al.*, 1994; Reverdiau-Moalic *et al.*, 1996; Gross, 1997), which would suggest that this may be the ideal species for the preclinical evaluation of the thrombogenic potential of a prosthetic device. *in vivo* studies specifically looking at the thrombogenicity of implantable devices, both

cardiac and noncardiac, have already been performed in swine (Rodgers *et al.*, 1990; Walpoth *et al.*, 1993; Scott *et al.*, 1995). Similar investigations have shown that stent thrombosis may occur early in this model (within 6 hours of implantation), suggesting that if a pig survives the first 12 hours (coronary stent remains patent), it is highly likely that it will not suffer a stent occlusion later (Schwartz and Holmes, 1994). Observations of such rapid restenosis led Schwartz *et al.* to suggest that the pig should be used as an accelerated thrombotic model capable of predicting stent thrombosis within hours of implant (Schwartz and Holmes, 1994). Stenting or balloon inflation in the swine model leads to intimal smooth muscle cell proliferation that closely resembles the cell size, density, and histopathological appearance of that seen in human restenosis (Karas *et al.*, 1992; Bonan *et al.*, 1996; Willette *et al.*, 1996). Additionally, as in humans, there is a predictable relationship between vascular injury and restenosis (i.e., more neointima is formed with deeper lesions) (Willette *et al.*, 1996; Jordan *et al.*, 1998).

Although investigation of stents and balloon injury has mainly been done on coronary arteries (Karas *et al.*, 1992; Bonan *et al.*, 1996; Willette *et al.*, 1996), studies on other arteries such as the iliacs have also been performed (White *et al.*, 1989). Swine have also been used to study the feasibility of percutaneous repair of abdominal aortic aneurysms (AAA). Jordan *et al.* (1998) developed an AAA model using rectus abdominus fascia and demonstrated prolonged survival in stented AAA in comparison to unstented controls. Unfortunately, this AAA model did not accurately mimic aneurysms seen in humans, as the AAA created was sacular and did not reproduce the geometric configuration or collateral circulation and back bleeding observed in human disease (Jordan *et al.*, 1998). Whitbread *et al.* (1996) created an AAA model in swine by interposing fusiform segments of glutaraldehyde-treated bovine internal jugular vein into the infrarenal aorta. This resulted in a pulsatile, nonthrombogenic AAA that approximates human dimensions (20 mm) and geometry (fusiform) (Whitbread *et al.*, 1996). Both AAA models have been used to develop stents and stent placement technology with the goal of reducing the pulsatility and diameter of the aneurysm while maintaining location of the stent without occluding nearby vessels.

Swine have become a useful and popular model to study biomaterials and the devices manufactured from these materials. Anatomic and physiologic similarities to humans have made swine the species of choice to study many cardiac and vascular prostheses, especially in acute studies looking at hemodynamic profiles of different devices. However, difficulties with husbandry and species temperament and a rapid rate of somatic growth have made swine less desirable as models for the chronic evaluation of devices in our experience.

Sheep

Introduction

As a gentle, docile animal, sheep were among the first species to be domesticated approximately 10,000 years ago, as evidenced by pictures and statuettes depicting woolen sheep in the Middle Eastern region. They remain popular to this day as

a source of food and goods. The prevailing theory for the origin of the domestic sheep is that they originated from the wild sheep known as mouflon (*Ovis musimon*). Currently, mouflon can be found in two separate geographic locales: Asiatic mouflon in Asia Minor and southern Iran; and European mouflon on the islands of Sardinia and Corsica (Clutton-Brock, 1999a). The rapid expansion of agriculture and human consumption has been both the cause and effect of routine crossbreeding of sheep. Currently more than 200 different breeds exist worldwide. Common breeds used in surgical research include smaller breeds commonly used for meat commercially, such as the Hampshire and Dorset varieties, or the larger sheep, commonly used for wool commercially, such as the Merino and Rambouillet breeds.

Comparative Anatomy and Physiology

Specific organ differences between humans and sheep are notable (e.g., ruminant gut anatomy). However, in many instances the similarity in organ size of adult sheep to their human counterparts allows adequate approximation for the study of mechanical and bioprosthetic biomaterials and devices prior to human implantation. The ovine thorax has an exaggerated conical shape with a narrow spax (cranial aperture or thoracic inlet) and a caudal thoracic aperture that is six times wider. Cardiopulmonary anatomy is generally similar to that of humans, making sheep ideal models for cardiac research; however, a few anatomic differences require consideration (Hecker, 1974): for example, the single brachiocephalic artery arising from the aortic arch. In addition, tracheal anatomy varies slightly from humans, with the cranial lobe of the right lung arising directly from the trachea rather than the right mainstem bronchus. This variation can pose a difficulty during endotracheal intubation on induction of anesthesia and can result in nonventilation of a significant pulmonary segment (Carroll and Hartsfield, 1996).

Physiologic parameters (heart rate, blood pressure, cardiac index, and intracardiac pressures) have been established through numerous studies in both anesthetized and conscious sheep, including the percentage of blood flow to each major organ system (Matalon *et al.*, 1982; Nesarajah *et al.*, 1983; Newman *et al.*, 1983). In most instances, the hemodynamic and metabolic values are similar to those of other large mammals including humans (Tables 1 and 2).

In cardiovascular bioprosthesis studies, the similarities between human and animal hematologic systems is important. Adequate blood group typing should take place in the event transfusion is necessary. Coagulation parameters and the hematologic profile between sheep and humans reveal some differences, which become important in assessing the thrombogenicity of implanted cardiovascular prostheses. Notably, sheep possess decreased fibrinolytic activity and increased platelet number and adhesiveness (Gajewski and Povar, 1971; Tillman *et al.*, 1981; Karges *et al.*, 1994).

Perioperative Care

Anesthesia Sheep should be fasted preoperatively to decrease the likelihood of regurgitation on induction of

anesthesia and ET intubation. The reticulum, the most proximal rumen, has no sphincter mechanism at its oral end and often needs intubation and suction decompression to prevent regurgitation and aspiration (Holmberg and Olsen, 1987; Carroll and Hartsfield, 1996). Orogastric intubation is especially important if preoperative fasting does not occur. Typically, a sedative is administered IM to allow easy and safe placement of IV catheters for controlled administration of medication. Several sedatives are useful in the pre- and postoperative periods to aid in animal handling, and for performing minor procedures as shown in Table 3. Large named veins such as the internal or external jugular or femoral veins can be used to secure IV access for fluid administration and frequent blood draws. Specialized catheters such as pulmonary artery catheters or long-term tunneled venous catheters (Hickman) may also be placed in these easily accessible, large veins (Tobin and Hunt, 1996). Following placement of a secure IV catheter and the administration of short-acting relaxing agents, ET intubation can safely occur using standard cuffed ET tubes 5–10 mm in internal diameter. Anticholinergics or parasympatholytics, especially atropine, have been used on induction of anesthesia to decrease salivary and respiratory tract secretions. Use of these agents, however, is controversial in ruminants such as sheep, goats, and cattle because they inhibit gastrointestinal smooth muscle activity, which can cause rumen stasis in sheep (Carroll and Hartsfield, 1996). Table 3 lists the recommended dosing of anesthetic agents.

Analgesia Scheduled medication administration and periodic evaluation of behavior can help to ensure adequate pain relief. Sheep should be assessed for changes from their preoperative temperament. Sheep tend to react stoically to pain, and their refusal to move can often indicate even minor discomfort (Carroll and Hartsfield, 1996). Other common clinical signs of postprocedural pain include tachycardia, tachypnea, grunting, grinding teeth, decreased appetite, vocalization on movement, and guarding of the operative site. Commonly used analgesics include narcotics administered via a subcutaneous, IV, or epidural route. Nonsteroidal antiinflammatory agents can be used in divided doses for additional analgesia. Please refer to Table 4 for recommended dosing of analgesics.

Existing Models

Cardiac Devices Because of the similar anatomic and physiologic characteristics of sheep and humans discussed earlier, sheep are often used in cardiovascular biomaterial research and several models have been developed for studying compatibility and function of biomaterials. A total artificial heart model was developed in sheep at the University of Utah's Artificial Heart Laboratory in the 1980s (Holmberg and Olsen, 1987). Other studies examined the potential use of synthetic or xenograft pericardial substitutes to reduce adhesion formation following coronary artery bypass or valve replacement (Gabbay *et al.*, 1989; Bunton *et al.*, 1990).

Many investigators have employed sheep in the preclinical testing of mechanical valves in both the aortic and mitral positions (Barak *et al.*, 1989; Vallana *et al.*, 1992; Irwin *et al.*, 1993; Cremer *et al.*, 1995; Bhuvaneshwar *et al.*, 1996; Okazaki *et al.*,

1996). Our experience reveals juvenile sheep (younger than 20 weeks) to be an excellent long-term model for mechanical prosthetic valve evaluation. Careful standardization to prevent infectious complications, short cardiopulmonary bypass time, whole sheep blood transfusion to minimize anemia, and rumen decompression with an orogastric tube to prevent vena caval compression were found to be useful in the successful implementation of this model (Irwin *et al.*, 1993).

Acute and chronic models of stented bioprosthetic valves are well established through several studies in both the mitral and aortic position in sheep (Gott *et al.*, 1992; Liao *et al.*, 1993; Bianco *et al.*, 1996; Vyavahare *et al.*, 1997; Northrup *et al.*, 1998; Ouyang *et al.*, 1998; Salerno *et al.*, 1998; Spyt *et al.*, 1998). Sheep grow at a rate that allows valves to be subjected to changing physical environment. In contrast, larger ruminants such as cattle and large varieties of swine experience rapid and prolonged growth, until reaching a large adult size (Bianco *et al.*, 1996; Grehan *et al.*, 2000). Such rapid growth can cause difficulties in size matching between prosthetic valves and the native valve annulus, resulting in paravalvular leaks and functional valve stenosis (Braunwald and Bonchek, 1967; Gallo and Frater, 1983; Spyt *et al.*, 1998). Premature leaflet calcification can occur in stented bioprosthetic valves because of abnormal mechanical loading characteristics. This is most consistently reproduced in juvenile sheep (younger than 6 months). We and others currently employ a model in sheep younger than 20 weeks to study both the dynamic environment related to their growth and the chronic effect of calcification in stented porcine bioprosthetic valves in the aortic position (Gott *et al.*, 1992; Liao *et al.*, 1993; Bianco *et al.*, 1996; Ouyang *et al.*, 1998).

Sheep also provide an important model for the study of low-profile stentless aortic valves (David *et al.*, 1988; Brown *et al.*, 1991; Hazekamp *et al.*, 1993; Schoen *et al.*, 1994; Salerno *et al.*, 1998). In this regard we found that, with careful surgical technique including a two-thirds transverse aortotomy for superior exposure and meticulous avoidance of coronary ostial obstruction by the scalloped valve edges, sheep provide an excellent *in vivo* preclinical model to test these aortic valves (Salerno *et al.*, 1998).

In addition to the subcoronary implantation of these stentless devices, this laboratory has also developed a juvenile sheep model of aortic root replacement to allow for the pre-clinical evaluation of new or modified stentless devices using implantation techniques that parallel those seen in clinical practice. Again, careful attention to surgical technique proved to be very important in the success of this model including creation of very generous-sized coronary buttons, inclusion of a posterior "rim" of native aorta in the proximal anastomosis, and the creation of a tension-free distal anastomosis by removing little if any native aorta (Grehan *et al.*, 2001).

Vascular Devices In addition to cardiac devices, researchers have studied the interface between blood and several biomaterial surfaces in the evaluation of biosynthetic vascular grafts placed in sheep. Several authors have noted the reduction in thrombogenicity provided by endothelial seeding of small-diameter synthetic vascular grafts constructed of expanded PTFE or woven Dacron prior to placement in sheep

(James *et al.*, 1992; Taylor *et al.*, 1995; Jensen *et al.*, 1997; Dunn *et al.*, 1996; Poole-Warren *et al.*, 1996). Placement of vascular grafts composed of several engineered surface textures into sheep has also been performed in order to assess characteristics of the pseudointima layer (Fujisawa *et al.*, 1999). Additionally, the important problem of intimal hyperplasia in the venous anastomosis of high-flow arteriovenous fistulas has recently been evaluated in a sheep model (Kohler and Kirkman, 1999).

Recent progress in the development of large-vessel endovascular stents has occurred in part due to research with specific vascular disease models in adult sheep and has been spurred by interest in minimally invasive techniques. As in graft studies, there is significant interest in both the short- and long-term patency of endovascular stents. Stent incorporation into native tissue and the role of foreign-body reaction in normal arterial systems with respect to thrombogenicity and intimal hyperplasia has been evaluated in sheep aortic and iliac arteries (Rousseau *et al.*, 1987; Neville *et al.*, 1994; Schurmann *et al.*, 1998; White *et al.*, 1998). Current efforts have been directed at determining the role of endovascular stenting in the prevention of rupture of abdominal aortic aneurysms and the prevention of complications such as spinal cord ischemia through the use of these stents (Boudghene *et al.*, 1998; Beygui *et al.*, 1999).

Current cardiovascular research has embraced the humane use of sheep for the testing of a variety of cardiac and vascular devices composed of many different biomaterials. In all of these investigations, sheep have proved a useful and reliable model, as evidenced by this laboratory's continued success using both juvenile and adult sheep for a variety of investigations. Current research supports the broader application of emerging endovascular technologies. With many anatomic and physiologic similarities to humans and a temperament that facilitates handling, sheep should continue to serve an important role in future investigations into biomaterials testing and development.

TESTING HIERARCHIES

Introduction

The ultimate fate for many new or modified biomaterials is to become a cardiac or vascular device intended for clinical use. Before this can occur, however, extensive testing must be performed and specific criteria must be met. This section will focus on preclinical *in vivo* evaluation standards that new or modified cardiac and vascular devices must meet before clinical evaluation can be considered. These criteria have been established by the International Organization for Standardization (ISO) and can be found in document CV5840-1996 (Cardiovascular implants—Cardiac valve prostheses) and CV7198-1994 (Cardiovascular implants—Tubular vascular prostheses). These documents contain information on all aspects of testing from the initial *in vitro* assessment to final packaging requirements. We will limit our discussion to the established standards for *in vivo* preclinical evaluation of cardiac valvular and tubular vascular prostheses. The standards that apply to the experimental methodology used in the investigation and the specific

study criteria that must be met, as well as required results documentation, will be delineated. Following this, a short discussion on the future directions of these standards and the predicted impact these changes may have on the study of these types of devices will be presented.

Current Recommendations

Cardiac Devices

Rationale The objective of preclinical *in vivo* testing is to evaluate the performance characteristics of cardiac devices such as surgical handling characteristics, hemodynamic performance, and the development of valve-related pathology. Although it is not feasible to assess the long-term durability of a cardiac device using an animal model, valuable data on hemodynamic performance and biological compatibility can be obtained. Additionally, during *in vivo* testing unanticipated side effects of the device can be discovered. In order to ensure that new or modified cardiac valvular prostheses are assessed in a uniform manner, the ISO has established a set of guidelines to direct both designers and investigators.

Methods Before any new or modified cardiac valve is allowed to undergo clinical evaluation the ISO requires that it be tested in an *in vivo* animal model in at least one of its intended anatomic positions. The device tested must be of clinical quality and of the same design and size of those intended for clinical use. Additionally, ISO requires that implantation be carried out using the same surgical technique for all of the implants being evaluated (e.g., suture technique, anatomic location, and valve orientation). The devices should be evaluated in at least six animals of the same species (preferably the same sex and age as well) for a duration of 20 weeks. At least two of the animals should be implanted with a reference (clinically approved) device to serve as concurrent controls.

Further specifications require each animal in which a cardiac device has been implanted to undergo a post-mortem examination. This ensures that data will be obtained from all animals; whether or not they survive the 20-week study period. An evaluation of hemodynamic performance of the device during or after the 20-week implantation period must be performed. This assessment should include measurement of the pressure gradient across the implanted device at a cardiac index of approximately 3 L/min/m². Additionally, an assessment of resting cardiac output and prosthesis regurgitation should be performed. A pathologic evaluation of the study animals should also be performed and should include an assessment of the major organs for valve-related pathology; an evaluation for any device-related hematological consequences; and an assessment of any structural changes of the heart valve substitute.

Reporting Results from these evaluations should be documented in an official report that describes the findings of the investigation in detail. This report should include the name of the institution(s) and investigator(s) involved in the study. A detailed description of the animal model used in the investigation and the rationale for its use should also be included. A pretest health assessment, including study animal age at the

time of implantation, should also be included for each animal used in the study. A description of the operative procedure, including the suture technique, the orientation of the heart valve substitute, and any operative complications, should also be detailed. Descriptions of any adjuvant procedures the animals underwent during the study period (e.g., phlebotomy, angiography) should also be provided. The results of all blood tests, including a statement of the time elapsed between implantation and procurement of the sample should be provided. Blood tests should include an evaluation of the hematologic profile (with emphasis on hemolysis), and blood chemistries. Additionally, the report should include a subjective assessment of specific surgical handling characteristics of the device and any accessories. This assessment should include a discussion of unusual and/or unique attributes the device might possess. The report must contain a complete list of medications administered to the animals during the study period. Finally, the report should contain the results obtained from the hemodynamic studies to assist in the assessment of hemodynamic performance.

Pathologic documentation should include a gross and microscopic report on each animal in which a heart valve substitute was implanted, including any animal that did not survive for the minimum postimplantation period. Documentation should include visual records of the heart valve substitute *in situ* and evidence of any thromboembolic events occurring in the major organs. The cause of death of any animal that was not euthanized should be investigated and reported. Detailed examination of the explant must be performed, with specific attention to any structural changes in the device. If appropriate, further *in vitro* functional studies of the heart valve substitute should be undertaken (i.e., hydrodynamic testing).

Vascular Devices

Rationale As with cardiac devices, the purpose of *in vivo* preclinical testing of vascular prostheses is to evaluate the characteristics of a prosthesis that are difficult, if not impossible, to obtain using *in vitro* testing models. The capacity of the prosthesis to maintain physiologic function when used in the circulatory system, the biologic compatibility of the prosthetic, and the surgical handling characteristics of the prosthesis are all important features that can be evaluated using an *in vivo* model and cannot be obtained with *in vitro* testing methods. This testing is not intended to demonstrate the long-term performance of the prosthesis, but rather the short-term (less than 20 weeks) response and patency of the prosthesis being investigated.

Methods In designing an experimental protocol that will ensure clinical relevance, researchers should consider the intended application of the device being studied as well as the necessary diameter and length of the prosthesis. Additionally, investigators should reflect on any specific biological characteristic of the chosen animal model and the impact of those characteristics on their conclusions. Current ISO requirements state that a rationale for the use of a particular species, the site of implantation, the selection of a control prosthesis, the method and interval of patency observations, and the number of animals used in each group being studied be provided. Each

type of prosthesis shall have been tested by implantation at the intended, or at an analogous, vascular site in not fewer than six animals for not less than 20 weeks in each animal unless a justification for a shorter-term study can be provided. A prosthesis shall not be tested in a species from which it was derived, unless appropriate justification can be provided. Angiography or Doppler should be used to monitor the duration of patency for each prosthesis and the results recorded. Each investigation should include a control group in which a clinically approved vascular prosthesis is implanted and studied in the same fashion as the experimental prosthesis.

Preoperative data should include the sex and weight of the animal, documentation of satisfactory preoperative health status, and any preoperative medications. Operative data must include the name of the implanting surgeon and a detailed description of the surgical procedure, to include the type and technique used in performing the proximal and distal anastomoses. The *in situ* length and diameter of the prosthesis in addition to any adverse intraoperative events (e.g., transmural blood leakage) must also be documented. Postoperative medications, patency assessments (method and interval from implantation), and any adverse event or deviation from protocol must be noted. Loss of patency before the intended study duration does not necessarily exclude the animal from the study population used to assess prosthetic function and host tissue response. All animals implanted with either test or control prostheses, including those excluded from the final analysis, shall be recorded and reported. Termination data should include an assessment of prosthesis patency (documenting the method used) and an assessment of prosthesis explant pathology.

Reporting At the conclusion of the study, a detailed report should be compiled in which the study protocol is delineated. The report should include the rationale for selection of animal species; implantation site; control prosthesis; method of patency assessment; and the intervals of observation. Additionally, documentation of sample size and pertinent operative, perioperative, and termination data must be presented. The results should include the patency rates and any adverse event that was encountered during the study interval and should be compared between the study and control groups. All animals entered into the study must be accounted for in the report. If data are excluded a rationale must be provided. A summary of pathology including photographs of the prosthesis *in situ* and micrographs should also be provided. In addition to these objective results, a subjective statement of the investigator's opinion of the device must be included. Finally, conclusions drawn from the study and a summary of the data auditing procedures should be documented.

Future Directions

The use of animals to predict clinical safety is an essential (and required) phase in the development of new or modified medical device technology. It is extremely unlikely, however, that preclinical use of animal models to assess new technology will ever evolve to the point that absolute statements can be offered regarding future clinical performance. Therefore, the

enhancement of the predictive qualities of human safety and efficacy based on preclinical *in vivo* evaluations should be our priority.

Enhanced prediction of human safety and efficacy can be achieved by developing increasingly more relevant models of human disease and developing models in which new or modified devices are implanted orthotopically in each intended clinical location (site specific testing). Additionally, each preclinical study design should include an appropriate control "arm." This "arm" of the study should include animals implanted with a device that is currently approved and being used clinically. The control device should be of similar design (or preservation technique) as the device undergoing investigation and should be implanted using the same techniques. The use of concurrent control implants offers several advantages. First, it provides a direct clinical bridge to assess performance of a new or modified device. Second, it provides an assessment of the model utilized in the investigation relative to a device with a known clinical history. Finally, it can reduce the number of implants required in each investigation by providing a correlation to historical animal and clinical data.

The use of animals to predict human safety will and should remain a crucial part of the regulatory requirements governing medical device development and modification. In order to enhance the predictive quality of preclinical *in vivo* evaluations current models need to be refined and new models need to be developed that more closely mimic both human disease and the intended clinical use of the device under investigation. As these models are developed and perfected they should become part of the current standards to be met by investigators working in prostheses development. In addition, each preclinical evaluation should include the concurrent implantation of appropriate control devices so that comparisons of the investigational data obtained can be made to that of concurrent and historic animal and clinical control data. This will allow more accurate assessments of both the investigational device and the model to be made.

Acknowledgments

The authors thank Agustin P. Dalmaso for his editorial assistance and the staff and student employees of the University of Minnesota Department of Surgery's Division of Experimental Surgical Services for their commitment to achieving scientific accuracy and providing humane care to the investigational animals.

5.6 MICROSCOPY FOR BIOMATERIALS SCIENCE

Kip D. Hauch

Along with test tubes, beakers, and a white lab coat, the microscope is an icon of the professional scientist's toolchest. Of all the senses, the scientist relies most heavily on vision; thus the advent of the light microscope is among the earliest and arguably most powerful tools in the history of science. Today, microscopy in its various forms still remains as the preeminent tool at the forefront of scientific exploration. Thus the biomaterials scientist makes extensive use of both light and electron microscopes to help fabricate and characterize new materials, coatings, and devices, and to study the behavior of cells and tissues at the biomaterials interface. This chapter will familiarize the reader with the more common microscopy tools used in current biomaterials research. The key concepts of magnification, resolution, and contrast are first introduced and then their meaning explored in the context of light microscopy. Digital Imaging is very briefly addressed. Attention then moves to the electron microscopies, specifically SEM. Fortunately, the ubiquitous importance of microscopy in the practice of science means that there exist numerous excellent resources to consult on these topics. A brief guide to some useful resources is found at the end of the chapter.

MAGNIFICATION, RESOLUTION, AND CONTRAST

The art of Scientific Instrumentation is to devise tools to observe natural phenomena and present them appropriately to

our senses for interpretation (e.g., to our eyes as an image). Three concepts apply to this process: magnification, resolution, and contrast. The three concepts are interdependent, and frequently limitations in one aspect or the others lead to trade-offs.

Magnification is the appropriate scaling of the phenomena to our detectors (ultimately, for our purposes here, the human visual system). In a standard light microscope this is accomplished through the millennia old traditions of refracting light through curved glass lenses (e.g., an objective lens, or an ocular). In the electron microscope, as well as the other scanning microscopies (e.g., laser scanning confocal, multiphoton, scanning tunneling, or atomic force microscopies), photons or electrons are used to probe the sample discretely at a single point. The location of this sampling point is then rastered across the sample. Magnification is achieved by displaying the combined results from this "probing" on a more appropriate scale.

Resolution is dependent on the information present in the collected data sufficient to allow one to achieve perception. In microscopy we are usually interested in spatial resolution—the ability to resolve one location from another in an image. Resolution is often limited by the physical nature of the probe and/or the measurement of the signal thereof.

Contrast is the ability to detect specific differences in the signal. More than just signal/noise, contrast implies some aspect of specificity—the ability to tell one particular part of an image or signal from another. Resolution and contrast are often related—one is often gained at the expense of the other. With respect to light microscopes, the fundamental limits of magnification and resolution have generally been reached long ago. New and varied methods for the generation of contrast are what lead to the many different modalities of light microscopy—and as will be shown here, continue to be a source of technological development.

CONFIGURATIONS

A specimen can be imaged by passing illuminating photons or electrons through the sample (transmission microscopy, diascopic illumination) or by reflecting the illumination off the sample (reflected microscopy, episcopic illumination) to a detector.

In transmission microscopy, the sample must be thin enough to allow the probe to pass through the sample and reach the detector. For example, in transmitted light microscopy (probe = photons), samples may be up to 100 μm thick (although for typical high-resolution histology work, sections of tissue are prepared that are nominally only 5 μm thick.) In transmission electron microscopy (TEM, probe = electrons), samples are prepared that are only 50 nm thick.

Reflected techniques are used when the sample is opaque. The sample must reflect the illumination or otherwise generate a signal that is directed from the surface back to a detector. Reflected light is how we are used to viewing the everyday world around us. Reflected light techniques include simple magnifying hand lenses, stereoscopes and dissecting/operating room microscopes, and compound microscopes commonly

used in the material sciences or manufacturing sector. As will be discussed, fluorescence-based techniques are almost always performed with episcopic illumination. Scanning electron microscopy (SEM) can be considered in this category as well, although the signal generated is somewhat more complex than simply the detection of reflected electrons.

LIGHT MICROSCOPY

The biomaterials scientist relies daily on a variety of light microscopes for tasks ranging from routine materials inspection to detailed complex biologic analyses. The interests of the biomaterials engineer are often focused on the biologic responses at the cell–biomaterial interface. These are studied *in vitro*, e.g., using cell culturing approaches, or studied *in vivo* through the examination of a tissue–implant interface. In this regard, the microscopy needs of the biomaterials scientist overlap significantly with those of the molecular cell biologist or pathologist. The presence of a biomaterial in the sample is often just another (sometimes complicating) factor to be dealt with.

Platforms

Light microscopes can be configured on several different platforms—for different purposes and with varying levels of customization. Hand lenses, loupes, stereoscopes, and dissecting microscopes are essential for fabrication and inspection of small biomedical devices and coatings. Likewise, operating microscopes are often helpful for implant work in small animal models. An upright microscope is one in which the sample is observed from above by an objective lens. Upright microscopes are used most often for histology work and are equipped with high-resolution but short-working-distance optics. A typical sample might be a slice of tissue mounted between a microscope slide and a coverslip. An inverted microscope is the mainstay of the tissue culture laboratory, where specimens are viewed through objective lenses positioned underneath the specimen stage. This allows for the observation of live cells in culture, e.g., through the transparent bottoms of tissue culture flasks or multiwell plates. The large open stage of the inverted instrument allows for more experimental versatility, e.g., the use of complicated flow cells, micromanipulators, or environmental enclosures. An inverted instrument is often equipped with slightly lower resolution, but longer working-distance optics. Either platform may be augmented for the specialized techniques to be discussed later, namely phase contrast, differential interference contrast, and fluorescence microscopy. With respect to research-grade instruments, there are more similarities than differences in the capabilities of the upright and inverted platforms. However, it is crucial that the choice of instrument platform and the experimental design receive mutual consideration early in the experimental planning stages.

Magnification in Light Microscopy

Magnification refers to the ratio of a feature dimension in the presented image to the corresponding feature dimension in

the original specimen. In common practice, the range of magnification available in light microscopy reaches from $5\times$ to about $1000\times$ (a $100\times$ objective lens and a $10\times$ ocular). These values describe the magnification of the sample at the plane of the primary detector—our eyes at the ocular. Herein lies danger for the modern microscopist, since invariably it is not our eyes, but rather a digital camera that acquires an image for dissemination to our colleagues. The camera does not use the $10\times$ ocular; rather it uses a combination of extension tubes, transfer optics, intermediate magnifiers or reducers, camera coupling lenses, etc. Further, the acquired digital data are then displayed on computer monitors directly as images or embedded in mixed content files (.pdf) at different “zoom levels”; printed on paper for reports, reduced in journal pages, or plastered on poster boards for conferences; perhaps even displayed using data projectors onto huge screens in an auditorium. What then does magnification mean?

The days of conveying the level of magnification in an image by reporting the magnification of the objective lens alone, or using vague terms such as “low power” or “high power,” are long gone. In the digital age it is far preferable to include a true size scale bar as part of every published image. This is conveniently done by separately acquiring an image containing objects of known size, most commonly a stage micrometer available through any microscopy supply house. With an image containing an object of known dimension, it is then straightforward to establish the relationship between distance (μm) in the specimen and pixels, the individual element of the acquired digital image. A scale bar can then be embedded in the images used for presentation, and measurements of feature size reported directly in appropriate units. Further—no matter how the image is then later displayed, the viewer will have a direct feel for the size of the features in the image. Modern software makes these operations relatively painless, and the side-by-side presentation of images taken at macroscopic, microscopic, and nanoscopic scales makes this practice indispensable to the scientific audience.

Resolution in Light Microscopy

The Rayleigh criterion is often used to describe the resolving power in light microscopy.

$$d = 1.22\lambda / (\text{NA}_{\text{condenser}} + \text{NA}_{\text{obj}}) \text{ for brightfield,}$$

and

$$d = 0.61\lambda / \text{NA}_{\text{obj}} \text{ for fluorescence,}$$

where λ is the wavelength of light. NA is the numerical aperture of the condenser or objective lens and is defined as

$$\text{NA} = n \sin \Theta$$

where n is the index of refraction of the medium between the lens and the sample (1.0 for air, 1.515 for oil) and Θ is the half-angle of the cone of light collected by the lens (Fig. 1). Similarly, the depth of focus, which is the thickness in the sample within which features will all appear in focus, is given by

$$Z = n\lambda / \text{NA}_{\text{obj}}^2$$

FIG. 1. Numerical aperture: Θ = half the acceptance angle of the lens, n = the refractive index of the medium between the sample and the objective, $n = 1.00$ for air, $n = 1.515$ for oil.

These equations are idealized and are based on the first overlap of the diffraction patterns of two infinitely small point sources in the specimen. For monochromatic light at 546 nm and a high-quality oil immersion lens with a NA of 1.3, this equates to a resolving power of about $0.26 \mu\text{m}$, easily adequate to resolve many subcellular organelles. Most modern research-grade microscopes are quite capable of realizing this resolution limit. However, the use of polychromatic white light may increase this value twofold. Further, the large values of NA_{cond} , which lead to optimal resolution, actually reduce the contrast available in the image. Thus, we may achieve superb resolution but not be able to distinguish the features which we seek to resolve! Here we find one of the classic trade-offs—between resolution and contrast.

It is important to understand the resolution available in an image when considering the tools for digital image acquisition. Ideally, the physical size of the individual sensing elements (e.g., the pixel on a digital imager) will be less than half the smallest resolvable feature size, after magnification by the objective and any intermediate magnifiers between the microscope and the imaging plane. The appropriate matching of physical pixel size in the detector to the resolving power of the optics is crucial, and if overlooked can result in degraded system performance. One finds that our eyes, and high-quality film, are well suited to the task. Lower power but relatively higher NA objectives (e.g. $10\times/0.4$, $20\times/0.75$) are the most demanding, i.e., they require the smallest pixels, and hence largest number of pixels in the detector.

Contrast and the Various Modes of Light Microscopy

The interaction of light with matter is what generates the contrast that we detect in a microscope image. Light can

be characterized by its amplitude, wavelength, phase, and polarization. Unfortunately, our human eyes, and most other electronic detectors, are sensitive only to amplitude and wavelength! Thus a light microscope must convert these many interactions of light and matter into differences in amplitude or wavelength that can be detected in the image. The various ways in which contrast is generated lead to the various light microscopy techniques, or modalities. These are described here in quite general terms—the reader is encouraged to explore the many excellent introductory texts on optical microscopy for more thorough coverage.

Transmitted Light Microscopy

The simplest way to view a thin specimen is to shine light through the specimen and view the magnified image directly. In this method, brightfield, we rely on the sample to provide its own contrast. Different features in the specimen may absorb some of the light and/or do so unequally at various wavelengths, thus leading to amplitude or color contrast. In many instances this may work—but consider a layer of unadulterated cultured cells on a glass slide. These cells, if well spread, may only be a few microns thick; made mostly of water, they absorb very little light and provide almost no contrast. Indeed it may be very difficult to see the unstained cells at all!

Another technique is darkfield microscopy. In darkfield the sample is illuminated obliquely, at such glancing angles that the illumination light, if undisturbed by the specimen, does not even enter the objective lens. Thus the empty areas (the background areas or “surround”) in the image are completely black. Only where elements in the sample scatter light into the objective lens is light collected. Thus a darkfield image appears as pinpoints of light on a black background. Darkfield is particularly effective if the specimen contains small particulates.

Adding Contrast Agents: Chromophores and Fluorophores

How then can one generate more contrast in a specimen? The simplest answer is to cheat! Exogenous contrast agents can be added to the specimen. These are strongly absorbing or fluorescing large molecules or nanoparticles that are placed into the sample and ideally reside only in certain structures or features of the investigator’s choosing. This, of course, is what is done in the staining of cells or tissue sections for histology. Many of these chromophores or stains date to ancient times when they were used to dye biologic materials, such as plant and animal tissues, skins, or textile fibers. Perhaps the most common histologic stains are hematoxylin and eosin (H and E). Hematoxylin (which appears blue) is termed a basophilic dye and binds to basic components such as those found in the cell nucleus. Eosin (which appears pink and is also quite fluorescent) is acidophilic and generally stains cytoplasmic proteins. A plethora of histologic stains is available to stain a myriad of cells, or structures within cells and tissues. Other common examples include Masson’s trichrome, which is used to stain connective tissue or fibrosis around implants (collagen is

green); alizarin red, for calcific deposits; ver Hoeff's for elastin; Geimsa and Wright's stain for blood cells; and the Gram stain for bacteria.

It is easy to see the beauty in chromophores (both literally and figuratively) since not only do they generate contrast in the image, but they do so with specificity. The investigator not only can see the cell, but can now see which part is a nucleus, determine the specific location of structural proteins, etc. This power of specificity can be enhanced by directly (covalently) linking chromophores or fluorophores to specific proteins or other molecules of interest, and then identifying and following the location of these reporter-linked conjugates on surfaces, inside cells, and in tissues.

Further, chromogenic substrates have been synthesized for certain key enzymes. These substrates are converted from colorless to colored (or otherwise undergo a color change) upon cleavage by the enzyme. Examples are the many substrates available for horseradish peroxidase, alkaline phosphatase, and β -galactosidase. These substrates can be used to detect enzymatic activity in certain cells and tissues directly.

Reaching yet another level of specificity, these enzymes can be conjugated to antibodies to impart molecular-level specificity in their binding. Thus the location of specific molecular antigens can be elucidated by allowing these antibody conjugates to bind, and then revealing the location of the antibodies by using the chromogenic substrates. This process (immunohistochemistry) is directly analogous to forms of the enzyme-linked immunosorbent assays (ELISA) used on the benchtop. Alternatively, the antibodies may be labeled directly with a fluorophore (direct immunofluorescence), or their locations revealed by the binding of a second labeled antibody that recognizes the first (secondary or indirect immunofluorescence). Finally, similarly labeled nucleic acid strands can be used to probe for and reveal the presence of certain sequences of genomic material in cells (*in situ* hybridization) or on surfaces (so-called microarray analysis) and thus give a glimpse into the genomic profile of cells and tissues.

The immense power and versatility afforded by the use of chromophores and fluorophores is now made clear. Beyond simply generating contrast, they provide molecular-level specificity. This enables the investigator not only to simply visualize cells and structures, but to begin to ask specific cell-physiology and bioengineering questions: is a particular species (a molecule, protein, receptor, enzyme) present? If so where is it, when does it appear, and in what quantities? Here in this generation of contrast lies the power of modern microscopy and its contribution to the cell biology and pathology fields so integral to the study of the biomaterials–biology interface. Because fluorophores play such a prominent role in these techniques, and since their use requires specialized technical approaches, fluorescence microscopy will be addressed in more detail in a separate section.

Optical Tricks: More Contrast—but No Cheating

So far, to generate contrast we have relied on the inherent contrast in the specimen (often inadequate) or the addition of contrast agents. Many of these contrast agents are toxic

to cells. Histologic stains are typically used on tissue sections where cells have been fixed, embedded in a support matrix, and sliced open. Probes that bind to intracellular components have to cross the cell membrane; thus cells are permeabilized to allow access. Although there are “vital dyes” that can be used on living cells, many of the approaches described above interfere with the normal physiologic functioning of the cell. Thus, they are best suited for endpoint analysis. How then can one more safely generate contrast in living cells? How can one generate contrast without the addition of these exogenous agents? How can one generate contrast without “cheating?”

Fortunately the answer lies in several types of optical “tricks.” Cells have limited ability to cause absorbance or color changes. However, there is plenty of diffraction (bending of light around organelles), refraction (bending of light at interfaces of structures with different indices of refraction, e.g., membranes), and other optical phenomena that can be used to our advantage. Unfortunately, our eyes are insensitive to all but changes in light intensity and color. The tricks, therefore, will be used to convert these other phenomena into differences in intensity or color, which we then can detect. These techniques all involve optical elements placed in the light path that modulate the incoming light, as well as elements that modulate the light collected by the objective. As such the sample usually resides in the middle of these two elements, and thus these can be thought of as the “sandwich techniques” (Foster, 1997).

Polarization

Molecules and materials that exhibit a strong regular repeat in their electronic structures are likely to induce orientationally specific changes in polarization during their interactions with light. Examples of such polarizing (birefringent) materials include metals, inorganic and organic crystals, collagen, certain organelles, muscle sarcomeres, and many others. Recall that light polarized by a polarizing filter will not be transmitted through a second polarizing filter oriented at 90° to the first (extinction). If the first filter is placed in the illumination path before reaching the sample, and the second filter is placed in the imaging path after sample, extinction will take place. No light will get through, provided that the sample does not impart any additional polarization to the transmitted light. However, if the sample *does* impart additional polarization, the conditions for extinction will be unsatisfied and the location of the polarizing materials immediately revealed. The degree of this additional polarization induced by the sample can even be measured with yet a third polarizing element (a compensator). The directionality of the polarization can be determined by rotating the specimen stage.

Synthetic polymers, of course, can also contain strong regular repeats in their electronic structure. This can be very useful in locating and identifying remnants of implanted polymeric materials in explanted tissue. The polarization induced by polymers can also be a disadvantage, however, as the plastics used in common tissue-culture ware make polarization microscopy nearly impossible using these substrates.

Phase Contrast and Hoffman Modulation Contrast

While there may be little amplitude change when light traverses a cell, there is plenty of diffraction of light by organelles, structures, and membranes. These rays that have interacted with the specimen experience an (unnoticeable) change in phase, having experienced an optical path-length difference $\Delta = (n_2 - n_1)(\text{thickness})$. Typically, the light is retarded in phase by an amount approximately $-\lambda/4$. In the 1930s, Dutch physicist Fritz Zernicke invented a method to convert these phase changes into changes in intensity. The result was phase contrast microscopy and the method helped foster the major advances in cell biology developed through the study of living cells in culture. For his work, Zernicke received the Nobel prize in 1953.

The key to phase contrast is to somehow separate those rays of light that pass through the specimen undisturbed (undiffracted) and thus contribute to the background (called the surround, S), from those rays that have been diffracted by interaction with the specimen (D). This can be accomplished spatially at a special plane in the optical path, the diffraction plane. At this plane an image is not formed; rather one can envision that rays of light are separated spatially by their degree of diffraction. Here each can be manipulated or treated selectively. In phase contrast, an annulus is placed in the illumination light path in a plane conjugate to this diffraction plane (Fig. 2). This results in a ring or cone of illumination approaching the specimen. Next, a special plate is placed at the diffraction plane, beyond the sample (actually located within the objective lens). This plate is constructed such that its thickness is less in a ring shaped region that matches exactly that of the ring in the annulus plate. Thus rays of light that are not diffracted (S) will pass through this “phase ring,” while diffracted rays (D) will pass through the remaining portions of the phase plate. This phase ring results in a relative $+\lambda/4$ advancement in the phase of light that is undiffracted. Further this ring is made semitransparent, so that the light transmitted (i.e., the light that will contribute to the background in the final image) is reduced in intensity and thus appears gray. The diffracted rays have already experienced a retardation in their phase caused by their interactions with the specimen ($-\lambda/4$). When the surround (S) and the diffracted rays (D) are recombined in the real image plane, the resulting phase difference is $(\lambda/2)$ and destructive interference takes place. Now, the changes in phase are converted to a reduction in intensity—which is made manifest in the recombined image as areas of dark (black).

We see that phase contrast is again a “sandwich technique” utilizing a phase ring in the illumination path, and a matching ring in the image-forming path. The sample is in the middle. This latter ring is actually physically built into the objective lens, and thus phase contrast microscopy requires a special phase contrast objective and the use of a matching and carefully aligned phase annulus for each objective. Fortunately phase contrast objectives can also be used for routine brightfield observation and most fluorescence applications, so for many labs they are a good value.

Phase contrast is ideal for thinly spread cells such as those in cell culture. They appear in high contrast, their organelles

FIG. 2. Phase contrast microscopy in an inverted microscope.

and pseudopodia revealed in areas of bright and dark on a gray background. Rounded cells, however, are surrounded by a strong halo of bright light. Simple phase contrast systems (often with fixed and prealigned annuli) are commonplace on inexpensive inverted microscopes found in tissue culture suites.

In Hoffman modulation contrast (no relation to this text’s editor!) use is made again of the spatial separation of diffracted and undiffracted rays at the diffraction plane (Fig. 3). This time, instead of a cone of illumination an asymmetric slit is placed in the illumination path. Again a modulation plate is built into the objective placed at the diffraction plane. Also again, a semitransparent region is constructed to catch the rays of light emanating from the illumination slit and transversing the specimen undisturbed, thus resulting in a gray background. To one side of this surround region in the modulation plate, the plate is made fully transparent, while to the other side the plate is made opaque. The result then is that rays that are diffracted slightly in one direction appear quite bright, while rays diffracted in the opposite direction appear dark. In the recombined real image these variations in intensity appear as shades from light to dark across structural boundaries in the specimen. Our eyes conveniently interpret these gradations as shadows! The specimen takes on a distinct and crisp three-dimensional appearance. Hoffman modulation contrast also

FIG. 3. Hoffman modulation contrast. Oblique illumination is provided by an off-axis slit in the condenser aperture. A modulator plate with matching complementary slit is placed in the objective back aperture and differentially blocks one sideband of diffracted light. From Murphy (2001).

requires the use of special objectives and illumination systems. Its use is compatible with tissue culture plasticware, unlike the other, more familiar shadow-like technique, DIC, which is discussed next.

Differential Interference Contrast Microscopy

The techniques discussed so far have converted differences in the optical path length through the specimen into variations in image intensity by utilizing oblique illumination and tricks at the diffraction plane. In differential interference contrast (DIC) microscopy; also called Nomarski, gradients in optical path length are sensed in a slightly different way—by splitting the incoming light into two parallel rays and allowing each ray to sample nearby areas of the sample, before being recombined to form an image. DIC is akin to an imaging version of a dual-beam interferometer.

DIC starts with linearly polarized light; thus a polarizer is again the first extra element in the illumination path (Fig. 4). Next, mounted near the condenser is a modified Wollaston prism that separates the incoming light into two parallel rays. These two rays of light are physically separated by a small fraction of a micron—indeed, a distance less than the resolved distance of the microscope. These two rays traverse

FIG. 4. Differential interference contrast on an upright microscope. Light is first linearly polarized, then split by the condenser prism (#1) into two spatially separate beams (shown as solid and dashed). If the two beams do not experience an optical path difference (inset), then they are recombined by the objective prism (#2) into a single ray that is again linearly polarized. This ray is then rejected by the second polarizer (the analyzer). If the two beams do experience an optical path difference in the sample, then the recombined ray is elliptically polarized and is partially transmitted by the analyzer. In this way spatial difference or gradients of refractive index in the sample are converted to differences in intensity (After Murphy, 2001).

the specimen, and should they experience the same optical path through the specimen (i.e., no optical path difference), they are then recombined by a second prism located beyond the objective, again at the diffraction plane. This recombined light is again linearly polarized and can be selectively rejected by the use of a second polarizer (termed an analyzer) oriented at 90° to the first. In the presence of an optical path difference (e.g., due to a gradient in the index of refraction in the sample), the two rays are recombined and result in an elliptically polarized beam, which is now only partially attenuated by the analyzer. Thus, gradients in refractive index present in the sample are converted into gradients in intensity in the image. Our eyes perceive these as shadows and the sample takes on the striking appearance of three-dimensional relief. In practice, the objective prism is typically offset slightly so that the surround is not purely attenuated (black), but rather appears in shades of gray along the diagonal of the image.

Since DIC utilizes polarization in generating the contrast, it is not suitable for use with tissue culture plasticware, which will induce extraneous polarization. DIC produces crisp clear images in unstained specimens, with extraordinarily shallow depth of focus. This makes it ideal for optical sectioning tasks. DIC components are expensive and must be made from strain-free glasses. DIC is particularly amenable to combination with fluorescence techniques—where the fluorescence labeling provides the spatial localization of specific intracellular features (e.g., a nucleus or cytoskeleton) and DIC provides clarity to the body of the cell and other organelles.

FLUORESCENCE MICROSCOPY

Like chromophores, fluorophores are (usually) exogenous large molecules whose unique spectral properties make them readily identifiable under the microscope and thus generate contrast. Fluorescence techniques have had a wide-ranging and tremendous impact in the fields of molecular and cell biology, genomics, biophysics, bioengineering, and many others.

In the process of fluorescence, the fluorophore absorbs energy of a particular wavelength. While a small amount of this absorbed energy is lost to heat, the remainder is very quickly given up by the fluorophore as it reemits the energy as light of a slightly longer (less energetic) wavelength. The difference between these excitation and emission wavelengths is called the Stokes shift and provides the basis upon which the incoming and outgoing (emitted) light can be spectrally separated.

Fluorescein (known, together with its covalent linkage group isothiocyanate, as FITC) is perhaps the best known fluorophore. Today, there exist hundreds of new fluorophores, with various chemistries and spectral properties ranging from those excited by light in the UV range to the far red. The synthesis of new fluorophores with improved properties (e.g., increased quantum efficiency, resistance to photobleaching, narrower spectral characteristics) is an active enterprise. Excellent resources are available from vendors to help guide the choice of fluorophores for a myriad of applications (e.g., Molecular Probes, Inc.).

The applications of fluorescence are indeed numerous. As discussed earlier, fluorophores can be conjugated to a variety of biologically important molecules (lipids, membrane components, proteins, enzymes, antibodies, nucleotides, specific organelles) to serve a variety of reporting functions. Just a few common examples are the fluorophore DAPI to label cell nuclei and observe nuclear fragmentation during apoptosis; fluorescent conjugates of the mushroom toxin phalloidin which bind to f-actin in the cytoskeleton; and DiI for long-term cell tracking. The enzymatic activity of cells can be assessed by fluorescence, e.g., in the Live/Dead cell assay (Molecular Probes), where a masked nonfluorescent form of the green fluorophore calcein is cleaved by intracellular esterases in living cells, while dead cells fail to exclude the nuclear binding dye ethidium homodimer from their nuclei, which are then stained red. In this and many other systems, simultaneous labeling and imaging of multiple fluorophores is the norm.

Fluorophores can also be used to sense microenvironmental parameters, e.g., pH or the concentration of various ions

such as Na^+ , K^+ , Cl^- , Ca^{2+} . The technique of FRAP, fluorescence recovery after photobleaching, can be used to study the intracellular dynamics or mobility of labeled macromolecules. In the technique named FRET, Förster resonance energy transfer, the proximity of two labeled molecules (or even two labeled domains on the same macromolecule) can be detected, as a donor fluorophore directly excites an acceptor fluorophore only when the two species are within a molecular distance of each other. This is truly an intermolecular ruler! Finally, the gene for the photoprotein from the jellyfish *Aequorea victoria*, green fluorescent protein (GFP), has been cloned. This has been used to create numerous fluorescent chimeric proteins that can be directly expressed in living cells. A number of mutations have yielded blue, cyan, and yellow variants. Another class of photoproteins, dsRed, from *Anemone* is also in use. These advances give biologists unprecedented power to observe the processes of protein expression in cell populations.

Instrumentation for Fluorescence

Because of the small number of fluorophores often present and the potentially low quantum efficiency, fluorescence techniques require special, strong illumination sources. These are typically mercury or xenon arc lamps, or lasers. Fluorescence benefits from the use of very efficient collection optics, i.e., objective lenses with the highest possible NA. Detection is typically achieved with sensitive imagers, e.g., cooled CCD cameras or photomultiplier tubes (PMTs).

Fluorescence microscopy can be performed on upright or inverted microscopes equipped with an arc lamp, and appropriate filters and mirrors. This is known as wide-field fluorescence microscopy. (An alternative technique, laser scanning confocal, and multiphoton instruments will be discussed in the next section.) In wide-field epifluorescence microscopy, illumination light from a Hg arc lamp is first passed through a band-pass filter that rejects all light save those wavelengths required to excite the fluorophore (the excitation band pass filter) (Fig. 5). Next, this excitation light hits a special mirror, the dichroic mirror, located directly behind the objective lens. The purpose of the dichroic mirror is to reflect shorter wavelength excitation light, but allow longer wavelength emission light to pass. The shorter wavelength excitation light is reflected by the dichroic mirror into the objective and delivered to the specimen. There the light is absorbed by the fluorophore and reemitted at a longer wavelength. This light is emitted in all directions; however, a portion of the emitted light is collected again by the objective lens to form the image. This light passes back through the objective and again hits the dichroic mirror. Now the longer wavelength emitted light is passed by the dichroic mirror (not reflected) and the beam travels on to one last filter. This last filter, the emission filter or barrier filter, rejects all but the emission wavelengths, thus leaving a clean signal that is composed only of light from the excited fluorophore. This illumination is apiscopic, a reflected light technique. The substrate can be opaque as long as the fluorophore is accessible at the surface.

The three filter elements, the excitation filter, the dichroic mirror and the emission filter, together form a filter set. Each filter set is specific to the spectral characteristics of one

FIG. 5. Filter set. Dashed line represents shorter wavelength excitation light; solid line is longer wavelength emission light.

particular fluorophore. More complex filter sets that allow for the simultaneous use of two or more fluorophores are available, but it is usually more convenient to capture separate images, each comprising the signal from an individual fluorophore, and then overlay these images later.

Confocal Microscopy: A Special Tool for Fluorescence Microscopy

Excited fluorophores in the sample send their emitted light in all directions. In wide-field fluorescence microscopy it is inevitable that, in addition to the fluorescence emanating from the fluorophores residing in the in-focus plane, some fluorescence from slightly out-of-focus planes (above and below the desired focal plane) will also be collected and contribute to the image. The result can be a muddled or hazy image, especially in thick or highly scattering specimens. A solution is the confocal microscope.

In a laser scanning confocal microscope (LSCM), a physical barrier (a pinhole) is placed at a confocal location in the imaging path between the objective and the detector (Fig. 6). This pinhole allows only those rays of light that emanate from precisely the focal plane of the objective lens to pass through to the detector. The result is a very clean, if very weak, signal. Further, instead of flooding the field of view with illumination from an arc lamp, a laser is used to excite the fluorophore. The laser beam forms a small diffraction-limited spot in the plane of the specimen. This spot is then rastered across the specimen using scanning mirrors and optics. Instead of imaging the entire field of view at once with an imager, a simpler more sensitive PMT can be used in synchrony with the laser to simply count the photons arriving as the result of the laser illumination at each location in the specimen. The completed image is then composed by digitally presenting the measured intensities at

FIG. 6. Laser scanning confocal microscopy. The sample is illuminated by a laser that is reflected into the objective via dichroic mirror. This beam forms a diffraction-limited spot in the specimen at the focal plane. This beam is rastered across the specimen by scanning mirrors (not shown). Fluorescence from the focal plane is captured by the objective, passes through the dichroic mirror and emission filters, and arrives precisely at the opening of the pinhole aperture, which is found directly in front of the detector (a photomultiplier tube). Fluorescence from an out-of-focus plane (a below-focus plane is shown, dotted) arrives to either side of the pinhole and is rejected. (After Murphy, 2001).

each location (pixel) in the specimen. The diffraction-limited illumination spot provides for superb lateral resolution, and the confocal pinhole rejects all out-of-focus fluorescence contributions. The result is a crisp clean image that represents a thin optical plane virtually sliced through the specimen. By repeating the process at different focal planes (with the help of nanometer-resolution stepper motors attached to the focus drive) one can collect images from hundreds of planes in thick specimens (up to 100–200 μm deep) and composite these into three-dimensional fluorescent representations of the sample.

Laser scanning confocal microscopes were once considered to require a dedicated operator to care for complex lasers, complicated electronics, and fragile detectors. Presently, the advent of solid-state lasers and simpler, more robust electronics, scanners, and detectors has led to new generations of confocal instruments that promise improved affordability and ease of use. Like wide-field fluorescence, laser scanning confocal microscopy can be implemented on either upright or inverted platforms.

Two new advances in confocal microscopy are worthy of note. The first is the use of multispectral array detectors and

spectral unmixing to provide for the simultaneous use of up to eight fluorophores. This technology is featured in an instrument produced by Zeiss. The second is the advent of the multiphoton microscope.

A fluorophore can be excited equally well by one properly tuned excitation photon; or by two excitation photons, each half the nominal excitation energy (twice the wavelength); or by three excitation photons, each a third the nominal excitation energy, etc. These multiple excitation photons must all reach the fluorophore molecule at precisely the same time, however—at least within the fluorescence decay lifetime of the fluorophore, which is measured in nanoseconds. This requires a femtosecond pulsed laser excitation source at long wavelengths (almost infrared). There are several advantages to this mode of illumination. First, longer wavelengths can penetrate deeper into cells and tissue, and do so with less biologic damage. Second, the pulsed nature of the excitation laser means that lower energy doses are delivered to the specimen. The effective excitation volume, the volume at the focal point of the objective where the spatial and temporal density of excitation photons is actually great enough to trigger a fluorescence emission, is exceedingly small—on the order of femtoliters. Thus, the emission signal produced and detected is always of very high spatial resolution, in both lateral as well as the axial dimensions.

DIGITAL IMAGING

It is not enough that we build instruments to produce magnified and resolved images of the microscopic world. We must be able to detect these images, to visualize the information, record and archive images, and make useful quantitative measurements of our observations. This is the science of imaging.

Detectors: Eyes, Film, Digital Imagers

Our human eyes are by far the most commonly used and relied upon detectors in light microscopy. Together with the ocular lenses, the lens of the eye serves as part of the microscope system and the final image is focused on the retina, the detector. The human eye is a remarkable, yet limited, living detection instrument. Obviously, our eyes are acutely tuned to the visible portion of the light spectrum, with the greatest sensitivity found in the mid-green. The eye can be very sensitive (as few as 100 photons in the dark-adapted eye) and can adapt to a wide range of signal intensity from very dim to very bright. However, this adaptation takes time; and the intra-scene dynamic range, the range of dim to bright within one field of view, is only about 1000-fold. The individual sensing elements in the eye, the rods and cones, have an effective size of about 2 μm , which can be compared to the pixel size in other detectors. The signal response in the eye is nonlinear, and the signals from our eyes receive considerable postprocessing by the visual systems in the brain. This is particularly true with regard to edges, shadows, and objects in motion. We are all familiar with many “optical illusions” that prey upon some of the foibles of the human visual system. As discussed earlier, we

make use of some of these illusions in light microscopy—e.g., the gradations of intensity in DIC and Hoffman are interpreted as shadows, when really there is little topographic information in the image.

Unfortunately, scientists with photographic memory are rare; thus the storage and archival capability of the human visual system is nil. The quantitative abilities of the eye are also limited. Although we can distinguish thousands of colors, we can barely discern between roughly 64–100 different gradations of gray (intensity)! Thus data that come from human observations are qualitative, or semiquantitative at best. The scientist must rely on careful subjective measurements, ideally with standardized scoring schemes, copious controls, blinded observers, and comparisons between multiple independent observers.

For more than a century the standard media for imaging was photographic film. Film can be made to detect broader spectral ranges than the eye, can be very sensitive, and has a dynamic range of about 2.5 log units. The grain size (individual sensing element or pixel) in film is typically 30 μm . The archival capability of film is excellent, and when properly used, the signal response can be made to be linear and the data analyzed quantitatively. However, the cost, time and chemical reagents required for film development are significant. The replacement of film with digital imagers in modern scientific imaging is essentially complete.

Digital Imaging Devices

Solid-state imaging devices are now a common part of our everyday world. Digital imaging devices are found in photocopiers, scanners, professional and consumer-grade video cameras and still cameras, surveillance cameras, toys, personal computers, and cell phones. The medical and scientific imaging fields have benefited greatly from this explosion of technology. The gaps in performance and sensitivity between consumer-grade and research-grade imagers are quickly closing.

The most common digital imaging device is the charge-coupled device (CCD). A CCD is a silicon chip that comprises a physical array of photodetectors, which correspond to the picture elements (pixels) in the image. As photons arrive at each photodiode they are converted to electrons, and the charges are accumulated and held locally on the chip in a potential well. Later, these groups of charges are transferred off the chip in a sequential manner, and the signal from each well is amplified and converted to a voltage. At this point the signal is still analog. An analog-to-digital converter is used to convert the steady stream of voltages into an array of numeric values that represent the relative intensity of photons at each photodiode in the detector array. It is this array of numbers that is the digital image.

Charge-coupled devices are available in several different architectures. In a full-frame camera, every spot on the chip is exposed to light. A physical shutter is used to control the exposure. After the exposure, the shutter is closed, and the charges are transferred and read. The operation is much like that found in a standard film camera. In a frame transfer camera, the CCD array is divided into two separate adjacent fields. The first is used for sensing light, while the second area on the

chip is protected from light by an opaque mask and is used only to transfer and hold charges. The frame transfer camera has the advantage of speed. Thus in a frame transfer camera, one image is acquired in the sensing region, then the charges are transferred quickly to the masked area. While the charges in the masked area are being read out, a new image can be acquired in the sensing region. Finally, many modern cameras take this concept one step further by simply masking every other line of photodiodes on a chip, a so-called interline camera. This allows for imaging at video frame rates; built-in microlenses can be used to funnel photons away from the masked pixels and to the sensing pixels.

The performance of a scientific imaging device depends on several important parameters. The resolution is determined by the number of sensing elements (photodiodes, i.e., pixels) as well as the physical size of each photodiode. The size of each element also determines the capacity of each well, i.e., the number of charges that can be held before reaching saturation. This “full-well capacity” determines the dynamic range, which is the range between the brightest and the darkest intensities possible in the image. The sensitivity is determined by the signal/noise ratio. The signal is affected by the quantum yield, which is the ratio of charges created to photons hitting the detector. The quantum yield can vary significantly with wavelength. The noise in the signal can arise from several factors. At very low light levels, the stochastic nature of the incoming photons themselves contributes some variability, the “shot noise.” Thermal events also generate electrons in the chip. Thus very sensitive detectors are often cooled with thermoelectric cooling devices or even liquid nitrogen to reduce this “thermal noise.” Finally, noise can be generated in the process of transferring, reading, and amplifying the signals, and this “read noise” often scales with the speed of the reading process. Thus, very different and specialized imaging systems are used for various imaging tasks: e.g., very low-light fluorescence imaging; video-rate imaging; or very high-speed imaging for following millisecond or microsecond events.

Although there is some variation in the quantum efficiency with wavelength, a CCD camera is basically a monochrome imaging detector. Often this is adequate. For example, in fluorescence imaging the signal is ideally composed of only single-emission-wavelength photons—fluorescence microscopy is actually a monochrome technique! But as discussed earlier in this section, we often use multiple colored stains to create complex contrast in an image, and this requires a color imaging device.

A color CCD camera achieves color sensitivity by using filters to separate the image into its red, green, and blue components. This can be accomplished in several different ways. In the first example, a separate tunable color filter is placed in front of a monochrome camera. The filter is sequentially set for red, green, or blue, and three separate images are acquired. The images can then be compiled computationally to represent the color digital image. An advantage is that the full resolution of the imaging camera is maintained; however, the time required for the acquisition of three images means that the sample must hold still for a while (no sample motion!). In the second approach, a prism is used to split the incoming image into three separate images, representing red, green, and blue.

Three separate imaging chips are placed after the prism to collect the three separate images simultaneously. However, the third and most common approach is to use microprisms or colored filters mounted as a mask directly on the chip itself. In this arrangement, some photodiodes will be assigned to sense red, some green, and some blue. A computer algorithm keeps track of which pixels are which, and then combines the signals from adjacent R, G, and B sensing pixels and reports the result as one “virtual” pixel with R, G, and B values. Since the values from three (or more typically four) photodiodes are used to create one pixel, some resolution is sacrificed. Like all other areas of computing and electronics, imaging technology is advancing at a very rapid pace. Thus the reader is urged to consult current literature and vendor specifications for the latest advancements.

Digital Images, Image Processing, and Image Output

A full treatment of image processing and image analysis is beyond the scope of this chapter. However, a few thoughts are worthwhile for any scientist dealing with image data.

A digital image is ultimately an array of numbers where the value at each location in the array represents the intensity of one pixel in the image. A color image is represented by three values at each pixel. This array of numbers may be stored electronically in any of a myriad of proprietary file formats or in cross-platform formats such as bitmap (.bmp) or TIFF (.tif). In any event, the data should always be safely stored and archived in their raw, unadulterated form, before any image-processing steps or image-compression methods are applied. Subsequent processing steps should always be applied to a copy of the original data. Most vendors of imaging devices also offer software that controls image acquisition and offers some image-processing capabilities. Common image-processing packages include the NIH IMAGE software available from the U.S. National Institutes of Health, Research Services Branch (<http://rsb.info.nih.gov/nih-image>), as well as programs primarily meant for the professional graphic arts world such as Adobe Photoshop. There is often uncertainty about the scientific propriety of digital image manipulation. In general the least amount of processing necessary is preferable, and no processing should be applied if quantitative data are being extracted from the images. Certain modest operations such as histogram stretching (which is scaling the intensity values in an image so that they span a more full range of output values) or gamma correction (a nonlinear display of data to accentuate dim features while maintaining bright features) are commonly applied for aesthetic images where quantitative analysis is not employed. Scientific guidelines are beginning to be formulated and a good reference is the Microscopy Society of America’s policy statement (www.microscopy.org). As with any treatment of scientific data, the methods of image manipulation must be documented and communicated such that others are capable of reproducing the findings from the raw data set, or through independent experimental work.

Of course, the road to imaging productivity is not complete until the image is communicated to others in the scientific community. Image output must be considered as part of the

scientific process. Digital images are embedded in other media files and viewed using a variety of means. Typical CRT computer monitors or LCD displays unfortunately have fairly limited resolution, displaying only about a million pixels at roughly 70 dots per inch. Scientific journals typically print at about 300 dpi. Standard data projectors also only display about a million pixels; the fact that the image is hugely magnified on a screen does not “create” added resolution! Likewise, images overly enlarged for printing on scientific posters can suffer if they do not contain sufficient resolution (pixels). If color information is important, then special care must be taken to ensure color fidelity throughout the image acquisition, display and output processes. The responsibility for clear unbiased image presentation ultimately lies with the scientist. The image must be presented to the audience with adequate magnification, resolution, and contrast such that an independent observer can identify the features that are important and independently reach the conclusions the author wishes to convey.

ELECTRON MICROSCOPY

The resolution of any probing technique is ultimately dependent upon the size of the probe and the nature of the probe–specimen interaction. The Rayleigh criterion above describes how resolving power is related to wavelength in light microscopy. How then can we achieve much greater resolution? Although we can certainly use shorter wavelengths, the visible light spectrum is actually quite limited. To make really large strides in the achievement of resolution, the answer is to reduce the size of the probe drastically, and use electrons. Electrons indeed provide extraordinary resolution. However, in addition to interacting with the samples, electrons are also absorbed and scattered by even the small molecules in the atmosphere! Thus electron microscopy techniques must be conducted under high-vacuum conditions such as those described in Chapter 1.4.

Electron microscopy can be performed in either transmission or reflected modes. In transmission electron microscopy (TEM), images are formed by diffraction or phase contrast mechanisms, much as has been described earlier for transmitted light microscopy. The detectors are phosphor screens coupled with digital imagers. Samples must be very, very thin (50 nm). This is achieved by embedding samples in hard plastic resins and using very sharp diamond knife ultramicrotomes. TEM provides extraordinary resolution of organelle and membrane structures in single cells. For biomaterials, there is perhaps no other instrument that provides a higher resolution image of the intimate cell membrane–biomaterial interface. Unfortunately the challenging nature and limitations of TEM sample preparation mean that this technique is underutilized in biomaterials. By far the most common electron microscopy tool is scanning electron microscopy (SEM).

Scanning Electron Microscopy

The scanning electron microscope was developed in the 1960s and 1970s, and has had a tremendous impact on the

materials sciences and engineering fields, as well as the biologic community. SEM provides 3D-like topographical information of bulk specimens at nanometer resolutions. It is remarkable that, while complex to generate, SEM images are easily accessible for even a child to interpret. The SEM has been truly instrumental in opening doors to the micro- and nano-world for the general public! In biomaterials the SEM is on an equal footing with Light Microscopy, as it is used to study the micro and nanoscale structure of materials and devices, and cell–biomaterial interactions.

The scanning electron microscope (Fig. 7) is somewhat analogous to the scanning confocal microscope discussed earlier. Instead of a diffraction limited laser beam, a beam of electrons is focused and swept across the surface of the specimen. The interaction of the electrons with the sample is localized and results in the generation of a signal, in this case other electrons escaping the specimen. These electrons are collected and counted by a detector, just as the photons are collected and counted by a photomultiplier tube (PMT) in LSCM. The counts collected at each raster point are then compiled into a digital image. The LSCM has very shallow depth of focus, and three-dimensional information has to be reconstructed by taking many images at various focus planes. A key advantage of the SEM is its extraordinarily large depth of focus, allowing for the direct imaging of complex, even somewhat tortuous, microscale structures.

To start with, in SEM, we wish a plentiful (bright) and narrow beam of electrons for illumination. Conventional SEMs generate electrons by heating a hairpin-shaped filament of

FIG. 7. Schematic drawing of the electron column in an SEM showing the electron gun, lenses, the scanning system and the electron detector. From Goldstein *et al.* (2003).

FIG. 8. Signal generation in SEM. Incident electrons enter the sample, collide with sample atoms, and may eventually exit the sample as backscattered electrons (BSE). Secondary electrons (SE_I , SE_{II}) are generated and can escape the sample if they are generated close enough to the surface (typically within five mean free path lengths). BSEs can also collide with the chamber walls or other components to generate even more secondary electrons (SE_{III}). The electrons are drawn to the E-T detector by the positively charged Faraday cage and the positively charged coating on the scintillator (S). The electrons are converted to photons and carried by the light guide (LG) out of the chamber, where the photons are counted by a photomultiplier tube (PMT). After Goldstein *et al.* (2003).

tungsten. The emitted electrons are quickly focused to a point by the Wehnelt cap and then accelerated toward an anode at high voltage. Alternatively a crystal of LaB_6 can be used as a source—this provides $5\text{--}10\times$ greater brightness (more electrons) but requires a higher vacuum (10^{-4}Pa) and is much more expensive. Many modern instruments now utilize an alternative source, the field emission (FE) gun. The element is again tungsten, but the filament is now shaped into a very sharp wire tip ($<100\text{ nm}$ radius). Electrons are pulled from the tip by a very high electric field, either without (cold field emission) or with (Schottky or thermal FE) the aid of heating. An FE source can provide a very narrow beam that is $1000\times$ brighter than the conventional thermal source. However, the vacuum required at the tip is much higher, on the order of 10^{-9} Pa .

Focusing the illuminating beam of electrons onto the sample is accomplished by lenses; however, these lenses are electromagnetic, not glass. Typically one or two condenser lenses begin to narrow the beam down and a final “objective” lens focuses the beam onto the sample. Scanning coils are used to deflect the beam slightly from side to side to accomplish the rastering of the beam across the specimen. Unlike glass lenses, the focal length of magnetic lenses can be changed simply by changing the magnetic field. A beam-limiting aperture is placed in the path and used to limit the diameter of the probe and ensure a narrow beam angle. A standard conically shaped objective lens can accommodate almost any size sample capable of fitting into the chamber. The lens may reside $1\text{--}20\text{ mm}$ away from the sample (the working distance). If the sample is small enough, it actually may be placed inside the objective lens field (an immersion lens instrument) with the advantages of lower aberrations, smaller probe size, and greater resolution.

Operation of the instrument requires balancing several operational parameters and making trade-offs. The diameter of the probe, the number of electrons in the probe (probe current),

and the aperture angle are all crucial and quite interrelated parameters. Resolution is dependent upon small probe size, but there must be sufficient electrons to generate contrast (probe current): the familiar resolution/contrast trade-off again. Aperture angle also affects these, as well as determining the depth of focus. Thus operational parameters such as source current, condenser strength, working distance, aperture size, and acceleration voltage are all adjusted depending upon the particular needs of the situation: e.g., high-resolution imaging, large depth of focus, a need for high current, or surface sensitivity (low voltage).

The probe diameter of the incident electron beam may be as small as a few nanometers as it arrives at the surface. Unfortunately, the signal that is measured arises from interactions of this beam from within a much larger volume in the sample, the interaction volume. The incoming electrons may result in several measurable signals upon hitting the specimen (Fig. 8). First, the very energetic electrons may bounce off, or far more likely, bounce through the upper layers of the specimen, before getting turned around and again escaping the sample and returning to the chamber. These elastically scattered electrons are detected as backscattered electrons (BSEs). Depending on their energies, and the nature of the specimen (e.g., the atomic number), these backscattered electrons might travel as deep as $5\text{--}10\text{ }\mu\text{m}$ into the sample and reemerge as far as a micrometer or two away from their point of entry! Next, as these BSEs are bouncing through the specimen, much weaker secondary electrons (SEs) are generated. If these secondary electrons are generated near enough to the sample surface (say within five mean free path lengths), then they too will escape and can be detected as a secondary electron signal. Not only can secondary electrons be generated and escape near the point of entry of the incident beam, but secondary electrons can also be generated near the point of exit of a BSE, and these also escape and count

toward the measured SE signal. Finally, escaped BSEs that hit the walls of the chamber can also generate SEs, and these too are counted. Most commonly, the signal used to form an image is the combination of counts from BSEs and all the SEs mentioned. Understanding the size and depth of the interaction volume in the specimen is crucial to interpreting the resolution and surface sensitivity in SEM imaging.

The detector is most commonly an Everhart-Thornly (E-T) detector located somewhere on the wall of the chamber. The E-T detector works by attracting escaped electrons (BSEs and all the SEs) with a positively biased grid placed directly in front of a positively charged scintillator. Electrons hitting the scintillator generate photons of light that are carried out of the chamber through a light guide to a PMT where they are counted. A negative bias on the grid will result in only the BSEs being detected.

All the incident electrons used for illumination have to be drained somewhere. Thus samples need to be conductive (or at least semiconductive) and grounded to the instrument. When current is unable to be discharged adequately it builds up on the surface and is manifest as "charging" in the image that degrades system performance. For this reason, many nonconducting samples (including biologic samples and polymers) are often coated with a very thin layer of metal, typically Au/Pd. The energetic incident electrons can also be damaging to some beam-sensitive samples, including polymers and delicate biologic structures.

Elemental Analysis in the SEM

In addition to the BSE and SE discussed above, incident electrons may also cause the emission of X-rays from the sample. Measurement of the energy and intensity of these X-rays can provide for elemental composition mapping across the specimen. This technique, energy dispersive X-ray (EDX) analysis, is conceptually the reverse of ESCA or XPS discussed in the chapter on surface analysis. This technique is electrons in, X-rays out.

Low-Voltage Imaging

Another key advantage of instruments designed around FE sources is that they can be operated at very low accelerating voltages, as low as 100 eV as compared to the typical 5–30 KeV in conventional instruments. This results in a much smaller interaction volume, and thus more sensitivity to surface topography. The samples receive less beam damage, and in fact many samples may be imaged without a metalized coating.

Variable Pressure and ESEM

A major drawback to SEM is the requirement of operating under high vacuum, 10^{-3} – 10^{-6} Pa or even lower pressures. Biologic samples must be fixed and dehydrated with hopes that the structure will be preserved somehow under vacuum. Polymers too can undergo significant structural rearrangement

when under high-vacuum conditions (e.g., hydrogels). Porous structures such as bone can be difficult to pump down to such vacuum levels.

Solutions are now appearing in the form of the Environmental SEM (ESEM) and numerous variable-pressure (VP) SEM instruments. The approach in both instruments is the same: basically, to make a "leaky" SEM. These instruments are differentially pumped, meaning that the portions of the instrument housing the electron gun and optics are kept under high vacuum, while the sample chamber is allowed to reach some larger (but not really atmospheric!) pressure. The opening between the optics column and the specimen chamber (the leak) is kept as small as possible, and the sample is kept as close to this opening as possible so that the incident electrons have only a short distance to travel through the scattering gas atmosphere. The ESEM, which has several fairly elaborate differential pumping systems, can reach chamber pressures as high as 2700 Pa (20 torr) and utilizes a special SE detector capable of operating in the presence of such gas pressures. This pressure is the saturated vapor pressure of water at room temperature, and thus fully hydrated specimens can be viewed directly. All SEM vendors now offer some form of these variable-pressure systems with chamber pressures reaching 250 Pa (2 torr) and utilizing a variety of detectors. This pressure is not adequate to keep samples fully hydrated, but samples can be observed "partially hydrated."

The advantages are obvious. Cells and tissues have been imaged under fully hydrated conditions. Colloids, emulsions, and hydrated polymers are no longer excluded from SEM analysis. The resolution in this operating mode, however, does not equal that under high vacuum, and scattering of the incident beam from column to sample is the culprit. For this reason, standard thermal electron guns and high accelerating voltages are typically used. Fortunately, the presence of the gas near the sample means that charging is much reduced. The flexibility that this mode of operation offers is tremendously attractive, and "VP-capable" SEMs have become big sellers.

Focused Ion Beam Instruments

Instead of an incident beam of electrons, a focused beam of positively charged ions can be delivered to the specimen, e.g., gallium ions from a liquid metal ion gun. This beam can also be used to generate images of very high resolution, but the technique is destructive. However, this can be an advantage, in that the focused ion beam (FIB) can be used as an extremely precise machining tool at the microscopic and, indeed, nanoscopic scale. Several new instruments now combine a FIB column with a SEM column to create the ultimate fabrication and imaging instrument for nanoscale engineering.

CONCLUSIONS

Although many of the techniques discussed here can trace their roots back for centuries, advances in modern microscopic imaging continue to abound. This section has not addressed scanning tunneling microscopy (STM) and atomic

force imaging (AFM), important newer molecular imaging tools, which are covered elsewhere in this text. Surface analytical tools, such as ESCA and SIMS, are now being adapted to provide imaging capability at the microscopic scale. Conventional medical imaging tools, such as X-ray computed tomography (CT) and magnetic resonance imaging (MRI), are now being practiced at nearly microscopic resolutions. Electron tomography applied in high-voltage TEM instruments is revealing extraordinary three-dimensional representations of intracellular organelles and other structures. Modern computing power is reinvigorating the serial sectioning and reconstruction approaches of the past. The detection of intrinsic fluorescence via second harmonic generation in the multiphoton microscope is opening new doors to the imaging of biologic structures deeper in tissues. Optical coherence tomography promises important advances in tissue imaging for both clinical and research use. New nanoparticle fluorophores (quantum dots) provide extraordinarily bright emissions with narrow spectral signatures, enabling even further advancements in multilabel fluorescence imaging, biophotonics, and biosensors.

At first blush, microscopy may seem little more than a suite of tools for making little things appear larger so they can be examined. This is an accurate, but very incomplete, description of how microscopy is used in modern science. The wealth of microscopy tools available to the modern scientist allows one to move beyond simple visual exploration, and to begin to ask tailored mechanistic questions, pose hypotheses, and prove them with solid quantitative data. This is essential for scientific publications, as well as for the documentation required by regulatory agencies. The detailed description of structure; the localization of species in two and three dimensions with molecular specificity; the ability to follow and visualize molecular biological process such as gene expression over time—these are all powerful tools in the biomaterial scientist's arsenal. To be successful, the scientist must include microscopy and imaging considerations from the very onset of any experimental planning.

Degradation of Materials in the Biological Environment

ARTHUR J. COURY, ROBERT J. LEVY, BUDDY D. RATNER, FREDERICK J. SCHOEN,
DAVID F. WILLIAMS, AND RACHEL L. WILLIAMS

6.1 INTRODUCTION: DEGRADATION OF MATERIALS IN THE BIOLOGICAL ENVIRONMENT

Buddy D. Ratner

The biological environment is surprisingly harsh and can lead to rapid or gradual breakdown of many materials. Superficially, one might think that the neutral pH, low salt content, and modest temperature of the body would constitute a mild environment. However, many specialized mechanisms are brought to bear on implants to break them down. These are mechanisms that have evolved over millennia specifically to rid the living organism of invading foreign substances and they now attack our contemporary biomaterials. First, consider that, along with the continuous or cyclic stress many biomaterials are exposed to, abrasion and flexure may also take place. This occurs in an aqueous, ionic environment that can be electrochemically active to metals and plasticizing (softening) to polymers. Then, specific biological mechanisms are invoked. Proteins adsorb to the material and can enhance the corrosion rate of metals. Cells secrete powerful oxidizing agents and enzymes that are directed at digesting the material. The potent degradative agents are concentrated between the cell and the material where they act undiluted by the surrounding aqueous.

To understand the biological degradation of implant materials, synergistic pathways should be considered. For example, the cracks associated with stress crazing open up fresh surface area to reaction. Swelling and water uptake can similarly increase the number of site for reaction. Degradation products can alter the local pH, stimulating further reaction. Hydrolysis of polymers can generate more hydrophilic species, leading to polymer swelling and entry of degrading species into the bulk of the polymer. Cracks might also serve as sites initiating calcification.

Biodegradation is a term that is used in many contexts. It can be used for a reaction that occurs over minutes or over years. It can be engineered to happen at a specific time after implantation, or it can be an unexpected long-term consequence of the severity of the biological environment. Implant materials

can solubilize, crumble, become rubbery, or become rigid with time. The products of degradation may be toxic to the body, or they may be designed to perform a pharmacologic function. Degradation is seen with metals, polymers, ceramics, and composites. Thus, biodegradation as a subject is broad in scope and rightfully should command considerable attention for the biomaterials scientist. This chapter, in three sections, introduces biodegradation issues for a number of classes of materials and provides a basis for further study on this complex but critical subject.

6.2 CHEMICAL AND BIOCHEMICAL DEGRADATION OF POLYMERS

Arthur J. Coury

Biodegradation is the chemical breakdown of materials by the action of living organisms which leads to changes in physical properties. It is a concept of vast scope, ranging from decomposition of environmental waste involving microorganisms to host-induced deterioration of biomaterials in implanted medical devices. Yet it is a precise term, implying that specific biological processes are required to effect such changes (Williams, 1989). This chapter, while grounded in biodegradation, addresses other processes that contribute to the often complex mechanisms of polymer degradation. Its focus is the unintended chemical breakdown in the body of synthetic solid-phase polymers. (See Chapter 2.7 for a description of systems engineered to break down in the body.)

POLYMER DEGRADATION PROCESSES

Polymeric components of implantable devices are generally reliable for their intended lifetimes. Careful selection and extensive preclinical testing of the compositions, fabricated

components, and devices usually establish functionality and durability. However, with chronic, indwelling devices, it is infeasible during qualification to match all implant conditions in real time for years or decades of use. The accelerated aging, animal implants, and statistical projections employed cannot expose all of the variables that may cause premature deterioration of performance. The ultimate measure of the acceptability of a material for a medical device is its functionality for the device's intended lifetime as ascertained in human postimplant surveillance (Coury, 1999).

No polymer is totally impervious to the chemical processes and mechanical action of the body. Generally, polymeric biomaterials degrade because body constituents attack the biomaterials directly or through other device components, sometimes with the intervention of external factors.

Numerous operations are performed on a polymer from the time of its synthesis to its use in the body (see, e.g., Table 1). Table 2 lists mechanisms of physical and chemical deterioration, which may occur alone or in concert at various stages of a polymer's history. Moreover, a material's treatment prior

TABLE 1 Typical Operations on an Injection-Moldable Polymer Biomaterial

Polymer: Synthesis, extrusion, pelletizing
Pellets: Packaging, storage, transfer, drying
Components: Injection molding, post-mold finishing, cleaning, inspecting, packaging storage
Device: Fabrication storage (presterilization) cleaning, inspecting, packaging, storage (packaged), sterilization, storage (sterile), shipment, storage (preimplant), implantation, operation is body

TABLE 2 Mechanisms Leading to Degradation of Polymer Properties^a

Physical	Chemical
Sorption	Thermolysis
Swelling	Radical scission
Softening	Depolymerization
Dissolution	Oxidation
Mineralization	Chemical
Extraction	Thermooxidative
Crystallization	Solvolysis
Decrystallization	Hydrolysis
Stress cracking	Alcoholysis
Fatigue fracture	Aminolysis, etc.
Impact fracture	Photolysis
	Visible
	Ultraviolet
	Radiolysis
	Gamma rays
	X-rays
	Electron beam
	Fracture-induced radical reactions

^aSome degradation processes may involve combinations of two or more individual mechanisms.

to implant may predispose it to stable or unstable end-use behavior (Brauman *et al.*, 1981; Greisser *et al.*, 1994; Ling *et al.*, 1998). A prominent example of biomaterial degradation caused by preimplant processing is the gamma irradiation sterilization of ultra-high molecular weight polyethylene used in total joint prostheses. The process generates free radicals within the material which react with oxygen to produce undesirable oxidation products. Chain oxidation and scission can occur for periods of months to years, causing loss of strength and embrittlement with limited shelf life (McKellop *et al.*, 1995; Furman and Li, 1995; Weaver *et al.*, 1995; Daly *et al.*, 1998; Blanchet and Burroughs, 2001). Polypropylene and polytetrafluoroethylene are also notable as polymers that are generally chemically stable in the body but can be severely degraded during processing by sterilization with ionizing radiation (Williams, 1982; Portnoy, 1997). Gamma irradiation may also cause optical changes such as darkening of poly(methyl methacrylate) intraocular lenses (Hoffman, 1999). It is crucially important, therefore, that appropriate and rigorous processing and characterization protocols be followed for all operations (Coury *et al.*, 1988; Shen *et al.*, 1999).

After a device has been implanted, adsorption and absorption processes occur. Polymeric surfaces in contact with body fluids immediately adsorb proteinaceous components, and the bulk begins to absorb soluble components such as water, ions, proteins, and lipids. Cellular elements subsequently attach to the surfaces and initiate chemical processes. With biostable components, this complex interplay of factors is of little functional consequence. At equilibrium fluid absorption, there may be some polymer plasticization, causing dimensional and mechanical property changes (Coury *et al.*, 1988). On the surface, a powerful acute attack by cells and many chemical agents, including oxidants and enzymes, will have been substantially withstood. With the resolution of this acute inflammatory phase, a fibrous capsule will likely have formed over the device, and the rate of release of powerful chemicals from activated cells will have markedly decreased.

For those polymers subjected to chemical degradation *in vivo*, few if any reports have comprehensively described the multistep processes and interactions that comprise each mechanism. Rather, explant analysis and occasionally metabolite evaluation are used to infer reaction pathways. The analysis of chemically degraded polymers has almost always implicated either hydrolysis or oxidation as an essential component of the process.

HYDROLYTIC BIODEGRADATION

Structures of Hydrolyzable Polymers

Hydrolysis is the scission of susceptible molecular functional groups by reaction with water. It may be catalyzed by acids, bases, salts, or enzymes. It is a single-step process in which the rate of chain scission is directly proportional to the rate of initiation of the reaction (Schnabel, 1981). A polymer's susceptibility to hydrolysis is the result of its chemical structure, its morphology, its dimensions, and the body's environment.

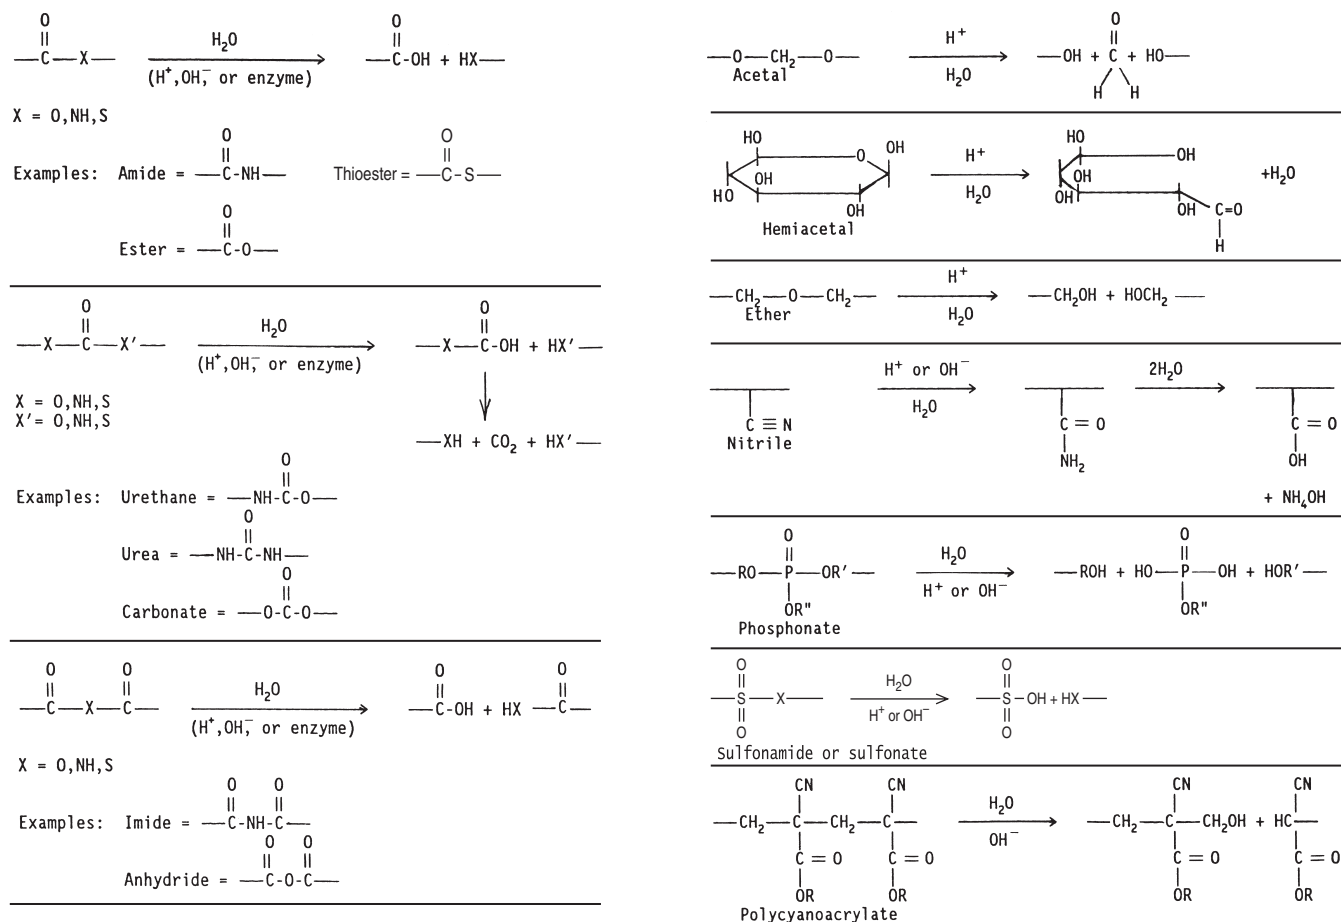

FIG. 1. Hydrolyzable groups in polymer biomaterials.

In a commonly used category of hydrolyzable polymeric biomaterials, functional groups consist of carbonyls bonded to heteroatom elements (O, N, S). Examples include esters, amides, urethanes, and carbonates, and anhydrides. (Fig. 1). Other polymers containing groups such as ether, acetal, nitrile, phosphonate, sulfonate, sulfonamide or active methylenes hydrolyze under certain conditions (Fig. 1). Hydrolytically susceptible groups exhibit differing rates of degradation, which are dependent on the intrinsic properties of the functional group and on other molecular and morphological characteristics. Among carbonyl polymers, anhydrides display the highest hydrolysis rates followed, in order, by esters and carbonates. Polymers containing such groups, in fact, comprise many of the resorbable devices (Chapter 2.7). Other carbonyl groups such as urethane, imide, amide and urea can demonstrate long-term stability *in vivo* if contained in a hydrophobic backbone or highly crystalline morphologic structure. Groups that are normally very stable to hydrolysis are indicated in Fig. 2.

The rate of hydrolysis tends to increase with a high proportion of hydrolyzable groups in the main or side chain, other polar groups which enhance hydrophilicity, low crystallinity, low or negligible cross-link density, a high ratio of exposed surface area to volume, and, very likely, mechanical stress. Porous hydrolyzable structures undergo especially rapid property loss

because of their large surface area. Factors that tend to suppress hydrolysis rate include hydrophobic moieties (e.g., hydrocarbon or fluorocarbon), cross-linking, high crystallinity due to chain order, thermal annealing or orientation, low stress, and compact shape. While the molecular weight of linear polymers *per se* may not have a great effect on degradation rate, physical property losses may be retarded for a given number of chain cleavage events with relatively high-molecular-weight polymers. Property loss caused by chain cleavage is more pronounced in polymers with weak intermolecular bonding forces.

Host-Induced Hydrolytic Processes

The body is normally a highly controlled reaction medium. Through homeostasis, the normal environment of most implants is maintained at isothermal (37°C), neutral (pH 7.4), aseptic, and photoprotected aqueous steady state. By *in vitro* standards, these conditions may appear mild. However, complex interactions of humoral and cellular components of body fluids involving activators, receptors, inhibitors, etc., produce aggressive responses to any foreign bodies through the processes of adhesion, chemical reaction, and particulate transport.

FIG. 2. Groups highly stable to hydrolysis.

Several scenarios leading to hydrolysis in the host can be considered. Whatever the scenario, hydrolysis can only occur at a site other than the surface of a polymer mass after water of permeation reaches that site. First, essentially neutral water is capable of hydrolyzing certain polymers (e.g., polyglycolic acid) at a significant rate (Chapter 2.7 and Zaikov, 1985). However, this simple mechanism is unlikely to be significant in polymer compositions selected for long-term *in vivo* biostability.

Next, ion-catalyzed hydrolysis offers a likely scenario in body fluids. Extracellular fluids contain ions such as: H^+ , OH^- , Na^+ , Cl^- , HCO_3^- , PO_4^{3-} , K^+ , Mg^{2+} , Ca^{2+} , and SO_4^{2-} . Organic acids, proteins, lipids, lipoproteins, etc. also circulate as soluble or colloidal components. It has been shown that certain ions (e.g., PO_4^{3-}) are effective hydrolysis catalysts, enhancing, for example, reaction rates of polyesters by several orders of magnitude (Zaikov, 1985). Ion catalysis may be a surface effect or a combined surface-bulk effect, depending on the hydrophilicity of the polymer. Very hydrophobic polymers (e.g., those containing <2% water of saturation) absorb negligible concentrations of ions. Hydrogels, on the other hand, which can absorb large amounts of water (>15% by weight) are essentially "sieves," allowing significant levels of ions to be absorbed with consequent bulk hydrolysis via acid, base, or salt catalysis.

Localized pH changes in the vicinity of the implanted device, which usually occur during acute inflammation or infection, can cause catalytic rate enhancement of hydrolysis (Zaikov, 1985). Organic components, such as lipoproteins, circulating in the bloodstream or in extracellular fluid, appear to be capable of transporting catalytic inorganic ions into the polymer bulk by poorly defined mechanisms.

Enzymes generally serve a classic catalytic function, altering reaction rate (via ion or charge transfer) without being consumed by modifying activation energy but not thermodynamic

equilibrium. While enzymes function in extracellular fluids, they are most effectively transferred onto target substrates by direct cell contact (e.g., during phagocytosis). Hydrolytic enzymes or hydrolases (e.g., proteases, esterases, lipases, glycosidases) are named for the molecular structures they affect. They are cell-derived proteins which act as highly specific catalysts for the scission of water-labile functional groups.

Enzymes contain molecular chain structures and develop conformations that allow "recognition" of chain sequences (receptors) on biopolymers. Complexes form between segments of the enzyme and the biopolymer substrate which result in enhanced bond cleavage rates. Lacking the recognition sequences of susceptible natural polymers, most synthetic polymers are more resistant to enzymatic degradation. Nevertheless, comparative studies have shown some enhancement of hydrolysis rates by enzymes, particularly with synthetic polyesters and polyamides (Zaikov, 1985; Smith *et al.*, 1987; Kopecek *et al.*, 1983). Apparently the enzymes can recognize and interact with structural segments of the polymers, or more accurately, of the polymers coated with serum proteins, to initiate their catalytic action *in vivo* (Pitt, 1992).
