Enzymes with demonstrated effects on hydrolysis rates can be quite selective in the presence of several hydrolyzable functional groups. For example, polyether urethane ureas and polyester urethane ureas exposed to hydrolytic enzymes (an esterase, cholesterol esterase, and a protease, elastase) were observed for rate and site of hydrolysis. Enzyme catalysis was clearly observed for the ester groups while the hydrolytically susceptible urea, urethane, and ether groups did not show significant hydrolysis as indicated by release of radiolabeled degradation products (Santerre *et al.*, 1994; Labow *et al.*, 1995).

Many enzymes exert predominantly a surface effect because of their great molecular size, which prevents absorption. Even hydrogels [e.g., poly(acrylamide)], which are capable of absorbing certain proteins, have molecular weight cutoffs for absorption well below those of such enzymes. However, as the degrading surface becomes roughened or fragmented, enzymatic action may be enhanced as a result of increased surface area if the substrates remain accessible to phagocytic cells that contain the active enzymes. Implanted devices that are in continuous motion relative to neighboring tissue can provoke inflammation, stimulating enzyme release.

Hydrolysis: Preclinical and Clinical Experience

A discussion of *in vivo* responses of several prominent polymer compositions known to be susceptible to hydrolysis follows. The structures of these polymers are described in Chapter 2.2.

Polyesters

Poly(ethylene terephthalate) (PET), in woven, velour, or knitted fiber configurations, remains a primary choice of cardiovascular surgeons for large-diameter vascular prostheses, arterial patches, valve sewing rings, etc. It is a strong, flexible polymer, stabilized by high crystallinity as a result of chain rigidity and orientation and is often considered to be biostable.

FIG. 3. Structure of implantable poly(ester urethane), poly(ether urethane) and poly(ether urethane urea).

Yet, over several decades, there have been numerous reports of long-term degeneration of devices *in vivo*, owing to breakage of fibers and device dilation. Proposed causes have been structural defects, processing techniques, handling procedures, and hydrolytic degradation (Cardia *et al.*, 1989).

Systematic studies of PET implants in healthy dogs have shown slow degradation rates, which were estimated to be equivalent to those in humans. For woven patches implanted subcutaneously, a mean total absorption time by the body of 30 ± 7 years, with 50% deterioration of fiber strength in 10 ± 2 years was projected. In infected dogs, however, where localized pH dropped to as low as 4.8, degradation was enhanced exponentially, with complete loss of properties within a few months (Zaikov, 1985). Human implant retrieval studies have shown significant evidence of graft infection (Vinard *et al.*, 1991). Besides the obvious pathological consequences of infection, the enhanced risk of polymer degradation is a cause for concern.

Aliphatic polyesters are most often intended for use as biodegradable polymers, with poly(ϵ -caprolactone), for example, undergoing a significant decrease in molecular weight as indicated by a drop of 80–90% in relative viscosity within 120 weeks of implant (Kopecek *et al.*, 1983).

Poly(ester urethanes)

The earliest reported implants of polyurethanes, dating back to the 1950s, were cross-linked, aromatic poly(ester urethane) foam compositions (Blais, 1990; Bloch *et al.*, 1972). Their use in plastic and orthopedic reconstructive surgery initially yielded promising results. Acute inflammation was low. Tissue ingrowth promoted thin fibrous capsules. However, within months they were degraded and fragmented, producing untoward chronic effects (Bloch *et al.*, 1972). Foci of initial degradation are generally considered to be the polyadipate ester

soft segments which undergo hydrolysis (Fig. 3). By comparison, corresponding poly(ether urethanes) are very resistant to hydrolysis, although more susceptible to oxidation (see the section on oxidative biodegradation). Whether such hydrolytically degraded poly(ester urethanes) subsequently produce meaningful levels of aromatic amines (suspected carcinogens) by hydrolysis of urethane functions *in vivo* is currently an unresolved subject of considerable debate (Szycher *et al.*, 1991; Blais, 1990).

It is noteworthy that poly(ester urethane) foam-coated silicone mammary implants have survived as commercial products for decades (Blais, 1990), despite their known tendency to degrade. Apparently, the type of fibrous capsules formed on devices containing degradable foam were favored by some clinicians over those caused by smooth-walled silicone implants. In large device, unstabilized by tissue ingrowth, the frictional effects of sliding may cause increased capsule thickness and contraction (Snow *et al.*, 1981) along with extensive chronic inflammation.

Polyamides

Nylon 6 (polycaprolactone) and nylon 6,6 [poly(hexamethylene adipamide)] contain a hydrolyzable amide connecting group, as do proteins. These synthetic polymers can absorb 9–11% water, by weight, at saturation. It is predictable, then, that they degrade by ion-catalyzed surface and bulk hydrolysis (Fig. 1). In addition, hydrolysis due to enzymatic catalysis leads to surface erosion (Zaikov, 1985). Quantitatively, nylon 6,6 lost 25% of its tensile strength after 89 days, and 83% after 726 days in dogs (Kopecek, 1983). An example of polyamide degradation of particular consequence involved the *in vivo* fragmentation of the nylon 6 tail string of an intrauterine contraceptive device. This string consisted of a nylon 6-sheath around nylon 6

multifilaments. The combination of fluid absorption (>10%) and hydrolysis was claimed to produce environmental stress cracking. The cracked coating allegedly provided a pathway for bacteria to travel from the vagina into the uterus, resulting in significant pelvic inflammatory disease (Hudson and Crugnola, 1987).

Degradation of a poly(arylamide) intended for orthopedic use (the fiber-reinforced polyamide from *m*-xylylene diamine and adipic acid) was also shown in a rabbit implant study. [Although the material provoked a foreign-body reaction comparable to a polyethylene control, surface pitting associated with resolving macrophages was noted at 4 weeks and became more pronounced by 12 weeks. This result was not predicted since polyarylamides are very resistant to solvents and heat (Finck *et al.*, 1995).]

Polyamides with long aliphatic hydrocarbon chain segments [e.g., poly(dodecanamide)] are more hydrolytically stable than shorter chain nylons and correspondingly degrade slower *in vivo*.

Poly(alkyl cyanoacrylates)

This class of polymers used as tissue adhesives is noteworthy as a rare case in which carbon-carbon bonds are cleaved by hydrolysis (Fig. 1). This occurs because the methylene (-CH₂-) hydrogen in the polymer is highly activated inductively by electron-withdrawing neighboring groups. Formation of the polymer adhesive from monomers is base catalyzed, with adsorbed water on the adherend being basic enough to initiate the reaction.

Catalysts for equilibrium reactions affect the reverse, as well as the forward reaction. Therefore, water associated with tissue can induce polycyanoacrylate hydrolysis by a "reverse Knoevenagel" reaction (Fig. 1). More basic conditions and (as suggested by *in vitro* cell culture or implant studies) enzymatic processes are much more effective. In chick embryo liver culture (a rich source of a variety of enzymes), methyl cyanoacrylate degraded much faster than in cell culture medium alone. In animal implants, poly(methyl cyanoacrylate) was extensively degraded within 4-6 months (Kopecek, 1983). Higher alkyl (e.g., butyl) homologs degraded slower than the methyl homolog and were less cytotoxic (Hegyeli, 1973; Vauthier *et al.*, 2003).

Polymers Containing Hydrolyzable Pendant Groups

Certain polymers intended for long-term implantation consist of biostable main-chain sequences and hydrolyzable pendant groups. Poly(methyl methacrylate) (PMMA) used in bone cements and intraocular lenses is an example of a hydrophobic polymer with a stable hydrocarbon main chain and hydrolyzable ester side groups. It has been proven, over decades of use, to provide reliable, stable service.

Another polymer system with a hydrocarbon backbone, poly(methyl acrylate-*co*-2-hydroxyethyl acrylate) also contains hydrolyzable ester side groups. This polymer, which forms hydrogels in an aqueous environment, has been used as a "scleral buckling" device for retinal detachment surgery. Basically, the dry polymer, shaped as a band or ring, placed as a "belt" around the sclera, expands through hydration to create an

indentation in the zone of the retinal detachment to reestablish retinal contact. The device is left in place as a permanent implant (or "exoplant" as it is sometimes called because it is external to the sclera) (Braunstein and Winnick, 2002).

This hydrogel device, introduced into clinical practice in the 1980s (Refojo and Leong, 1981; Colthurst *et al.*, 2000), apparently performed satisfactorily for years as an approved product. However, in the 1990s, reports of long-term complications of these hydrogel scleral buckles began to surface (Hwang and Lim, 1997; Roldan-Pallares *et al.*, 1999). The hydrogel structures resumed swelling, sometimes with fragmentation, after maintaining stable dimensions for years. One report described a difficult explanation 13 years after implantation (Braunstein and Winnick, 2002). Pressures applied to the eye by this swelling have led to blindness and loss of the eyeball. Hydrogel scleral buckles are no longer used in retinal surgery (Watt, 2001).

Very little speculation has been provided in published articles about the mechanism of failure of acrylate scleral buckling devices other than that chemical degradation has occurred (Roldan-Pallares, *et al.*, 1999). I suggest that a likely mechanism involves hydrolysis of the ester side groups enhanced by the hydrophilic nature of the polymer (as contrasted to hydrophobic polymers such as PMMA). Hydrolysis of either of the two acrylate esters in the polymer chain provides an acrylic acid moiety. Linear poly(acrylic acid) is fully water soluble and each hydrolytic event renders the polymer more hydrophilic and subject to enhanced swelling. This process is slow but inexorable in the case of the scleral buckling device. The valuable lesson is that devices with intrinsically susceptible groups can eventually degrade by predictable mechanisms. This may take longer than is required for pivotal preclinical qualification studies (typically 2-year animal implants). If late degradation is suspected, therefore, accelerated aging studies should be performed *in vitro* with correlations made to *in vivo* studies. Such efforts give valuable, if not completely trustworthy, information. (See this chapter, "Polymer Degradation Processes" section.)

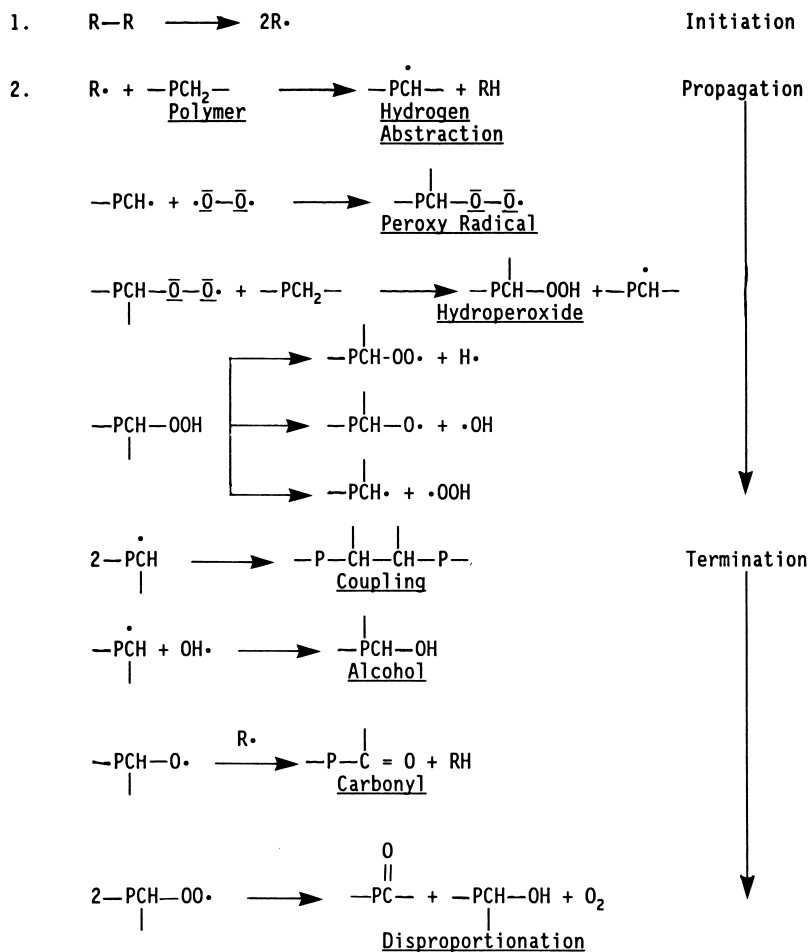

OXIDATIVE BIODEGRADATION

Oxidation Reaction Mechanisms and Polymer Structures

While much is known about the structures and reaction products of polymers susceptible to oxidative biodegradation, confirmation of the individual reaction steps has not yet been demonstrated analytically. Still, mechanistic inferences are possible from extensive knowledge of physiological oxidation processes and polymer oxidation *in vitro*.

The polymer oxidation processes to be discussed may be consistent with a homolytic chain reaction or a heterolytic mechanism. Species such as carbonyl, hydroxyl, and chain scission products are detectable. Classic initiation, propagation, and termination events for homolysis and ionic heterolytic processes are detailed in Fig. 4.

Except for the nature of susceptible functional groups, the principles of polymer degradation resistance stated in the

HomolysisHeterolysis**FIG. 4.** Proposed homolytic chain reaction and heterolytic oxidation mechanisms.

section on the structures of hydrolyzable polymers are valid for predicting relative oxidation resistance of polymers. Sites favored for initial oxidative attack, consistent with a homolytic or heterolytic pathway, are those that allow abstraction of an atom or ion and provide resonance stabilization of the resultant

radical or ion. Figure 5 provides a selection of readily oxidized groups and the atom at which initial attack occurs. In Fig. 6, examples of radical and ion stabilization by resonance in ether and branched hydrocarbon structures are provided. Peroxy, carbonyl, and other radical intermediates are stabilized by

FIG. 5. Readily oxidizable functional groups (* is site of homolysis or heterolysis).

similar resonance delocalization of electrons from the elements C, O, H, or N.

Two general categories of oxidative biodegradation, based on the source of initiation of the process, are direct oxidation by the host and device or external environment-mediated oxidation.

Direct Oxidation by Host

In these circumstances, host-generated molecular species effect or potentiate oxidative processes directly on the polymer. Current thinking, based on solid analytical evidence, is that such reactive molecules are derived from activated phagocytic cells responding to the injury and the properties of the foreign body at the implant site (Zhao *et al.*, 1991). These cells, which originate in the bone marrow and populate the circulatory system and connective tissues, are manifest as two types, the neutrophils (polymorphonuclear leukocytes, PMNs) and the monocytes. The latter can differentiate into macrophage and foreign body giant cell (FBGC) phenotypes.

Much work is under way to elucidate the sequence of events leading to phagocytic oxidation of biomaterials. Certain important processes of wound healing in the presence of biologically derived foreign bodies such as bacteria and parasites, are showing some relevance to biomaterial implants (Northup, 1987).

Neutrophils, responding to chemical mediators at the wound site, mount a powerful but transient chemical attack within the first few days of injury (Northup, 1987; Test

and Weiss, 1986). Chemically susceptible biomaterials may be affected if they are in close apposition to the wound site (Sutherland *et al.*, 1993). Activated macrophages subsequently multiply and subside within days at a benign wound site or in weeks if stimulants such as toxins or particulates are released at the site. Their fusion products, foreign body giant cells, can survive for months to years on the implant surface. Macrophages also remain resident in collagenous capsules for extended periods.

While we recognize that the mechanism of cellular attack and oxidation of biomaterials is as yet unconfirmed, the following discussion attempts to provide logical biological pathways to powerful oxidants capable of producing known degradation products.

Both PMNs and macrophages metabolize oxygen to form a superoxide anion (O_2^-). This intermediate can undergo transformation to more powerful oxidants on conceivably can initiate homolytic reactions on the polymer. Superoxide dismutase (SOD), a ubiquitous peroxidase enzyme, can catalyze the conversion of superoxide to hydrogen peroxide, which in the presence of myeloperoxidase (MPO) derived from PMNs, is converted to hypochlorous acid (HOCl). A potent biomaterial oxidant in its own right (Coury *et al.*, 1987), hypochlorite can oxidize free amine functionality (e.g., in proteins) to chloramines that can perform as long-lived sources of chlorine oxidant (Test and Weiss, 1986, Figs. 7, 8). Hypochlorite can oxidize other substituted nitrogen functional groups (amides, ureas, urethanes, etc.) with potential chain cleavage of these groups.

The following paragraphs describe potential cooperative reactions involving acquired peroxidase and free ferrous ions. Macrophages contain essentially no MPO, so their hydrogen peroxide is not normally converted to HOCl. However, PMN-derived MPO can bind securely to foreign body surfaces (Locksley *et al.*, 1982), and serve as a catalyst reservoir for macrophage- or FBGC-derived HOCl production. If free ferrous ion, which is normally present in negligible quantities in the host, is released to the implant site by hemolysis or other injury, it can catalyze the formation of the powerfully oxidizing hydroxyl radical via the Haber-Weiss cycle (Klebanoff, 1982; Fig. 7).

Figure 8 shows radical and ionic intermediates of HOCl that may initiate biomaterial oxidation. Figure 9 is a diagram showing a leukocyte phagocytic process that employs endogenous MPO catalysis of HOCl formation. In a more general sense, the MPO may come from within or outside of the cell.

The foregoing discussion of sources of direct oxidation focused primarily on acute implant periods in which bursts of PMN activity followed by macrophage activity normally resolve within weeks. However, since the foreign body subsequently remains implanted, a sustained if futile attempt to phagocytose an implanted device provides a prolonged release of chemicals onto the biomaterial. This phenomenon, called exocytosis, occurs over months to possibly years (Zhao *et al.*, 1990) and results primarily from the macrophage-FBGC line. It can contribute to long-term chemical degradation of the polymer.

The oxidation processes induced by phagocytes are the result of oxidants produced by general foreign body responses,

FIG. 6. (A) Resonance stabilization of ether and hydrocarbon radicals. (B) Resonance stabilization of ether and hydrocarbon cations.

not direct receptor–ligand catalysis by oxidase enzymes. Attempts to degrade oxidatively susceptible polymers by direct contact with oxidase enzymes have produced short-range or limited effects (Santerre *et al.*, 1994; Sutherland *et al.*, 1993).

Macrophages mediate other processes, such as fibrous capsule formation around the device. Their release of cellular regulatory factors stimulates fibroblasts to populate the implant site and produce the collagenous sheath. Any knowledge of the effects of factors such as fibroblasts or fibrous capsules on rates and mechanisms of polymer degradation is, at this time, extremely rudimentary.

Stress Cracking

An important category of host-induced biodegradation with an oxidative component is stress cracking as manifest in poly(ether urethane) elastomers. It differs from classic environmental stress cracking (ESC), which involves a susceptible material at a critical level of stress in a medium which may permeate but does not dissolve the polymer. Classic ESC is not accompanied by significant chemical degradation (Stroke, 1988). Instead, stress cracking of polyurethanes is characterized by surface attack of the polymer and by chemical changes induced by relatively specific *in vivo* or *in vitro* oxidizing

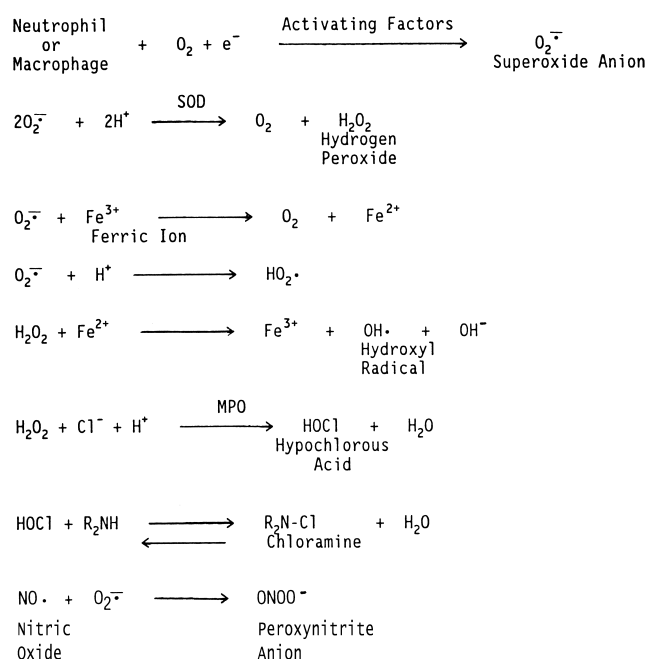

FIG. 7. Generation of potential oxidants by phagocytic processes.

Equilibrium ProductsRadical IntermediatesIonic Intermediates

FIG. 8. Hypochlorous acid: formation and potential reaction intermediates.

conditions. Conditions relevant to stress cracking of certain poly(ether urethane) compositions are stated in Table 3.

Recent information on the stress cracking of poly(ether urethanes) and poly(ether urethane ureas) (e.g., Fig. 3) has provided insights which may be valid for these and other

compositions that can be oxidized (e.g., polypropylene; Altman *et al.*, 1986; polyethylenes, Wasserbauer *et al.*, 1990; Zhao *et al.*, 1995).

Poly(ether urethanes), which are resistant to hydrolysis *in vivo*, are used as connectors, insulators, tines, and adhesives for cardiac pacemakers and neurological stimulators (Fig. 10). They have performed with high reliability in chronic clinical applications since 1975. Certain poly(ether urethane) pacing leads have displayed surface cracks in their insulation after residence times *in vivo* of months to years. These cracks are directly related in frequency and depth to the amount of residual stress (Figs. 11, 12) and the ether (soft segment) content of the polyurethane (Coury *et al.*, 1987; Martin *et al.*, 2001).

Morphologically, the cracks display regular patterns predominantly normal to the force vectors with very rough walls, occasionally with "tie fibers" bridging the gaps, indicative of ductile rather than brittle fracture (Figs. 13, 14). Infrared analysis indicates that oxidation does not take place detectably in the bulk, but only on the surface where extensive loss of ether functionality (1110 cm^{-1}) and enhanced absorption in the hydroxyl and carbonyl regions are observed (Stokes *et al.*, 1987). Possible mechanisms for the oxidative degradation of ethers are presented in Fig. 15. The participation of molecular oxygen in the degradation mechanism is supported by studies which showed that poly(ether urethane urea) degradation *in vitro* correlated with oxygen diffusion into the polymer bulk after surface oxidation was initiated by hydrogen peroxide/cobalt chloride (Schubert *et al.*, 1997).

In a seminal study, Zhao *et al.* (1990) placed polyurethane tubing in cages permeable to fluids and cells under strain (therefore under high initial stress, which was subject to subsequent stress relaxation) and implanted them in rats. In certain cases, antiinflammatory steroids or cytotoxic polymers were

coimplanted in the cages. Implants of up to 15 weeks were retrieved. The only prestressed samples to crack were those that did not reside in the cages with the coimplants. The authors concluded that adherent cells caused the stress cracking, and cell necrosis or deactivation inhibited crack induction.

Subsequently, viable phagocytic cells were implicated as a cause of crack initiation *in vivo* (Zhao *et al.*, 1991). By removing adherent foreign body giant cells after implantation of a curved poly(ether urethane urea) film in a wire cage for up to 10 weeks, exposed “footprints” showed localized surface cracking on the order of several microns deep and wide. Adjacent areas of polymer which were devoid of attached cells were not cracked. Owing to relatively low stresses in the implanted film, deep crack propagation was not observed.

In vitro studies of strained (Stokes, 1988) and unstrained poly(ether urethane) films (Phua *et al.*, 1987; Bouvier *et al.*, 1991; Ratner *et al.*, 1988; Wiggins *et al.*, 2003) using oxidants, enzymes, etc., have sought to duplicate *in vivo* stress cracking. Although some surface chemical degradation with products similar to those seen *in vivo* was demonstrated, stress crack morphology was not closely matched *in vitro* until recently, in two studies. A test which involves immersing stressed poly(ether urethane) tubing in a medium of glass wool, hydrogen peroxide, and cobalt chloride produces cracks which duplicate those produced *in vivo* but with rate acceleration

of up to seven times (Zhao *et al.*, 1995). These investigators also showed that human plasma proteins, particularly alpha₂-macroglobulin and ceruloplasmin, enhance *in vitro* stress cracking by oxidants in patterns morphologically similar to those observed *in vivo* (Zhao *et al.*, 1993). The potential of macrophages to contribute to stress cracking of poly(ether urethanes) was verified in a recent *in vitro* study which succeeded in potentiating macrophage oxidative effects with ferrous chloride and inhibiting them with the antiinflammatory steroid dexamethasone (Casas *et al.*, 1999). In another study, comparable crack patterns were produced when specimens of stressed tubing in rats were compared with those incubated with PMNs in culture (Sutherland *et al.*, 1993). Moreover, this study revealed a difference in chemical degradation products with time of implant which correlated with products from oxidants generated primarily by PMNs (HOCl) and macrophages (ONOO⁻). Early implant times, activated PMNs, and HOCl caused preferential decrease in the urethane oxygen stretch peak while longer implant times and ONOO⁻ caused selective loss of the aliphatic ether stretch peak (by infrared spectroscopy).

Taken together, the foregoing observations are consistent with a two-step mechanism for stress cracking *in vivo*. This hypothesis, as yet unproven, is under investigation. In the first step, surface oxidation induces very shallow, brittle microcracks. The second step involves propagation of the cracks in which specific body fluid components act on the formed cracks to enhance their depth and width without inducing major detectable bulk chemical reactions. Should this hypothesis prove correct, the term “oxidation-initiated stress cracking” would be reasonably descriptive.

The above description of stress cracking has generally considered static stress such as that formed during the cooling of molten parts or the assembly of components. Dynamic stresses and strains such as those occurring during the operation of diaphragm or bladder heart pumps or artificial joints can cause related cracking in areas of high flex. The cracking has been purported to increase with time of device operation but to display only minor surface chemical changes (Wu *et al.*, 1999; Tomita *et al.*, 1999).

This type of stress cracking has been controlled by reducing residual stress, isolating the polymer from cell contact (Tang *et al.*, 1994), protecting the polymer from stress cracking media, or using stress crack-resistant polymers (e.g., in the case of urethanes, ether-free) (Takahara *et al.*, 1994; Coury *et al.*, 1990; Tanzi *et al.*, 1997) and use of antioxidants such as hindered phenols (e.g., vitamin E, Monsanto Santowhite powder) (Schubert *et al.*, 1997). Stress cracking is next compared with another type of degradation, metal ion-induced oxidation.

Device- or Environment-Mediated Oxidation

Metal Ion-Induced Oxidation

A process of oxidative degradation that has, thus far, only been reported clinically for poly(ether urethane) pacemaker leads, requires, as does stress cracking, a very specific set of conditions. The enabling variables and fracture morphology are quite different from stress cracking, although oxidative degradation products are similar. Biodegradation of implanted

FIG. 11. Pellethane 2463-80A pacemaker lead tubing with high applied radial stress showing total breach.

FIG. 12. Pellethane 2363-80A pacemaker lead tubing showing "frosting" due to stress from tight ligation.

devices through stress cracking always occurs on polymer surfaces exposed to cells and provides characteristic rough-walled fissures (indicative of ductile fracture) oriented perpendicular to the stress vector (Figs. 11–14). Metal ion-induced oxidation initiates on the enclosed inner surfaces of pacing lead insulation near corroded metallic components and their entrapped corrosion products. Smooth crack walls and microscopically random crack orientation is indicative of brittle fracture (Figs. 16, 17). Macroscopically, crack patterns that track metal component configurations may be present (Fig. 18). Degradation

products which may be found deeper in the bulk than with stress cracking are again indicative of brittle fracture.

This phenomenon called metal ion-induced oxidation has been confirmed by *in vitro* studies in which polyether urethanes were aged in metal ion solutions of different standard oxidation potentials. Above an oxidation potential of about +0.77, chemical degradation was severe. Below that oxidation potential, changes in the polymer that are characteristic of simple plasticization were seen (Coury *et al.*, 1987; Table 4). This technique also showed that metal ion-induced oxidation was

FIG. 13. Stress crack pattern (frosting) near tight ligature. $\times 14$.

FIG. 14. Single stress crack in pacemaker lead tubing with rough walls and "tie fibers" indicative of ductile fracture. $\times 700$.

proportional to the ether content of the polyurethane (Coury *et al.*, 1987; Table 5).

The effect of various metals on oxidation *in vitro* and *in vivo* HAS also been studied. Different metallic components of pacing lead conductors were sealed in poly(ether urethane) (Dow Pellethane 2363-80A) lead tubing and immersed in 3% hydrogen peroxide at 37°C for up to 6 months (Stokes *et al.*, 1987) or implanted in rabbits for up to 2 years (Stokes *et al.*, 1990). Both techniques resulted in corroded metals and degraded tubing lumen surfaces under certain conditions within 30 days.

In particular, the *in vivo* interaction of body fluids with cobalt and its alloys resulted in oxidative cracking of the polymer.

The metal ion-induced oxidation process clearly involves corrosion of metallic elements to their ions and subsequent oxidation of the polymer. In operating devices, the metal ion may be formed by solvation, galvanic or electrolytic corrosion, or chemical or biochemical oxidation (Fig. 19). In turn, these metal ions develop oxidation potentials that may well be enhanced in body fluids over their standard half-cell potentials. As strong oxidants, they produce intermediates or attack the

FIG. 15. Pathways for oxidative fragmentation of polyethers.

polymer to initiate the chain reaction (Fig. 20). Metal ion-induced oxidation is therefore the result of a highly complex interaction of the device, the polymer, and the body.

Should metal ion-induced oxidation be a possibility in an implanted device, several approaches are available to control this problem. They are not universally applicable, however,

and should be incorporated only if functionality and biocompatibility are retained. Potentially useful techniques include using corrosion-resistant metals, "flushing" corrosive ions away from the susceptible polymer, isolating the metals and polymer from electrolyte solutions, incorporating appropriate antioxidants, and using oxidation-resistant polymers if available.

Recently, polyurethane elastomers with enhanced oxidation stability have been developed. They are segmented, ether- and ester-free polymers with unconventional soft segments, including, for example, hydrogenated polybutadiene, polydimethylsiloxane, polycarbonate, and dimerized fat acid derivatives (Takahara *et al.*, 1991, 1994; Coury *et al.*, 1990; Pinchuk *et al.*, 1991; Kato *et al.*, 1995; Mathur *et al.*, 1997). In implant tests, they have shown reduced tendency to stress crack, and some of them have shown high resistance to metal ion oxidants *in vitro*. Early attempts to stabilize polyurethanes by laminating more biostable polymers (such as silicone rubbers) to tissue-facing surfaces have met with limited success (Pinchuk, 1992) in dynamic applications due to delamination tendencies.

More recent approaches to stabilizing polyurethanes to oxidative attack *in situ* have involved the use of surface modifying macromolecules (SMMs) (Santerre *et al.*, 2000) and surface modifying end groups (SMEs) (Ward, *et al.*, 1995, 1998). SMMs, typically fluorocarbon-based polymers, are blended with the polyurethanes during processing and migrate to the surface prior to implantation. SMEs are moieties (typically polysiloxane) bonded to polyurethane as end groups. The covalently modified polyurethanes may be used in bulk or as additives to conventional polyurethanes. Both approaches have provided enhanced *in vivo* stability for polyurethane implants; however, the long-term effects of these treatments are not, as yet, known. SMMs have been covalently modified with bioactive agents such as antioxidants to provide further degradation resistance (Ernsting *et al.*, 2002).

All of the "barrier" strategies to protecting polyurethanes described above appear to have validity, at least for protecting polyurethanes in the short term. The long-term (multiyear) benefits of these approaches remain to be seen in light of issues such as surface dynamics, interfacial interactions, and coating durability.

A caveat relevant to the opening paragraphs of this chapter is that all of these polyurethane modifications, while potentially providing enhanced resistance to biodegradation, still allow susceptibility to attack by biological components, often at slow rates. With poly(carbonate urethanes), for example, superior oxidation resistance has been observed in several studies (Tanzi *et al.*, 1997; Mathur *et al.*, 1997). However, in aqueous media *in vitro* and *in vivo*, slow degradation attributable to simple hydrolysis was also detected (Zhang *et al.*, 1997). The body fluid environment provides a relatively stable long-term hydrolytic medium, generally less subject to "respiratory bursts" that strongly enhance oxidative processes. Although phagocytic processes may also produce hydrolytic enzymes, their effects on synthetic polymers are specific and limited (Labow *et al.*, 2002). Hydrolysis, therefore, may be expected to take place continuously with poly(carbonate urethane) integrity susceptible to a combination of mechanical stress and vigorous oxidizing conditions (Fare *et al.*, 1999;

FIG. 16. Random crack pattern of Pellethane 2363-80A lead insulation caused by metal ion-induced oxidation. $\times 480$.

FIG. 17. Smooth crack wall indicative of brittle fracture caused by metal ion-induced oxidation. $\times 830$.

Labow *et al.*, 2002). Studies of up to 3 years' implantation have indicated detectable hydrolysis (Seifalian *et al.*, 2003). Only long-term implant studies (e.g., 5 years or greater) would confirm the acceptability of poly(carbonate urethanes) or, for that matter, other new polymers having potentially susceptible groups.

Oxidative Degradation Induced by External Environment

Under very limited circumstances, the body can transmit electromagnetic radiation that may affect the integrity

of implanted polymers. For example, the cornea and vitreous humor of the eye as well as superficial skin layers allow the passage of long-wave (320–400 nanometer) “ultraviolet A” radiation. Absorption of ultraviolet radiation causes electron excitation that can lead to photo-oxidative degradation. This process has been suggested in the breakdown of polypropylene components of intraocular lenses (Altman *et al.*, 1986).

In maxillofacial exo- and very likely endoprotheses, elastomers may undergo undesirable changes in color and physical properties as a consequence of exposure to natural sunlight-frequency radiation (Craig *et al.*, 1980). Photo-oxidation

TABLE 5 Effect of Ether Content of Poly(ether urethane) on Susceptibility to Metal Ion-Induced Oxidation^a

Polyetherurethane	Polyether content	Change in tensile strength (%)	Change in elongation (%)
Pellethane 2363-80A	High	- 54	- 42
Pellethane 2363-55D	Low	- 23	- 10
Model segmented polyurethane	None	+ 9	+ 3

^aConditions: 0.1 M AgNO₃/90°C/35 days vs controls aged in deionized water; ASTM (D-1708) microtensile specimens.

FIG. 19. Formation of metal ion from metal.

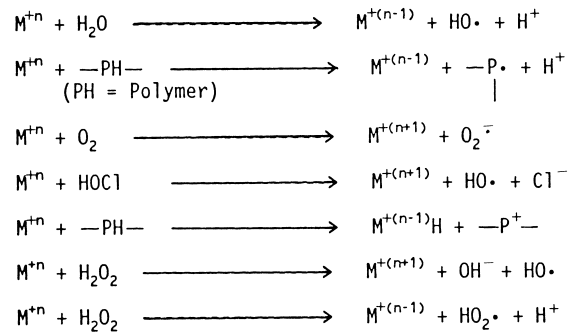

FIG. 20. Initiation of oxidation pathways by metal ions.

mechanisms involving the urethane function of aromatic poly(ether- or poly(ester urethanes) are shown in Fig. 21. Antioxidants and ultraviolet absorbers provide limited protection for these materials.

FIG. 21. Photo-oxidative reactions of aromatic polyurethanes. (A) Formation of quinone-imide from aromatic polyurethane. (From A. J. Coury *et al.*, *J. Biomater. Appl.* 3, 1988.) (B) Photolytic cleavage of urethane link. (From S. K. Brauman *et al.*, *Ann. Biomed. Eng.* 9, 1981.)

CONCLUSION

Polymers that are carefully chosen for use in implanted devices generally serve effectively for their intended lifetimes if they are properly processed and device-material-host interactions are adequately addressed. In certain limited circumstances, unintended hydrolytic or oxidative biodegradation occurs. This may be induced by direct attack by the host or via the intermediacy of the device or the outside environment. With susceptible polymers, protective measures can be taken to ensure extended efficacy, although new, biodegradation resistant polymer which are on the horizon may require less protection. Knowledge of biodegradation mechanisms and the employment of appropriate countermeasures will promote the continued growth in compositions and uses of polymers as implantable biomaterials.

Acknowledgments

The author is very grateful to Dr. R. C. Allen for providing the drawing on activated phagocyte redox metabolism. For their technical, advice and contributions, I sincerely thank Drs. James Anderson, Jonathan Sears, John Eaton, Allan Woffman, John Mahoney, Maurice Kreevoy, Grace Picciolo, and Buddy Ratner. For the preparation of this manuscript, I am deeply indebted to my "computer wizard,"

Mrs. Jayne McCaughey. For help in updating literature sources, I thank Ms. Mari Ferentinos.

QUESTIONS

1. The two major mechanisms of chemical degradation of polymers *in vivo* are hydrolysis and oxidation. Given the following polymers, indicate whether they are susceptible to hydrolysis, oxidation or both processes. If they would be highly resistant to both processes, so indicate.
 - Poly(carbonate urethane)
 - Poly(ether urethane)
 - Poly(ester urethane)
 - Aromatic polyester, poly(ethylene terephthalate)
 - Polypropylene
 - Polyethylene (linear)
 - Polytetrafluoroethylene
 - Polydimethylsiloxane
2. What are some common polymer functional groups susceptible to hydrolysis?
3. In the past, investigators have fabricated heart valves from "aromatic polyurethanes" which contain polyether, urethane, and urea functional groups. These devices

were intended to last for several years in use, but have generally failed to perform for those periods.

- What physical and chemical forces are acting on the heart valves *in vivo*?
 - What are the most likely mechanisms (physical and chemical) of degradation leading to failure of these devices? State at least three mechanisms.
4. As a materials scientist, you have experience with polyurethanes as biomaterials. Among the readily available commercial elastomers, they demonstrate the best combination of physical properties, but are susceptible to biodegradation, mostly through their polyether or polyester soft segments. You are charged with designing a biostable elastomer (polyurethane or otherwise).
- Choose an approach to produce a chemically stable elastomer that retains reasonable physical properties for at least 3 years.
 - Describe 5 tests/analyses (*in vitro/in vivo*) which may be used to characterize this elastomer and confirm its potential stability.

6.3 DEGRADATIVE EFFECTS OF THE BIOLOGICAL ENVIRONMENT ON METALS AND CERAMICS

David F. Williams and Rachel L. Williams

The environment to which biomaterials are exposed during prolonged use (i.e., the internal milieu of the body) can be described as an aqueous medium containing various anions, cations, organic substances, and dissolved oxygen. The anions are mainly chloride, phosphate, and bicarbonate ions. The principal cations are Na⁺, K⁺, Ca²⁺, and Mg²⁺, but with

TABLE 1 Ionic Concentrations in Blood Plasma and Extracellular Fluid

Anion, cation	Blood plasma (mM)	Extracellular fluid (mM)
Cl ⁻	96–111	112–120
HCO ₃ ⁻	16–31	25.3–29.7
HPO ₄ ²⁻	1–1.5	193–102
SO ₄ ²⁻	0.35–1	0.4
H ₂ PO ₄ ⁻	2	—
Na ⁺	131–155	141–15
Mg ²⁺	0.7–1.9	1.3
Ca ²⁺	1.9–3	1.4–1.55
K ⁺	35–5.6	3.5–4

(Bundy, 1994)

TABLE 2 Major Proteins and Other Organic Constituents of Blood Plasma

Major proteins and organic molecules in blood plasma (gl ⁻¹ unless stated otherwise)	
Albumin	30–55
α -Globulins	5–10
β -Globulins	6–12
γ -Globulins	6.6–15
α -Lipoproteins	3.5–4.5
Fibrinogen	1.7–4.3
Total cholesterol	1.2–2.5
Fatty acids	1.9–4.5
Glucose	0.65–1.1
Lactate	0.5–2.2 mM
Urea	3–7 mM

(Bundy, 1994)

smaller amounts of many others. Table 1 presents the range of values for the anion and cation concentrations in blood plasma and extracellular fluid (Bundy, 1994). This represents an environment with a chloride concentration of approximately a third of that of sea water (Hanawa, 2002). The concentration of dissolved oxygen also influences the aggressive nature of the environment and in venous blood is approximately a quarter of that in air. The organic substances include low-molecular-weight species as well as relatively high-molecular-weight proteins and lipids. Table 2 gives examples of the concentration of various organic components of blood plasma. The protein content of the environment is known to have a significant influence on the corrosive nature of body fluids (Williams, 1985; Khan *et al.*, 1999a). The pH in this well-buffered system is around 7.4, although because of inflammation it may change for short periods following surgery to as low as 4 or 5 (Bundy, 1994). The temperature remains constant around 37°C.

On the basis of existing knowledge of the stability of materials in various environments, we should predict that metals, as a generic group, should be relatively susceptible to corrosion in this biological environment, whereas ceramics should display a varying susceptibility, depending on solubility. This

TABLE 3 Chemical Composition of Implant Alloys

Implant alloys	Composition
316L stainless steel	Cr, Mo, Ni, Mn, C, S, Si, P, Fe
Co–Cr based alloys	Cast Co–Cr–Mo Wrought Co–Cr–Mo Wrought Co–Cr–W–Ni Wrought Co–Cr–Mo–Ni Wrought Co–Cr–Mo–Ni–Fe Wrought Co–Cr–Mo–Ni–W–Fe
Cp titanium	Ti + traces of O, N, C, H, Fe
Titanium alloys	Ti–6Al–4V Ti–6Al–7Nb Ti–15Mo Ti–12Mo–6Zr–2Fe Ti–13Nb–13Zr Ti–15Mo–2.8Nb–0.2Si–0.26O Ti–16Nb–10Hf Ti–15Mo–5Zr–3Al Ti–Ni

TABLE 4 Chemical Composition of Common Implant Ceramics

Implant ceramics	Composition
Alumina	–Al ₂ O ₃ + <0.3 wt% MgO
Zirconia	Yttria stabilized tetragonal zirconia ZrO ₂ + 2–3 mol% Y ₂ O ₃
Calcium phosphates	Ca ₃ (PO ₄) ₂ –α- or β-tricalcium phosphate Ca ₁₀ (PO ₄) ₆ (OH) ₂ —hydroxyapatite

correlates fairly well with experimental observations and clinical experience, since it is well known that all but the most corrosion-resistant metals will suffer significant and destructive attack upon prolonged implantation. Also, even the most noble of metals and those that are most strongly passivated (i.e., naturally protected by their own oxide layer) will still show some degree of interaction. The important passivating implant alloys and their compositions are presented in Table 3.

There are some ceramics that have a combination of very strong partially ionic, partially covalent bonds that are sufficiently stable to resist breakdown within this environment, such as the pure simple oxide ceramics, and others in which certain of the bonds are readily destroyed in an aqueous medium so that the material essentially dissolves, for example certain calcium phosphates. Typical implant ceramics and their compositions are presented in Table 4.

With these general statements in mind, we have to consider the following questions in relation to the corrosion and degradation of metals and ceramics:

1. Within these groups, how does the susceptibility to corrosion and degradation vary; by what precise mechanisms do the interfacial reactions take place; and how

is material selection (and treatment) governed by this knowledge?

2. Are there variables within this biological environment other than those described above that can influence these processes?
3. What are the consequences of such corrosion and degradation phenomena?

We review each of these questions in this chapter. It is particularly important to bear in mind some general points as these questions are discussed.

1. Material selection cannot be governed solely by considerations of stability, and mechanical and physical properties especially may be of considerable importance. Since corrosion is a surface phenomenon, however, it may be possible to optimize corrosion resistance by attention to or treatment of the surface rather than by manipulation of the bulk chemistry (Trepanier *et al.*, 1999). This offers the possibility of developing sufficient corrosion resistance in materials of excellent bulk mechanical and physical properties. Thus, noble metals such as gold and platinum are rarely used for structural applications (apart from dental restoration) because of their inferior mechanical properties, even though they have excellent corrosion resistance; instead, base metal alloys with passivated or protected surfaces offer better all-around properties.
2. Medical devices are not necessarily used in mechanically stress-free conditions and indeed the vast majority of those using metals or ceramics are structurally loaded. It is well known that mechanical stress plays a very important role in the corrosion of metals (Gilbert *et al.*, 1993; Jacobs *et al.*, 1998) and the degradation process in ceramics (Piconi and Maccauro, 1999), both potentiating existing effects and initiating others. This has to be taken into consideration.
3. We cannot expect the biological environment to be constant. Within the overall characteristics described earlier, there are variations (with time, location, activity, health status, etc.) in, for example, oxygen levels, availability of free radicals, and cellular activity, all of which may cause variations in the corrosive nature of the environment (Fonseca and Barbosa, 2001; Tengvall *et al.*, 1989). Most important, corrosion is not necessarily a progressive homogeneous reaction with zero-order kinetics. Corrosion processes can be quiescent but then become activated, or they can be active but then become passivated and localized, with transient fluctuations in conditions playing a part in these variations.
4. The effects of corrosion or degradation may be twofold. First, and in the conventional metallurgical sense, the most obvious, the problem can lead to loss of structural integrity of the material and function. This may be undesirable, as in the case of many long-term prostheses, or desirable, as in devices intended for short-term function (e.g., ceramics for drug delivery systems) or where the material is replaced by tissue during the degradation process, as with ceramic bone substitution. In addition to this, however, and usually of much greater

significance with biomaterials, when released into the tissue, the corrosion or degradation products can have a significant and controlling effect on that tissue (Jacobs *et al.*, 1998; Bravo *et al.*, 1990). Indeed, it is likely that the corrosion process is the most important mediator of the tissue response to metallic materials. It is therefore important that we know both the nature of the reaction products and their rate of generation. In this respect it is important to recognize that a very small release of certain metallic ions that cause adverse biological reactions may be more significant than a larger amount of a less stimulating by product of corrosion or degradation.

METALLIC CORROSION

Basic Principles

The most pertinent form of corrosion related to metallic biomaterials is aqueous corrosion. This occurs when electrochemical reactions take place on a metallic surface in an aqueous electrolyte. There are always two reactions that occur: the anodic reaction, which yields metallic ions, for example, involving the oxidation of the metal to its salt:

and the cathodic reaction, in which the electrons so generated are consumed. The precise cathodic reaction will depend on the nature of the electrolyte, but two of the most important in aqueous environments are the reduction of hydrogen:

and the reduction of dissolved oxygen:

in acidic solutions or:

in neutral or basic solutions.

In all corrosion processes, the rate of the anodic or oxidation reaction must equal the rate of the cathodic or reduction reaction. This is a basic principle of electrochemically based metallic corrosion. It also explains how variations in the local environment can affect the overall rate of corrosion by influencing either the anodic or cathodic reactions. The whole corrosion process can be arrested by preventing either of these reactions.

From a thermodynamic point of view, first consider the anodic dissolution of a pure metal isolated in a solution of its salt. The metal consists of positive ions closely surrounded by free electrons. When the metal is placed in a solution, there will be a net dissolution of metal ions since the Gibbs free energy (ΔG) for the dissolution reaction is less than for the reverse reaction. This leaves the metal with a net negative charge, thus making it harder for the positive ions to leave the surface and increasing the ΔG for the dissolution reaction. There will come a point when the ΔG for the dissolution reaction will equal the ΔG for the reverse reaction. At this point, a dynamic equilibrium is reached and a potential difference will be set up across

TABLE 5 Electrochemical Series

Metal	Potential (V)
Gold	1.43
Platinum	1.20
Mercury	0.80
Silver	0.79
Copper	0.34
Hydrogen	0
Lead	-0.13
Tin	-0.14
Molybdenum	-0.20
Nickel	-0.25
Cobalt	-0.28
Cadmium	-0.40
Iron	-0.44
Chromium	-0.73
Zinc	-0.76
Aluminum	-1.33
Titanium	-1.63
Magnesium	-2.03
Sodium	-2.71
Lithium	-3.05

the charged double layer surrounding the metal. The potential difference will be characteristic of the metal and can be measured against a standard reference electrode. When this is done against a standard hydrogen electrode in a 1 N solution of its salt at 25°C, it is defined as the standard electrode potential for that metal (Table 5). The position of a metal in the electrochemical series primarily indicates the order with which metals displace each other from compounds, but it also gives a general guide to reactivity in aqueous solutions. Those at the top are the noble, relatively unreactive metals, whereas those at the bottom are the more reactive. This is the first guide to corrosion resistance, but, as we shall see, there are major difficulties related to the use and interpretation of reactions from this simple analysis.

Now consider a system in which the metal is in an aqueous solution that does not contain its ions. In this situation, the electrode potential at equilibrium (i.e., when the rate of the anodic reaction equals the rate of the cathodic reaction) will be shifted from the standard electrode potential and can be defined by the Nernst equation:

$$E = E_0 + (RT/nF) \ln(a_{\text{anod}}/a_{\text{cath}})$$

where E_0 is the standard electrode potential, RT/F is a constant, n is the number of electrons transferred, and a is the activity of the anodic and cathodic reactants. At low concentrations, the activity can be approximated to the concentration. In this situation, there is a net dissolution of the metal and a current will flow. At equilibrium, the rate of the metal dissolution is equal to the rate of the cathodic reaction, and the rate of the reaction is directly proportional to the current density by Faraday's law; therefore:

$$i_{\text{anodic}} = i_{\text{cathodic}} = i_{\text{corrosion}}$$

and the Nernst equation can be rewritten:

$$E - E_0 = \pm \beta \ln(i_{\text{corr}}/i_0)$$

where β is a constant and i_0 is the exchange current density, which is defined as the anodic (or cathodic) current density at the standard electrode potential. Current density is the current, measured in amperes, normalized to the surface area of the metal.

These conditions represent convenient models for the basic mechanisms of corrosion, but they are hardly realistic. Indeed, in this situation of a homogeneous pure metal existing within an unchanging environment, an equilibrium is reached in which no further net movement of ions takes place. In other words, the corrosion process takes place only transiently, but is effectively stopped once this equilibrium is reached.

In reality, we usually have neither entirely homogeneous surfaces or solutions, nor complete isolation of the metal from other parts of the environment, and this equilibrium is easily upset. If the conditions are such that the equilibrium is displaced, the metal is said to be polarized. There are several ways in which this can happen. Two main factors control the behavior of metals in this respect and determine the extent of corrosion in practice. The first concerns the driving force for continued corrosion (i.e., the reasons why the equilibrium is upset and the nature of the polarization), and the second concerns the ability of the metal to respond to this driving force.

It is self-evident that if either the accumulating positive metal ions in the surrounding media or the accumulating electrons in the metal are removed, the net balance between the dissolution and the replacement of the ions will be disturbed. This will occur in the biological environment surrounding implanted alloys due to the interaction of the proteins with the metal ions. Metal ions can form complexes with proteins (Steinemann, 1996; Jacobs *et al.*, 1998; Büdinger and Hertl, 2000) and these complexes can be transported away from the immediate vicinity. This removes the metal ions from the charged double layer at the interface allowing further release of metal ions to reestablish the equilibrium. Similarly, relative movement between the implant and the tissue, for example, at a bearing surface or on a cyclically loaded implant, will cause mixing at the interface and will modify the composition of the electrolyte and may modify the surface of the alloy (Khan *et al.*, 1999b). The equilibrium is established precisely because of the imbalance of charge, so that if the charge balance is disturbed, further corrosion will occur to attempt to reestablish the balance. The result will be continued dissolution as the system attempts to achieve this equilibrium, in other words, sustained corrosion. An environment that allows the removal of electrons in contact with the metal or stirring of the electrolyte will achieve this.

The process of galvanic corrosion may be used to demonstrate this effect. Consider a single homogeneous pure metal, A, existing within an electrolyte (Fig. 1). The metal will develop its own potential, V_A , with respect to the electrolyte. If a different metal electrode, B, is placed into the same electrolyte, but without contacting A, it will develop its own potential V_B . If V_A is not equal to V_B , there will be a difference in the numbers of excess free electrons in each. This is of no consequence if A and B are isolated from each other, but should they be placed

FIG. 1. When electrical contact is made between electrodes A and B, electrode B acts as an electron sink, thus upsetting the equilibrium and causing continued dissolution of A.

in electrical contact, electrons will flow from that metal with the greater potential in an attempt to make the two electrodes equipotential. This upsets the equilibrium and causes continued and accelerated corrosion of the more active metal (anodic dissolution) and protects the less active (cathodic protection).

Galvanic corrosion may be seen whenever two different metals are placed in contact in an electrolyte. It has been frequently observed with complex, multicomponent surgical implants such as modular total joint designs consisting of titanium alloy femoral stems and cobalt alloy femoral heads (Jacobs *et al.*, 1998). It is not necessary for the components to be macroscopic, monolithic electrodes for this to happen, and the same effect can be seen when there are different microstructural features within one alloy, such as the multi-phase microstructure evident in implants of sensitized stainless steel where the grain boundaries become depleted in chromium and corrode preferentially to the remaining surface (Disegi and Eschbach, 2000). In practice, it is the regional variations in electrode potential over an alloy surface that are responsible for much of the generalized surface corrosion that takes place in metallic components.

Many of the commonly used surgical alloys contain highly reactive metals (i.e., with high negative electrode potentials),

such as titanium, aluminum, and chromium. Because of this high reactivity, they will react with oxygen upon initial exposure to the atmosphere. This initial oxidation leaves an impervious oxide layer firmly adherent to the metal surface; thus all other forms of corrosion may be significantly reduced because the oxide layer acts as a protective barrier, passivating the metal. The manufacturing process for implant alloys may include a passivating step to enhance the oxide layer prior to implantation, for example nitric acid treatment of 316L stainless steel (Fraker and Griffith, 1985).

In summary, the basic principles of corrosion determine that:

1. In theory, corrosion resistance can be predicted from standard electrode potentials. This explains the nobility of some metals and the considerable reactivity of others, but is not useful for predicting the occurrence of corrosion of most alloy systems in practice.
2. Irrespective of standard electrode potentials, the corrosion resistance of many materials is determined by their ability to become passivated by an oxide layer that protects the underlying metal.
3. Corrosion processes in practice are influenced by variations in surface microstructural features and in the environment that disrupt the charge transfer equilibrium.

INFLUENCE OF THE BIOLOGICAL ENVIRONMENT

It is reasonable to assume that the presence of biological macromolecules will not cause a completely new corrosion mechanism. However, they can influence the rate of corrosion by interfering in some way with the anodic or cathodic reactions discussed earlier. Four ways in which this could occur are discussed next:

1. The biological molecules could upset the equilibrium of the corrosion reactions by consuming one or other of the products of the anodic or cathodic reaction. For example, proteins can bind to metal ions and transport them away from the implant surface. This will upset the equilibrium across the charged double layer and allow further dissolution of the metal; in other words, it will decrease ΔG for the dissolution reaction.
2. The stability of the oxide layer depends on the electrode potential and the pH of the solution. Proteins and cells can be electrically active and interact with the charges formed at the interface and thus affect the electrode potential (Bundy, 1994). Bacteria (Laurent *et al.*, 2001) and inflammatory cells (Hanawa, 2002; Fonseca and Barbosa, 2001) can alter the pH of the local environment through the generation of acidic metabolic products that can shift the equilibrium.
3. The stability of the oxide layer is also dependent on the availability of oxygen. The adsorption of proteins and cells onto the surface of materials could limit the diffusion of oxygen to certain regions of the surface. This could cause preferential corrosion of the

oxygen-deficient regions and lead to the breakdown of the passive layer. Alternatively the biomolecule adsorption layer could act as a capacitor preventing the diffusion of molecules from the surface (Hiromoto *et al.*, 2002).

4. The cathodic reaction often results in the formation of hydrogen, as shown earlier. In a confined locality, the buildup of hydrogen tends to inhibit the cathodic reaction and thus restricts the corrosion process. If the hydrogen can be eliminated, then the active corrosion can proceed. It is possible that bacteria in the vicinity of an implant could utilize the hydrogen and thus play a crucial role in the corrosion process.

There is sufficient evidence to support the premise that the presence of proteins and cells can influence the rate of corrosion of some metals (Williams, 1985; Khan *et al.*, 1999a, b; Hanawa, 1999, 2002). Studies have examined these interactions electrochemically and have found very few differences in many of the parameters measured (e.g., electrode potential, polarization behavior, and current density at a fixed potential). However, analysis of the amount of corrosion through weight loss or chemical analysis of the electrolyte has shown significant effects from the presence of relatively low concentrations of proteins. These effects have varied from severalfold increases for some metals under certain conditions, to slight decreases under other conditions.

It has been shown that proteins adsorb onto metal surfaces and that the amount adsorbed appears to be different on a range of metals (Williams and Williams, 1988; Wälivaara *et al.*, 1992). Similarly, proteins have been shown to bind to metal ions and it is suggested that they are transported away from the local site as a protein-metal complex and distributed systemically in the body (Jacobs *et al.*, 1998). It is therefore likely that proteins will influence the corrosion reactions that occur when a metal is implanted, although there is no direct evidence to explain the mechanism of the interaction at this time.

CORROSION AND CORROSION CONTROL IN THE BIOLOGICAL ENVIRONMENT

The need to ensure minimal corrosion has been the major determining factor in the selection of metals and alloys for use in the body. Two broad approaches have been adopted. The first has involved the use of noble metals, that is, those metals and their alloys for which the electrochemical series indicates excellent corrosion resistance. Examples are gold, silver, and the platinum group of metals. Because of cost and relatively poor mechanical properties, these are not used for major structural applications, although it should be noted that gold and its alloys are extensively used in dentistry; silver is sometimes used for its antibacterial activity; and platinum-group metals (Pt, Pd, Ir, Rh) are used in electrodes.

The second approach involves the use of the passivated metals. Of the three elements that are strongly passivated (i.e., aluminum, chromium, and titanium), aluminum cannot be used on its own for biomedical purposes because of toxicity problems; however, it has an important role in several Ti alloys.

Chromium is very effectively protected but cannot be used in bulk. It is, however, widely used in alloys, especially in stainless steels and in the cobalt–chromium-based alloys, where it is normally considered that a level of above 12% gives good corrosion resistance and about 18% provides excellent resistance. Titanium is the best in this respect and is used as a pure metal or as the major constituent of alloys (Long and Rack, 1998). In alloys the passivating layer promoting the corrosion resistance is predominantly composed of one of these metal oxides. For example, chromium oxide passivates 316L stainless steel and Co–Cr-based alloys and Ti oxide in Ti alloys. The other alloying elements may be present in the surface oxide and this can influence the passivity of the layer (Sittig *et al.*, 1999). Careful pretreatment of the alloys can be used to control the passivity of these alloys (Shih *et al.*, 2000; Trepanier *et al.*, 1998). In particular, production procedures need to be controlled because of their influence on the surface oxides, for example, the cleaning (Aronsson *et al.*, 1997) and sterilization (Thierry *et al.*, 2000) procedures.

Although these metals and alloys have been selected for their corrosion resistance, corrosion will still take place when they are implanted in the body. Two important points have to be remembered. First, whether noble or passivated, all metals will suffer a slow removal of ions from the surface, largely because of local and temporal variations in microstructure and environment. This need not necessarily be continuous and the rate may either increase or decrease with time, but metal ions will be released into that environment. This is particularly important with biomaterials, since it is the effect of these potentially toxic or irritant ions that is the most important consequence of their use. Even with a strongly passivated metal, there will be a finite rate of diffusion of ions through the oxide layer, and possibly a dissolution of the layer itself. It is well known that titanium is steadily released into the tissue from titanium implants (Jacobs *et al.*, 1998; Hanawa *et al.*, 1998). Second,

some specific mechanisms of corrosion may be superimposed on this general behavior; some examples are given in the next section.

Pitting Corrosion

The stainless steels used in implantable devices are passivated by the chromium oxide that forms on the surface. It has been shown, however, that in a physiological saline environment, the driving force for repassivation of the surface is not high (Seah *et al.*, 1998). Thus, if the passive layer is broken down, it may not repassivate and active corrosion can occur.

Localized corrosion can occur as a result of imperfections in the oxide layer, producing small areas in which the protective surface is removed (Rondelli and Vicentini, 1999). These localized spots will actively corrode and pits will form in the surface of the material. This can result in a large degree of localized damage because the small areas of active corrosion become the anode and the entire remaining surface becomes the cathode. Since the rate of the anodic and cathodic reactions must be equal, it follows that a relatively large amount of metal dissolution will be initiated by a small area of the surface, and large pits may form (Fig. 2).

Fretting Corrosion

The passive layer may be removed by a mechanical process (Khan *et al.*, 1999b; Okazaki, 2002). This can be a scratch that does not repassivate, resulting in the formation of a pit, or a continuous cyclic process in which any reformed passive layer is removed. This is known as fretting corrosion, and it is suggested that this can contribute to the corrosion observed between a fracture fixation plate and the bone screws attaching the plate to the bone. There are three reasons why fretting can

FIG. 2. This etched metallographic micrograph demonstrates the pitting corrosion of stainless steel.

affect the corrosion rate. The first is due to the removal of the oxide film as just discussed. The second is due to plastic deformation of the contact area; this can subject the area to high strain fatigue and may cause fatigue corrosion. The third is due to stirring of the electrolyte, which can increase the limited current density of the cathodic reaction.

Crevice Corrosion

The area between the head of the bone screw and counter-sink on the fracture fixation plate can also be influenced by the crevice conditions that the geometry creates (Fig. 3) (Cook *et al.*, 1987). Porous coated implants may also demonstrate crevice corrosion (Seah *et al.*, 1998). Accelerated corrosion can be initiated in a crevice by restricted diffusion of oxygen into the crevice. Initially, the anodic and cathodic reactions occur uniformly over the surface, including within the crevice. As the crevice becomes depleted of oxygen, the reaction is limited to metal oxidation balanced by the cathodic reaction on the remainder of the surface. In an aqueous sodium chloride solution, the buildup of metal ions within the crevice causes the influx of chloride ions to balance the charge by forming the metal chloride. In the presence of water, the chloride will dissociate to its insoluble hydroxide and acid. This is a rapidly accelerating process since the decrease in pH causes further metal oxidation.

Intergranular Corrosion

As mentioned earlier, stainless steels rely on the formation of chromium oxides to passivate the surface. If some areas of the alloy become depleted in chromium, as can happen if carbides are formed at the grain boundaries, the regions adjacent to the grain boundaries become depleted in chromium. The

passivity of the surface in these regions is therefore affected and preferential corrosion can occur (Fig. 4). Although this problem can easily be overcome by heat treating the alloys (Disegi and Eschbach, 2000), it has been observed on retrieved implants (Walczak *et al.*, 1998) and can cause severe problems since once initiated it will proceed rapidly and may well cause fracture of the implant and the release of large quantities of corrosion products into the tissue.

Stress Corrosion Cracking

Stress corrosion cracking is an insidious form of corrosion since an applied stress and a corrosive environment can work together and cause complete failure of a component, when neither the stress nor the environment would be a problem on their own. The stress level may be very low, possibly only residual, and the corrosion may be initiated at a microscopic crack tip that does not repassivate rapidly. Incremental crack growth may then occur, resulting in fracture of the implant. Industrial uses of stainless steels in saline environments have shown susceptibility to stress corrosion cracking and therefore it is a potential source of failure for implanted devices.

Galvanic Corrosion

If two metals are independently placed within the same solution, each will establish its own electrode potential with respect to the solution. If these two metals are placed in electrical contact, then a potential difference will be established between them, electrons passing from the more anodic to the more cathodic metal. Thus equilibrium is upset and a continuous process of dissolution from the more anodic metal will take place. This accelerated corrosion process is galvanic corrosion. It is important if two different alloys are used in an implantable device when the more reactive may corrode freely.

FIG. 3. Crevice corrosion is evident in the screw hole in this fracture fixation plate.

FIG. 4. Intergranular corrosion is demonstrated on this etched stainless steel specimen.

FIG. 5. Extensive corrosion on the titanium stem of a modular hip prosthesis.

Whenever stainless steel is joined to another implant alloy, it will suffer from galvanic corrosion. If both alloys remain within their passive region when coupled in this way, the additional corrosion may be minimal. Some modular orthopedic systems are made of titanium alloys and cobalt-based alloys on the basis that both should remain passive, but evidence of corrosion has been reported (Gilbert *et al.*, 1993). Certainly, as shown in Fig. 5, titanium stems of modular prostheses can exhibit extensive corrosion. Galvanic corrosion may also take place on a microscopic scale in multiphase alloys where phases are of considerably different electronegativity. In dentistry,

some amalgams may show extensive corrosion because of this mechanism.

CERAMIC DEGRADATION

The rate of degradation of ceramics within the body can vary considerably from that of metals in that they can be either highly corrosion resistant or highly soluble. As a general rule, we should expect to see a very significant resistance to degradation with ceramics and glasses. Since the corrosion process

in metals is one of a conversion of a metal to ceramic structure (i.e., metal to a metal oxide, hydroxide, chloride, etc.) we must intuitively conclude that the ceramic structure represents a lower energy state in which there would be less driving force for further structural degradation. The interatomic bonds in a ceramic, being largely ionic but partly covalent, are strong directional bonds and large amounts of energy are required for their disruption. As extraction metallurgists know, it takes a great deal of energy to extract aluminum metal from the ore aluminum oxide, but as we have seen, the reverse process takes place readily by surface oxidation. Thus, we should expect ceramics such as Al_2O_3 , ZrO_2 , TiO_2 , SiO_2 , and TiN to be stable under normal conditions (Dalglish and Rawlings, 1981). This is what is observed in clinical practice. There is limited evidence to show that some of these ceramics (e.g., polycrystalline Al_2O_3 and ZrO_2) do show “aging” phenomena (Marti, 2000; Piconi and Maccauro, 1999), with reductions in some mechanical properties, but the significance of this is unclear.

Alternatively, there will be many ceramic structures that, although stable in the air, will dissolve in aqueous environments. Consideration of the classic fully ionic ceramic structure NaCl and its dissolution in water demonstrates this point. It is possible, therefore, on the basis of the chemical structure, to identify ceramics that will dissolve or degrade in the body, and the opportunity exists for the production of structural materials with controlled degradation.

Since any material that degrades in the body will release its constituents into the tissue, it is necessary to select anions and cations that are readily and harmlessly incorporated into metabolic processes and utilized or eliminated. For this reason, it is compounds of sodium, and especially calcium, including calcium phosphates and calcium carbonates, that are primarily used.

The degradation of such compounds will depend on chemical composition and microstructure (Bohner, 2000). For example, tricalcium phosphate [$\text{Ca}_3(\text{PO}_4)_2$] is degraded fairly rapidly while calcium hydroxyapatite [$\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$] is relatively stable. Within this general behavior, however, porosity will influence the rates so that a fully dense material will degrade slowly, while a microporous material will be susceptible to more rapid degradation.

In general, dissolution rates of these ceramics *in vivo* can be predicted from behavior in simple aqueous solution. However, there will be some differences in detail within the body, especially with variations in degradation rate seen with different implantation sites. It is possible that cellular activity, either by phagocytosis or the release of free radicals, could be responsible for such variations.

In between the extremes of stability and intentional degradability lie a small group of materials in which there may be limited activity. This is particularly seen with a number of glasses and glass ceramics, based on Ca, Si, Na, P, and O, in which there is selective dissolution on the surface involving the release of Ca and P, but in which the reaction then ceases because of the stable SiO_2 -rich layer that remains on the surface. This is of considerable interest because of the ability of such surfaces to bond to bone, and this subject is dealt with elsewhere in this book.

On the basis of this behavior, bioceramics are normally classified under three headings:

- Inert, or “nearly inert” ceramics
- Resorbable ceramics
- Ceramics of controlled surface reactivity

This area is discussed in detail in other chapters within this book.

SUMMARY

This chapter has attempted to demonstrate that metals are inherently susceptible to corrosion and that the greatest care is needed in using them within the human body. In general, ceramics have much less tendency to degrade, but care still has to be taken over aging phenomena. The human body is very aggressive toward all of these materials.

Questions

1. (a) What are the three most common implant alloys used in structural applications? For each one, state which element in the alloy is chosen to enhance corrosion resistance, and how do they do it.
 - (b) Describe the mechanisms of intergranular corrosion and fretting corrosion.
 - (c) If you had an orthodontic appliance where Ni-Ti wire was placed in the groove of a stainless steel bracket, what corrosion problems might you encounter?
2. Consider a situation in which a 316L stainless steel fracture fixation plate has been used to treat a tibial fracture. Discuss the possible mechanisms of corrosion of the device with reference to the alloy composition, the geometry of the device, and the mechanical environment. Include a discussion on the fate of any corrosion products and their possible effect on the patient.
3. Discuss the potential disadvantages of using two different alloys for the components of modular orthopedic prostheses.

6.4 PATHOLOGICAL CALCIFICATION OF BIOMATERIALS

Frederick J. Schoen and Robert J. Levy

Biomaterials and prosthetic devices, particularly those used in the circulatory system, but also at other sites, may be affected by the formation of nodular deposits of calcium phosphate or other calcium-containing compounds, a process known as calcification or mineralization (Table 1). In many cases, this causes device failure. Calcification has been encountered in association with both synthetic and biologically derived biomaterials in various clinical and experimental settings, including bioprosthetic or homograft cardiac valve substitutes and vascular replacements, blood pumps used as cardiac assist devices, breast implants, intrauterine contraceptive devices, urinary prostheses, and soft contact lenses.

Deposition of mineral salts of calcium occurs as a normal process in bones and teeth (physiologic mineralization). Moreover, it is desirable that some implant biomaterials calcify, e.g., osteoinductive materials used for orthopedic or dental applications (Begley *et al.*, 1995). However, nonskeletal tissues and the biomaterials that comprise other medical devices are not intended to calcify (e.g., heart valves, breast implants), since mineral deposits can interfere with their function. Therefore, calcification of these tissues or biomaterials is abnormal or pathologic. The mature mineral phase of biomaterial-related and other forms of pathologic calcifications is a poorly crystalline calcium phosphate known as apatite. It closely resembles calcium hydroxyapatite, the mineral that provides the structural rigidity of bone and has the chemical formula Ca₁₀(PO₄)₆(HO)₂. Indeed, we will see later that many features are shared between biomaterials calcification, other pathologic

TABLE 1 Prostheses and Devices Affected by Calcification of Biomaterials

Configuration	Biomaterial	Clinical Consequence
Cardiac valve prostheses	Glutaraldehyde-pretreated porcine aortic valve or bovine pericardium, and allograft aortic/pulmonary valves	Valve obstruction or incompetency
Cardiac ventricular assist bladders	Polyurethane	Dysfunction by stiffening or cracking
Vascular grafts	Dacron grafts and aortic allografts	Graft obstruction or stiffening
Soft contact lens	Hydrogels	Opacification
Intrauterine contraceptive devices	Silicone rubber, polyurethane or copper	Birth control failure by dysfunction or expulsion
Urinary prostheses	Silicone rubber or polyurethane	Incontinence and/or infection

calcifications on the one hand and normal bone mineralization on the other. Pathologic calcification is also common in native arteries and heart valves, where it occurs as an important feature of the serious diseases atherosclerosis and degenerative aortic stenosis, respectively (Schoen, 1999).

Pathologic calcification is further classified as either dystrophic or metastatic, depending on its setting. Dystrophic calcification is the deposition of calcium salts (usually calcium phosphates) in damaged or diseased tissues or biomaterials in individuals with normal calcium metabolism. In contrast, metastatic calcification is the deposition of calcium salts in previously normal tissues in individuals with deranged mineral metabolism (for example, with elevated blood calcium levels). The conditions favoring dystrophic and metastatic calcification can act synergistically; thus, in the presence of abnormal mineral metabolism, calcification associated with biomaterials or injured tissues is enhanced. Moreover, the ability to form bone is physiologically regulated through adjustment of enhancing and inhibiting substances, many of which circulate in the blood. In young individuals the balance appropriately favors bone formation. However, this same chemical environment favors enhanced calcification of biomaterials in the young.

The cells and extracellular matrix of dead tissues are the principal sites of pathologic calcification. Calcification of an implant biomaterial can occur deep within the tissue (intrinsic calcification) or at the surface, associated with attached cells and proteins (extrinsic calcification). An important instance of extrinsic calcification is that associated with tissue heart valve infection (prosthetic valve endocarditis) (Schoen and Hobson, 1985).

THE SPECTRUM OF PATHOLOGIC BIOMATERIALS AND MEDICAL DEVICE CALCIFICATION

Heart Valves and Vascular Replacements

Calcific degeneration of glutaraldehyde-pretreated porcine bioprosthetic heart valves (Fig. 1) is the most clinically significant dysfunction of a medical device due to biomaterials calcification (Levy *et al.*, 1986a; Schoen and Levy, 1984; Schoen *et al.*, 1988; Schoen and Levy, 1999). The predominant pathologic process is intrinsic calcification of the valve cusps,

largely initiated in the deeply seated cells and the tissue from which the valve was fabricated and often involving collagen. Calcification leads to failure most commonly by causing cuspal tears, less frequently by cuspal stiffening, and rarely by inducing distant emboli. Overall, more than half of porcine bioprostheses fail within 12–15 years. Calcification is more rapid and aggressive in the young; for example, the rate of failure of bioprostheses is approximately 10% in 10 years in elderly recipients, but is nearly uniform in less than 4 years in most adolescent and preadolescent children (Grunkemeier *et al.*, 1994). Calcification has also complicated the clinical use and experimental investigation of heart valves composed of other tissues (e.g., bovine pericardium) (Schoen *et al.*, 1987; McGonagle-Wolff and Schoen, 1992) and polymers (e.g., polyurethane) (Hilbert *et al.*, 1987; Schoen *et al.*, 1992c).

In some young individuals with congenital cardiac defects or acquired aortic valve disease, human allograft/homograft aortic (or pulmonary) valves surrounded by a sleeve of aorta (or pulmonary artery) are used. Allograft valves are valves that are removed from a person who has died and transplanted to another individual; the tissue is usually cryopreserved but not chemically cross-linked. Allograft vascular segments (without a valve) can be used to replace a large blood vessel. Whether containing an aortic valve or nonvalved, allograft vascular tissue can undergo severe calcification, particularly in the wall; calcification can lead to allograft valve dysfunction or deterioration (Mitchell *et al.*, 1998). Synthetic vascular replacements composed of Dacron or expanded polytetrafluoroethylene (e-PTFE) also calcify in some patients.

Polymeric Bladders in Blood Pumps

Deposition of calcific crystals on flexing bladder surfaces (which are usually composed of polyurethane) occurs in and may limit the functional longevity of blood pumps used as ventricular assist systems or total artificial hearts. Massive deposition of mineral leading to failure has been noted in experimental animals, and a lesser degree of calcification has been encountered following extended human implantation (Fig. 2). Mineral deposits can result in deterioration of pump or valve performance through loss of pliability or the initiation of tears. Blood pump calcification, regardless of the type of polyurethane used, generally predominates along the flexing margins of the diaphragm, emphasizing the

FIG. 1. Calcified clinical porcine bioprosthetic valve removed because of extensive calcification, causing stenosis. (A) Inflow surface of valve. (B) Outflow surface of valve. (C) Closeup of large calcific nodule ulcerated through cuspal surface. (D) Radiograph of valve illustrating radiopaque, dense calcific deposits.

important potentiating role of mechanical factors in this system (Coleman *et al.*, 1981; Harasaki *et al.*, 1987).

Calcific deposits associated with blood pump components can occur either within the adherent layer of deposited proteins and cells (pseudointima) on the blood-contacting surface (extrinsic mineralization) or below the surface (intrinsic calcification) (Joshi *et al.*, 1996). In some cases, calcific deposits are associated with microscopic surface defects, either originating during bladder fabrication or resulting from cracking during function.

Breast Implants

Calcification of silicone-gel breast implant capsules occurs as discrete calcified plaques at the interface of the inner

fibrous capsule with the implant surface. Capsular calcification has also been encountered with breast implants in patients with silicone envelopes filled with saline. Calcification could interfere with effective tumor detection and diagnosis, which could potentially delay treatment, particularly in patients who have breast implants following reconstructive surgery for breast cancer. In a study of breast implants removed predominantly for capsular contraction, 16% overall demonstrated calcific deposits, including 26% of implants inserted for 11–20 years and all those > 23 years (Peters and Smith, 1995).

Capsular mineralization has also been associated with the Dacron patches used on silicone-gel implants in the 1960s and early 1970s to anchor implants to the chest wall in an attempt to prevent implant migration and sagging. Ivalon (polyvinyl

alcohol) sponge prostheses, used quite extensively during the 1950s, were also frequently associated with calcification. In Japan, where augmentation mammoplasty was frequently performed using injection of foreign material (liquid paraffin from approximately 1950 until 1964, and primarily liquid-silicone injections thereafter), the incidence of calcification has been much higher. One study showed calcification in 45% of breast augmentations which were done by injection (Koide and Katayama, 1979).

Intrauterine Contraceptive Devices

Intrauterine contraceptive devices (IUDs) are composed of plastic or metal and placed in a woman's uterus chronically to prevent implantation of a fertilized egg. Device dysfunction due to calcific deposits can be manifested as contraceptive failure or device expulsion. For example, accumulation of calcific plaque could prevent the release of the active contraception-preventing agent—either ionic copper from copper-containing IUDs or an active agent from hormone-releasing IUD systems. Studies of explanted IUDs using transmission and electron microscopy coupled with X-ray microprobe analysis have shown that surface calcium deposition is ubiquitous but variable among patients (Khan and Wilkinson, 1985).

Urinary Prostheses

Mineral crusts form on the surfaces of polymeric prostheses to alleviate urinary obstruction or incontinence (Goldfarb *et al.*, 1989). Observed in male and female urethral implants and artificial ureters, this problem can lead to obstruction and

device failure. The mineral crust consists of either hydroxyapatite or struvite, an ammonium- and magnesium-containing phosphate mineral derived from urine. There is some evidence that encrustation may both result from and predispose to bacterial infection.

Soft Contact Lenses

Calcium phosphate deposits can opacify soft contact lenses, typically composed of poly(2-hydroxyethyl methacrylate) (HEMA). Growing progressively larger with time, they are virtually impossible to remove without destroying the lens (Bucher *et al.*, 1995). Calcium from tear fluid is considered to be the source of the deposits found on HEMA contact lenses, and calcification may be potentiated in patients with systemic and ocular conditions associated with elevated tear calcium levels (Klintworth *et al.*, 1977).

ASSESSMENT OF BIOMATERIALS CALCIFICATION

Calcific deposits are investigated using morphologic and chemical techniques (Table 2). Morphologic techniques facilitate detection and characterization of the microscopic and ultrastructural sites and distribution of the calcific deposits and their relationship or tissue or biomaterials structural details. Such analyses yield important qualitative (but not quantitative) information. In contrast, chemical techniques, which require destruction of the tissue specimen, permit both identification and quantitation of bulk elemental composition and determination of crystalline mineral phases. However, such techniques

TABLE 2 Methods for Assessing Calcification

Technique	Sample preparation	Analytical results
Morphologic procedures		
Gross examination	Gross specimen	Overall morphology
Radiographs	Gross specimen	Calcific distribution
Light microscopy—von Kossa or alizarin red	Formalin or glutaraldehyde fixed	Microscopic phosphate or calcium distribution, respectively
Transmission electron microscopy	Glutaraldehyde fixed	Mineral ultrastructure
Scanning electron microscopy with electron microprobe	Glutaraldehyde fixed	Element localization/quantitation
Electron energy loss spectroscopy	Glutaraldehyde fixed or rapidly frozen	Elemental localization/quantitation (highest sensitivity)
Chemical procedures		
Atomic absorption	Ash or acid hydrolyzate	Bulk calcium
Colorimetric phosphate analysis	Ash or acid hydrolyzate	Bulk phosphorus
X-ray diffraction	Powder	Nature of crystal phase
Infrared spectroscopy	Powder	Carbonate mineral phase

generally cannot relate the location of the mineral to the details of the underlying tissue structure. The most comprehensive studies characterize both morphologic and chemical aspects of calcification.

Morphologic Evaluation

Morphologic assessment of calcification is done by means of several readily available and well-established techniques that range from macroscopic (gross) examination and radiographs (X-rays) of explanted prostheses to sophisticated electron energy loss spectroscopy. Each technique has advantages and limitations; several techniques are often used in combination to obtain an understanding of the structure, composition, and mechanism of each type of calcification. Careful visual examination of the specimen, often under a dissecting (low power) microscope, and radiography assess distribution of mineral in explanted bioprosthetic heart valves and ventricular assist systems. Specimen radiography typically involves placing the explanted prosthesis on an X-ray film plate and exposing to an X-ray beam in a special device used for small samples (e.g., we use the Faxitron, Hewlett-Packard, McMinnville, CA, with an energy level of 35 keV for 1 min for valves). Deposits of mineral appear as bright densities that have locally blocked the beam from exposing the film (see Fig. 1D).

Light microscopy of calcified tissues is widely used. Identification of mineral is facilitated through the use of either calcium- or phosphorus-specific stains, such as alizarin red (which stains calcium) or von Kossa (which stains phosphates) (see Fig. 2B and Fig. 3). These histologic stains are readily available, can be easily applied to tissue sections embedded in either paraffin or plastic, and are most useful for confirming and characterizing suspected calcified areas which have been noted by routine hematoxylin and eosin staining techniques. Sectioning of calcified tissue that has been embedded in paraffin often leads to considerable artifact due to fragmentation; embedding of tissue with calcific deposits in glycolmethacrylate polymer yields superior section quality.

Electron microscopic techniques, which involve the bombardment of the specimen with a highly focused electron beam in a vacuum, have much to offer in the determination of early sites of calcific deposits. In transmission electron microscopy (TEM), the beam traverses an ultra-thin section (0.05 μm) (Fig. 4); observation of the ultrastructure (submicron tissue features) of calcification by TEM facilitates the understanding of the mechanisms by which calcific crystals form. Scanning electron microscopy (SEM) images the specimen surface, and can be coupled with elemental localization by energy-dispersive X-ray analysis (EDXA), allowing a semiquantitative evaluation of the local progression of calcium and phosphate deposition in a site-specific manner. Electron energy loss spectroscopy (EELS) couples transmission electron microscopy with highly sensitive elemental analyses to provide a most powerful localization of incipient nucleation sites and early mineralization (Webb *et al.*, 1991). In general, the more highly sensitive and sophisticated morphologic techniques require more demanding and expensive preparation of specimens to avoid unwanted artifacts. Forethought about and careful planning of specimen handling optimizes the yield provided by the array of available techniques, and allows multiple approaches to be used on a single specimen.

Chemical Assessment

Quantitation of calcium and phosphorus in biomaterial calcifications permits characterization of the progression of deposition, comparison of severity of deposition among specimens and determination of the effectiveness of preventive measures (Levy *et al.*, 1983a, 1985a; Schoen *et al.*, 1985, 1986, 1987; Schoen and Levy, 1999). However, such techniques destroy the configuration of the specimen during preparation. Calcium has been quantitated by atomic absorption spectroscopy of acid-hydrolyzed or ashed samples. Recently, highly sensitive multielement integrated coupled plasma (ICP) instrumentation has become available. This permits high-resolution quantitation of not only calcium, but other relevant elements,

FIG. 3. Light microscopic appearance of progressive calcification of experimental porcine aortic heart valve tissue implanted subcutaneously in 3-week-old rats, demonstrated by specific staining. such as aluminum and ferric ion in the same sample. Phosphorus is usually quantitated as phosphate, using a molybdate complexation technique with spectrophotometric detection. The crystalline form of calcium phosphate (mineral phase) can be determined by X-ray diffraction. Carbonate-containing mineral phases may also be analyzed by infrared spectroscopy.

PATHOPHYSIOLOGY

General Considerations

The determinants of biomaterial mineralization include factors related to (1) host metabolism, (2) implant structure and chemistry, and (3) mechanical factors (Fig. 5). Natural cofactors and inhibitors may also play a role (see below). The most important host metabolic factor is related to young age, with more rapid calcification taking place in immature patients or experimental animals (Levy *et al.*, 1983a). Although the relationship is well established, the mechanisms accounting for this effect are uncertain. The structural elements of the biomaterial and their modification by processing may be important implant factors for bioprosthetic tissue is the pretreatment with glutaraldehyde, done to preserve the tissue (Golomb *et al.*, 1987; Grabenwoger *et al.*, 1996). It has been hypothesized that the cross-linking agent glutaraldehyde stabilizes and perhaps modifies phosphorus-rich calcifiable structures in the bioprosthetic tissue. These sites seem to be capable of mineralization upon

implantation when exposed to the comparatively high calcium levels of extracellular fluid. Calcification of the two principal types of biomaterials used in bioprostheses—glutaraldehyde-pretreated porcine aortic valves or glutaraldehyde-pretreated bovine pericardium—is similar in extent, morphology, and mechanisms. Furthermore, both intrinsic and extrinsic mineralization of a biomaterial is generally enhanced at the sites of intense mechanical deformations generated by motion, such as the points of flexion in heart valves or circulatory assist devices. In both physiologic and pathologic calcification, nucleation of apatite crystals is more difficult than subsequent growth, which occurs relatively easily since the concentrations of both calcium and phosphorus in blood and extracellular fluid are near saturation.

Regulation of Pathologic Calcification

Calcification has typically been considered a passive, unregulated, and degenerative process. However, the observations of matrix vesicles, hydroxyapatite mineral, and bone-related morphogenetic and noncollagenous proteins in pathological calcifications have suggested that the mechanisms responsible for pathologic calcification may be regulated, similarly to normal mineralization of bone and other hard tissues (Giachelli, 1999; Speer and Giachelli, 2004). In normal blood vessels and valves, inhibitory mechanisms outweigh procalcification inductive mechanisms; in contrast, in bone and pathologic tissues, inductive mechanisms dominate. In the process of

FIG. 4. Transmission of electron microscopy of calcification of experimental porcine aortic heart valve implanted subcutaneously in 3-week-old rats. FIG. 5. Hypothesis for calcification of clinical bioprosthetic heart valves emphasizing relationships among host and implant factors, nucleation and growth of calcific nodules, and clinical failure of the device. (Reproduced with permission from F. J. Schoen *et al.*, *Lab. Invest.* 52: 531, 1985.)

normal bone calcification, the growth of apatite crystals is regulated by several noncollagenous matrix proteins including: (1) osteopontin, an acidic calcium-binding phosphoprotein with high affinity to hydroxyapatite that is abundant in foci of dystrophic calcification; (2) osteonectin, and (3) osteocalcin, and other γ -carboxyglutamic acid (GLA)-containing proteins, such as matrix GLA protein (MGP). Naturally occurring inhibitors to crystal nucleation and growth may also play a role in biomaterial and other cardiovascular calcification (Schinke *et al.*, 1999). Specific inhibitors in this context include osteopontin (Steitz *et al.*, 2002) and high-density lipoprotein (HDL, the “good” cholesterol) (Parhami *et al.*, 2002). An active area of research is the role in pathological mineralization of naturally-occurring mineralization cofactors, such as inorganic phosphate (Jono *et al.*, 2000) bone morphogenetic protein (Bostrom *et al.*, 1993) and proinflammatory lipids (Demer, 2002) and other substances (e.g., cytokines) as well as inhibitors. The non-collagenous proteins osteopontin, TGF- β 1, and tenascin-C involved in bone matrix formation and tissue remodeling have been demonstrated in clinical calcified bioprosthetic heart valves, natural valves, and atherosclerosis, suggesting that they play a regulatory role in these forms of pathologic calcification in humans (Srivasta *et al.*, 1997; Bini *et al.*, 1999; Jian *et al.*, 2001; Li QY *et al.*, 2002, Jian *et al.*, 2003).

Evidence for the active regulation of cardiovascular calcification also derives from tissue culture models of vascular cell calcification, which mimic pathologic vascular calcification *in vivo*, and genetic studies in mice. For example, osteopontin inhibits and proinflammatory lipids and cytokines enhance the mineralization of smooth muscle cell cultures (Wada *et al.*, 1999, Parhami *et al.*, 2002). In transgenic mouse models, in which the gene for the matrix GLA protein (MGP) was knocked out (Luo *et al.*, 1997) or the osteopontin gene was inactivated (Speer *et al.*, 2002), severe calcification of blood vessels resulted. Moreover, inhibition of matrix remodeling metalloproteinases inhibits calcification of elastin implanted subcutaneously in rats (Vyavahare *et al.*, 2000).

Experimental Models for Biomaterials Calcification

Animal models have been developed for the investigation of the calcification of bioprosthetic heart valves, aortic homografts, cardiac assist devices, and trileaflet polymeric valves (Table 3). Experimental models used to investigate the pathophysiology of bioprosthetic tissue calcification and as a preclinical screen of new or modified materials and design

TABLE 3 Experimental Models of Calcification

Type	System	Typical Duration
Calcification of bioprosthetic or other tissue heart valve	In-vitro incubation of tissue fragment or flexing valves	Days to weeks
	Rat subdermal implant of tissue fragment	3 weeks
	Calf or sheep orthotopic valve replacement	3–5 months
	Rat or sheep descending aorta	1–5 months
Calcification of polyurethane	Rat subdermal implant of material sample	1–2 months
	Calf or sheep artificial heart implant	5 months
	Trileaflet polymeric valve implant in calf or sheep	5 months
Calcification of hydrogel	Rat subdermal implant of material sample	3 weeks
Calcification of collagen	Rat subdermal implant of material sample	3 weeks
Urinary encrustation	<i>In vitro</i> incubation	Hours to days
	<i>In vivo</i> bladder implants (rats and rabbits)	10 weeks

configurations include tricuspid or mitral replacements or conduit-mounted valves in sheep or calves, and isolated tissue (i.e., not in a valve) samples implanted in and around the heart and subcutaneously in mice, rabbits, or rats (Levy *et al.*, 1983a; Schoen *et al.*, 1985, 1986). In both circulatory and noncirculatory models, bioprosthetic tissue calcifies progressively with a morphology similar to that observed in clinical specimens, but with markedly accelerated kinetics. Static *in vitro* models of biomaterials calcification have been investigated but have generally not been useful (Schoen *et al.*, 1992a; Mako and Vesely, 1997). However, several groups have used flexing valve models for bioprosthetic and polymeric valve calcification, in which the morphology of the resulting mineralization seems more representative of pathologic calcification that occurs *in vivo* (Bernacca *et al.*, 1992, 1994, 1997; Deiwick *et al.*, 2001; Pettenazzo *et al.*, 2001).

Compared with the several years normally required for calcification of clinical bioprostheses, valve replacements in sheep

or calves calcify extensively in 3 to 6 months (Schoen *et al.*, 1985, 1994). However, expense, technical complexity, and stringent housing and management procedures pose important limitations to all the circulatory models using large animals. In addition, implantation in the heart requires the use of complex procedures such as cardiopulmonary bypass as well as a high level of surgical expertise and postoperative care. These limitations stimulated the development of subdermal (synonym subcutaneous—under the skin) implant models. In subdermal bioprosthetic implants in rats, rabbits, and mice, (1) calcification occurs at a markedly accelerated rate in a morphology comparable to that seen in circulatory explants; (2) the model is economical so that many specimens can be studied with a given set of experimental conditions, thereby allowing quantitative characterization and statistical comparisons; and (3) specimens are rapidly retrieved from the experimental animals, facilitating the careful manipulation and rapid processing required for detailed and high-resolution analyses (Levy *et al.*, 1983a; Schoen *et al.*, 1985, 1986). The subcutaneous model is a technically convenient and economically advantageous vehicle for investigating host and implant determinants and mechanisms of mineralization, as well as for screening potential strategies for its inhibition (anticalcification). Promising approaches may be investigated further in a large-animal valve implant model. Large-animal implants as valve replacements are also used (1) to elucidate further the processes accounting for clinical failures, (2) to evaluate the performance of design and biomaterials modifications in valve development studies, (3) to assess the importance of blood/surface interactions, and (4) to provide data required for approval by regulatory agencies (Schoen, 1992b). Polyurethane calcification has also been studied with subdermal implants in rats (Joshi *et al.*, 1996). Subcutaneous implants may also be used to investigate calcification of biomaterials intended for clinical use in other anatomic sites, for example, polyhydroxyethylmethacrylate hydrogels used in soft contact lenses.

Pathophysiology of Bioprosthetic Heart Valve Calcification

Data from valve explants from patients and subdermal and circulatory experiments in animal models using bioprosthetic heart valve tissue have elucidated the pathophysiology of this important clinical problem and enhanced our understanding of pathologic calcification in general (Fig. 6). The similarities of calcification in the different experimental models and clinical bioprostheses suggest a common pathophysiology, independent of implant site. Calcification appears to depend on exposure of a susceptible substrate (often containing phosphorus) to extracellular fluid containing calcium; both mechanical factors and local implant-related or circulating substances may play regulatory roles. However, since the morphology and extent of calcification in subcutaneous implants is analogous to that observed in clinical and experimental circulatory implants, despite the lack of the dynamic mechanical activity that occurs in the circulatory environment, it is clear that dynamic stress promotes but is not prerequisite for calcification of bioprosthetic tissue. Interestingly, in the subcutaneous model, calcification is enhanced in areas of

FIG. 6. There is a substantial physiologic (normal) gradient of free calcium across the cell membrane (10^{-3} M outside, 10^{-7} M inside) which is maintained as an energy-dependent process. With cell death or membrane dysfunction, calcium phosphate formation can be initiated at the membranous cellular structures. Reproduced by permission from Schoen, F. J., et al. (1988). Biomaterials-associated calcification: pathology, mechanisms, and strategies for prevention. *J. Applied. Biomater.* 22: 11–36.

tissue folds, bends, and areas of shear, suggesting that static mechanical deformation also potentiates mineralization (Levy *et al.*, 1983a, and unpublished results). Although these data suggest that local tissue disruption mediates the mechanical effect, the precise mechanisms by which mechanical factors influence calcification are uncertain.

Moreover, no definite role has been demonstrated for circulating macromolecules or cells and many lines of evidence suggest that neither nonspecific inflammation nor specific immunologic responses appear to favor bioprosthetic tissue calcification. Nevertheless, a potential role for inflammatory and immune processes has been postulated by some investigators (Love, 1993; Human and Zilla 2001a, b). Proponents of an immunological mechanism for failure cite the evidence that (1) experimental animals can be sensitized to both fresh and cross-linked bioprosthetic valve tissues, (2) antibodies to valve components can be detected in some patients following valve dysfunction, and (3) failed tissue valves often have brisk mononuclear inflammation; no causal immunologic basis has been demonstrated for bioprosthetic valve calcification. Nevertheless, in experiments in which valve cusps were enclosed in filter chambers that prevent host cell contact with tissue but allow free diffusion of extracellular fluid and implantation of valve tissue in congenitally athymic (“nude”) mice, who have essentially no T-cell function, calcification morphology and extent are unchanged (Levy *et al.*, 1983b). Clinical and experimental data detecting antibodies to valve tissue after failure probably reflect a secondary response to valve damage rather than a cause of failure. The conditions that must be satisfied to prove a cause immunological mechanism are summarized by Mitchell in Chapter 4.3.

The initial calcification sites in bioprosthetic tissue are predominantly dead cells and cell membrane fragments (Schoen and Levy, 1999) (Fig. 4A). This occurs because the normal handling of calcium ions is disrupted in cells which have been rendered nonviable by glutaraldehyde fixation. Normally, plasma

calcium concentration is 1 mg/ml (approximately 10^{-3} M); since the membranes of healthy cells pump calcium out, the concentration of calcium in the cytoplasm is 1000–10,000 times lower (approximately 10^{-7} M). Cell membranes and intracellular organelles are high in phosphorus (as phospholipids, especially phosphatidylserine, which can bind calcium); they can serve as nucleators of calcific crystals. Mitochondria are also enriched in calcium. Other initiators under various circumstances include collagen and elastic fibers of the extracellular matrix, denatured proteins, phosphoproteins, fatty acids, blood platelets, and bacteria. We have hypothesized that cells calcify after glutaraldehyde pretreatment because this cross-linking agent stabilizes all the phosphorus stores, but the normal mechanisms for elimination of calcium from the cells are not available in glutaraldehyde-pretreated tissue (Schoen *et al.*, 1986). Once initial calcification deposits form, they can enlarge and coalesce, resulting in grossly mineralized nodules that can cause a prosthesis to malfunction.

In addition to the calcification of valve cusps, calcification of the adjacent aortic wall portion of glutaraldehyde-pretreated porcine aortic valves and valvular allografts and vascular segments is also observed clinically and experimentally. Mineral deposition occurs throughout the vascular cross section but is accentuated in the dense bands at the inner and outer media, and cells and elastin (which itself not generally a prominent site of mineralization in cusps) are the major sites. In nonstented porcine aortic valves that have greater portions of aortic wall exposed to blood than in the currently used stented valves, calcification of the aortic wall is potentially deleterious. It could stiffen the root, altering hemodynamic efficiency, cause nodular calcific obstruction, potentiate wall rupture, or provide a nidus for emboli. Moreover, some anticalcification agents (see later) including 2-amino-oleic acid (AOA) and ethanol prevent experimental cuspal but not aortic wall calcification (Chen *et al.*, 1994b).

Calcification of Collagen and Elastin

Calcification of the extracellular matrix structural proteins collagen and elastin has been observed in clinical and experimental implants of bioprosthetic and homograft valvular and vascular tissue and has been studied using a rat subdermal model. Collagen-containing implants are widely used in various surgical applications, such as tendon prostheses and surgical absorptive sponges, but their usefulness is compromised owing to calcium phosphate deposits and the resultant stiffening. Cross-linking by either glutaraldehyde or formaldehyde promotes the calcification of collagen sponge implants made of purified collagen but the extent of calcification does not correlate with the degree of cross-linking (Levy *et al.*, 1986b). In contrast, the calcification of elastin appears independent of pretreatment (Vyavahare *et al.*, 1999).

PREVENTION OF CALCIFICATION

Three general strategies have been investigated for preventing calcification of biomaterial implants: (1) systemic therapy with anticalcification agents; (2) local therapy with

implantable drug delivery devices; and (3) biomaterial modifications, whether by removal of a calcifiable component, addition of an exogenous agent, or chemical alteration.

Investigations of an anticalcification strategy must demonstrate not only the effectiveness of the therapy but also the absence of adverse effects (Schoen *et al.*, 1992b). Adverse effects in this setting could include systemic or local toxicity, tendency toward thrombosis on infection, induction of immunological effects or structural degradation, with either immediate loss of mechanical properties or premature deterioration and failure. Indeed, there are several examples whereby an antimineralization treatment contributed to unacceptable degradation of the tissue (Jones *et al.*, 1989; Gott *et al.*, 1992; Schoen, 1998). The treatment should not impede normal valve performance, such as hemodynamics and durability. As summarized in more detail in Table 4, a rational approach for preventing bioprosthetic calcification must integrate safety and efficacy considerations with the scientific basis for inhibition of calcium phosphate crystal formation. This will of necessity involve the steps summarized in Table 5, before appropriate clinical trials can be done (Schoen *et al.*, 1992b; Vyavahare *et al.*, 1997a).

Experimental studies using bioprosthetic tissue implanted subcutaneously in rats have clearly demonstrated that adequate doses of systemic agents used to treat clinical metabolic bone disease can prevent its calcification (Levy *et al.*, 1987). However, because these agents may interfere with calcium metabolism or growth of calcific deposits, systemic drugs are associated with many side effects, including interruption of physiologic calcification (i.e., bone growth), and animals receiving doses sufficient to prevent bioprosthetic tissue calcification suffer growth retardation. Thus, the principal disadvantage of the systemic use of anticalcification agents for preventing pathologic calcification relates to side effects on bone. This difficulty can be avoided by localized drug release using coimplants of a drug delivery system adjacent to the prosthesis, in which the effective drug concentration is confined to the site at which it is needed (i.e., near the implant) and systemic

TABLE 4 Criteria for Efficacy and Safety of Antimineralization Treatments

Efficacy
Effective and sustained calcification inhibition
Safety
Adequate performance (i.e., unimpaired hemodynamics and durability)
Does not cause adverse blood-surface interactions (e.g., hemolysis, platelet adhesion, coagulation protein activation, complement activation, inflammatory cell activation, binding of vital serum factors)
Does not enhance local or systemic inflammation (e.g., foreign body reaction, immunologic reactivity, hypersensitivity)
Does not cause local or systemic toxicity
Does not potentiate infection

(Modified from Schoen FJ *et al.* Antimineralization treatments for bioprosthetic heart valves. Assessment of efficacy and safety. *J Thorac Cardiovasc Surg* 1992; 104:1285–1288.)

TABLE 5 Preclinical Efficacy and Safety Testing of Antimineralization Treatments

Type of study	Information derived
Subcutaneous implantation in rats	Initial efficacy screen Mechanisms Dose-response Toxicity
Biomechanical evaluation	Hemodynamics Accelerated wear
Morphologic studies of unimplanted valves	Structural degradation assessed by light and transmission electron microscopy Scanning electron microscopy
Circulatory implants in large animals	Device configuration, surgical technique, <i>in vivo</i> hemodynamics, explant pathology Durability, thrombi, thromboembolism, hemolysis, cardiac and systematic pathology

side effects would be prevented (Levy *et al.*, 1985b). Studies incorporating EHBP (see below) in nondegradable polymers, such as ethylene–vinyl acetate (EVA), polydimethylsiloxane (silicone), and polyurethanes, have shown the effectiveness of this strategy in animal models. This approach, however, has been difficult to implement in a clinically useful manner.

The approach that most likely to yield an improved clinical valve involves modification of the substrate, either by removing or altering a calcifiable component or binding an inhibitor. Forefront strategies should also consider (1) a possible synergism provided by multiple anticalcification agents and approaches used simultaneously; (2) new materials, and (3) the possibility of tissue-engineered heart valve replacements (Rabkin and Schoen, 2002). The agents most widely studied, for efficacy, mechanisms, lack of adverse effects, and potential clinical utility, are summarized hereafter and in Table 6. Combination therapies using multiple agents may potentially provide synergy of beneficial effects to permit simultaneous prevention of calcification in both cusps and aortic wall, particularly beneficial in stentless aortic valves (Levy *et al.*, 2003).

Inhibitors of Hydroxyapatite Formation

Bisphosphonates

Ethane hydroxybisphosphonate (EHBP) has been approved by the FDA for human use to inhibit pathologic calcification and to treat hypercalcemia of malignancy. Compounds of this type probably inhibit calcification by poisoning the growth of calcific crystals. Either cuspal pretreatment or systemic or local therapy of the host with diphosphonate compounds inhibits experimental bioprosthetic valve calcification (Levy *et al.*, 1985b, 1987; Johnston *et al.*, 1993). Controlled clinical trials have orally administered bisphosphonates have demonstrated the ability to stabilize osteoporosis. These agents, such

as Alindronate (Phosphomax, Merck, Inc.), are hypothesized to act by stabilizing bone mineral. However, the effects of such agents on bioprosthetic valve or other pathologic biomaterial calcification are not yet known.

Trivalent Metal Ions

Pretreatment of bioprosthetic tissue with iron and aluminum (e.g., FeCl₃ and AlCl₃) inhibits calcification of subdermal implants with glutaraldehyde-pretreated porcine cusps or pericardium (Webb *et al.*, 1991). Such compounds are hypothesized to act through complexation of the cation (Fe or Al) with phosphate, thereby preventing calcium phosphate crystal formation and growth. Both ferric ion and the trivalent aluminum ion inhibit alkaline phosphatase, an important enzyme used in bone formation, and this may also be a component of the mechanisms by which they prevent initiation of calcification. Furthermore, recent research from our laboratories has demonstrated that aluminum chloride prevents elastin calcification through a permanent structural alteration of the elastin molecule. Iron and aluminum may also active when released from polymeric controlled-release implants.

Calcium Diffusion Inhibitor

Amino-oleic Acid

2- α -Amino-oleic acid (AOA, Biomedical Design, Inc., Atlanta, GA) bonds covalently to bioprosthetic tissue through an amino linkage to residual aldehyde functions and inhibits calcium flux through bioprosthetic cusps (Chen *et al.*, 1994a, b). AOA is effective in mitigating cusp but not aortic wall calcification in rat subdermal and cardiovascular implants. This compound is used in an FDA-approved porcine aortic valve (Fyfe and Schoen, 1999).

Removal/Modification of Calcifiable Material

Surfactants

Incubation of bioprosthetic tissue with sodium dodecyl sulfate (SDS) and other detergents extracts the majority of acidic phospholipids (Hirsch *et al.*, 1993); this is associated with reduced mineralization, probably resulting from suppression of the initial cell-membrane oriented calcification (Fig. 7). This compound is used in an FDA-approved porcine valve (David *et al.*, 1998).

Ethanol

Ethanol preincubation of glutaraldehyde-cross-linked porcine aortic valve bioprostheses prevents calcification of the valve cusps in both rat subdermal implants and sheep mitral valve replacements (Vyavahare *et al.*, 1997a, 1998). Pretreatment with 80% ethanol (1) extracts almost all phospholipids and cholesterol from glutaraldehyde-cross-linked cusps, (2) causes a permanent alteration in collagen conformation as assessed by attenuated total reflectance–Fourier transform infrared spectroscopy (ATR-FTIR), (3) affects cuspal interactions with water and lipids, and (4) enhances cuspal resistance to collagenase. Ethanol is in clinical use as a porcine valve cuspal

TABLE 6 Prototypical Agents for Mechanism-Based Prevention of Calcification

Mechanisms	Strategy/Agent
Inhibition of hydroxyapatite formation	Ethane hydroxybisphosphonate (EHBP)
Inhibition of calcium uptake	Alpha-amino-oleic acid (AOA) TM
Inhibition of Ca-P crystal growth; inhibition of alkaline phosphate; chemical modification of elastin	Ferric/aluminum chloride exposure
Phospholipid extraction	Sodium dodecyl sulfate (SDS)
Phospholipid extraction and collagen conformation modification	Ethanol exposure
Eliminate GA potentiation of calcification	Modification of (alternatives to) glutaraldehyde fixation
<ul style="list-style-type: none"> • amino acid neutralization of glutaraldehyde residues • polyepoxide (polyglycidal ether), acyl azide, carbodiimide, cyanamide and glycerol crosslinking • dye-mediated photooxidation 	

AOATM (α -amino-oleic acid) is a trademark of Biomedical Designs, Inc., of Atlanta GA.

FIG. 7. Reduction of calcification of bioprosthetic tissue by preincubation in 1% SDS demonstrated in a rat subcutaneous model of glutaraldehyde cross-linked porcine aortic valve. These results support the concept that phospholipid extraction is an important but perhaps not the only mechanism of SDS efficacy. Reproduced by permission from Schoen, F. J., Levy, R. J., and Piehler, H. R. (1992). Pathological considerations in replacement cardiac valves. *Cardiovasc. Pathol.* 1: 29–52.

pretreatment in Europe, and its use in combination with aluminum treatment of the aortic wall of a stentless valve is under consideration.

Decellularization

Since the initial mineralization sites are devitalized connective cells of bioprosthetic tissue, some investigators have removed these cells from the tissue, with the intent of making the bioprosthetic matrix less prone to calcification (Wilson *et al.*, 1995; Courtman *et al.*, 1994).

Use of Tissue Fixatives Other Than Glutaraldehyde and Modification of Glutaraldehyde Fixation

Since previous studies have demonstrated that conventional glutaraldehyde fixation is conducive to calcification of bioprosthetic tissue, several studies have investigated modifications of and alternatives to conventional glutaraldehyde pretreatment. Paradoxically, fixation of bioprosthetic tissue

by extraordinarily high concentrations of glutaraldehyde (5–10× those normally used) appear to inhibit calcification (Zilla *et al.*, 1997, 2000). Residual glutaraldehyde residues in bioprosthetic tissue can be neutralized (detoxified) by treatment with lysine or diamine; this inhibits calcification of subdermal implants (Grabewoger *et al.*, 1992; Trantina-Yates *et al.*, 2003). Non-glutaraldehyde cross-linking of bioprosthetic tissue with epoxides, carbodiimides, acylazides, and other compounds reduces their calcification in rat subdermal implant studies (Myers *et al.*, 1995; Xi *et al.*, 1992). Photooxidative preservation inhibits experimental calcification, possibly owing to the formation of unique calcification-resistant cross-links (Moore and Phillips, 1997).

Alternative Materials

Polyurethane trileaflet valves have been fabricated and investigated as a possible alternative to bioprostheses or mechanical valve prostheses. Despite versatile properties, such as superior abrasion resistance, hydrolytic stability, high flexural endurance, excellent physical strength, and acceptable blood compatibility, the use of polyurethane has been hampered by calcification, thrombosis, tearing, and biodegradation. Although the exact mechanism of polyurethane calcification is as yet unclear, it is believed that several physical, chemical, and biologic factors (directly or indirectly) play an important role in initiating this pathologic disease process (Schoen *et al.*, 1992c; Thoma and Phillips, 1995; Joshi *et al.*, 1996).

Tissue Engineered Heart Valve Replacements

In the approach called tissue engineering, an anatomically appropriate construct containing cells seeded on a resorbable scaffold is fabricated *in vitro* in a bioreactor, then implanted (Langer and Vacanti, 1993; Mayer *et al.*, 1997; Rabkin and Schoen, 2002). Progressive tissue remodeling *in vivo* is intended to ultimately recapitulate normal functional architecture. Autologous tissue-engineered valve cusps have been implanted in the pulmonary valve position in lambs, demonstrating the initial feasibility of the concept of a tissue-engineered heart

valve leaflet (Shinoka *et al.*, 1996). With this concept, the cells comprising the prosthesis are intended to be viable and capable of renewal, thus theoretically inhibiting calcification. Heart valves utilizing this strategy have been implanted in growing sheep for extended periods (to 20 weeks) without calcification (Stock *et al.*, 1999; Hoerstrup *et al.*, 2000).

CONCLUSIONS

Calcification of biomaterial implants is an important pathologic process affecting a variety of tissue-derived biomaterials as well as synthetic polymers in various functional configurations. The pathophysiology has been partially characterized with a number of useful animal models; a key common feature is the involvement of devitalized cells and cellular debris. Although no clinically useful preventive approach has been proven to be safe and effective, several strategies based on either modifying biomaterials or local drug administration appear to be promising in some contexts.

7.1 INTRODUCTION

Jack E. Lemons and Frederick J. Schoen

Synthetic biomaterials have been evaluated and used for a wide range of medical and dental applications. From the earliest uses (~1000 B.C.) of gold strands as soft tissue sutures for hernia repairs, silver and gold as artificial crowns, and gemstones as tooth replacements (inserted into bone and extending into the oral cavity), biomaterials have evolved to standardized formulations. Since the late 1930s, high-technology polymeric, metallic, and ceramic substrates have played a central role in expanding the application of biomaterial devices.

Most students enter the biomaterials discipline with a strong interest in applications. Critical to understanding these applications is the degree of success and failure and, most important, what can be learned from a careful evaluation of past successes and failures. The following chapters present topics across the spectrum of applications, ranging from cardiovascular, orthopedic, ophthalmological, and dental therapeutic devices to skin substitutes, drug delivery systems, and sensors for diagnostic purposes. A central emphasis is the correlation of application limitations with the basic properties of the various biomaterials and devices and the biological interactions of the recipient with the biomaterials and strategies to extend and improve existing applications. Although the range of devices that constitute artificial organs is at present limited in clinical use, considerable research and development has involved devices that have active mechanical, biologic, or mass-exchange functions.

It is estimated that approximately 20 million individuals have an implanted medical device. Costs associated with prostheses and organ replacement therapies exceed \$300 billion U.S. dollars per year and comprise nearly 8% of total health-care spending worldwide (Lysaght and O'Loughlin, 2000).

Most implants serve their recipients well for extended periods by alleviating the conditions for which they were implanted. Considerable effort is expended in understanding biomaterials–tissue interactions and eliminating patient–device complications (the clinically important manifestations of biomaterials–tissue interactions). Moreover, many patients receive substantial and extended benefit despite complications. For example, heart valve disease is a serious medical problem. Patients with diseased aortic heart valves have a 50% chance of dying within approximately 3 years without surgery. Surgical replacement of a diseased valve leads to an expected survival of 70% at 10 years, a substantial improvement over the natural course. However, of these patients whose longevity and quality of life have clearly been enhanced, approximately 60% will suffer a serious valve-related complication within 10 years after the operation. Thus, long-term failure of biomaterials leading to a clinically significant event does not preclude clinical success overall.

The range of tolerable risk of adverse effects varies directly with the medical benefit obtained by the therapy. Benefit and risk go hand-in-hand and clinical decisions are made to maximize the ratio of benefit to risk. The tolerable benefit–risk ratio may depend on the type of implant and the medical problem it is used to correct. Thus, more risk can be tolerated in a heart assist device (a life-sustaining implant) than in a prosthetic hip joint (an implant that relieves pain and disability, while enhancing function) or, further along the spectrum, than a breast implant (an implant with predominantly cosmetic benefit).

Considering other examples, NIH sponsored consensus conferences (1990s) have provided documentation that total hip arthroplasties demonstrate that 90% of those placed will be in place and function after a decade for individuals over 65 years old. More recently, as described in the section on

orthopaedics, concerns have been raised about longer-term influences of dilute concentrations of elements transferred from devices. As with other disciplines, a confirmed need exists for longer-term controlled clinical trials based on prospective protocols.

This chapter explores the most widely used therapeutic approaches and applications of materials in medicine, biology and artificial organs. The progress made in many of these areas is substantial. In most cases, the sections describe a device category from the perspective of the clinical need, the armamentarium of devices available to the practitioner, the results and complications, and the challenges to the field that limit success.

7.2 NONTHROMBOGENIC TREATMENTS AND STRATEGIES

Michael V. Sefton and Cynthia H. Gemmell

In 1963, Dr. Vincent Gott at the Johns Hopkins University changed the field of biomaterials by failing to reproduce an earlier experiment. He was trying to show that an applied electric field could minimize thrombogenesis on a metal surface. He obtained this result, but was somewhat mystified when he discovered that the wire leading to his negative graphite electrode was broken. He soon realized the importance of rinsing his electrode with a common disinfectant (benzalkonium chloride) and heparin prior to implantation. Thus, the first heparinized material was born. Bob Lehninger (Leininger *et al.*, 1966) at Battelle Memorial Institute in Columbus, Ohio, followed up with better quaternary ammonium compounds and soon afterwards a host of chemical derivatization methods were devised to adapt the original GBH (graphite benzalkonium heparin) method to plastics and other materials. The principles underlying these strategies and others for lowering the thrombogenicity of materials are detailed here with a few examples. For a comprehensive review of nonthrombogenic treatments and strategies the reader is referred to a number of reviews (Sefton *et al.*, 1987; Engbers and Feijen, 1991; Amiji and Park, 1993; Ratner, 1995; Kim and Jacobs, 1996).

CRITERIA FOR NONTHROMBOGENICITY

Thrombogenicity is defined (Williams, 1987) as the ability of a material to induce or promote the formation of thromboemboli. Here we are concerned with strategies to lower thrombogenicity, if not actually reduce it to zero, “nonthrombogenicity.” Thrombogenicity should be thought of as a rate parameter, since low rates of thrombus or emboli formation are probably tolerable since the fibrinolytic or other clearance systems exist to remove “background” levels of thromboemboli. We are principally concerned with rates of thrombus formation that are sufficient to occlude flowpaths in medical devices (e.g.,

block the lumen of catheters) or rates of embolus formation that cause downstream problems such as myocardial infarction or transient ischemic attacks. The mechanism of thrombogenicity is described in Chapter 4.6, while the effects of fluid flow on thrombus development and embolization are described in Chapter 3.5.

Thrombi are produced through aggregation of activated platelets and/or the thrombin-dependent polymerization of fibrinogen into fibrin. Thrombin is directly responsible for fibrin formation but it is also an important agonist of platelet activation. A simple model of thrombin generation is illustrated in Fig. 1A. The variety of mechanisms that lead to thrombin generation are lumped into a single parameter, k_p (cm/sec), a rate constant that relates the rate of production of thrombin (per unit area), R_p (g/cm²sec), to the thrombin concentration at the surface of a material C_w (g/ml):

$$R_p = k_p C_w \quad (1)$$

k_p includes both the procoagulant effect of the material (via clotting factors and platelets) less any coagulation inhibition processes. A material balance (Basmadjian, 1990; Rollason and Sefton, 1992) equating the rate of production at the surface to the rate of transport away from the surface $k_L(C_w - C_b)$ for tubes greater than about 0.1 mm in diameter (Leveque region) gives:

$$\frac{C_w}{C_b^0} = \frac{1}{1 - k_p/k_L(x)} \quad (2)$$

where C_b^0 is the concentration of thrombin at the inlet to a tube. $k_L(x)$ is the local mass transfer coefficient which is infinite at the tube inlet and decreases as one proceeds down the tube. Hence, C_w/C_b^0 increases progressively down the tube (Fig. 1B). When $k_L = k_p$, C_w becomes infinite and a thrombus is expected. For a simple tube in laminar flow, k_L is on the order of 10^{-3} cm/sec and so k_p must be less than this to avoid a thrombus. Experimental results suggest that k_p is on the order of 10^{-3} for simple materials such as polyethylene but $<10^{-4}$ for heparinized materials (Rollason and Sefton, 1992). According to this model, only such low- k_p materials can be expected to minimize thrombin production. This is one of the reasons heparinization and other active methods of inhibiting thrombin formation are so popular as strategies for imparting low thrombogenicity. There are, however, other criteria that must also be met.

It is also a requirement that platelet interactions with the surface do not lead to thrombosis. To some extent platelet adhesion is an inevitability. Once adherent, platelets change shape and release their granule contents, which can activate bulk platelets. Although it is intuitive to suggest that a nonthrombogenic surface should not support platelet adhesion it has not, unfortunately, been that simple. While most studies focus on evaluating the platelet compatibility of surfaces by measuring *in vitro* platelet adhesion, some *ex vivo* studies (Hanson *et al.*, 1980; Cholakis *et al.*, 1989) have demonstrated that even in the absence of adhesion, platelets can be “consumed.” That is, the platelets are activated by the material, leading to their premature removal from the circulation. This becomes apparent as a significant shortening of platelet life span, if not also a decrease in systemic platelet count. Whether this process is initiated by nonadhesive direct contact with the

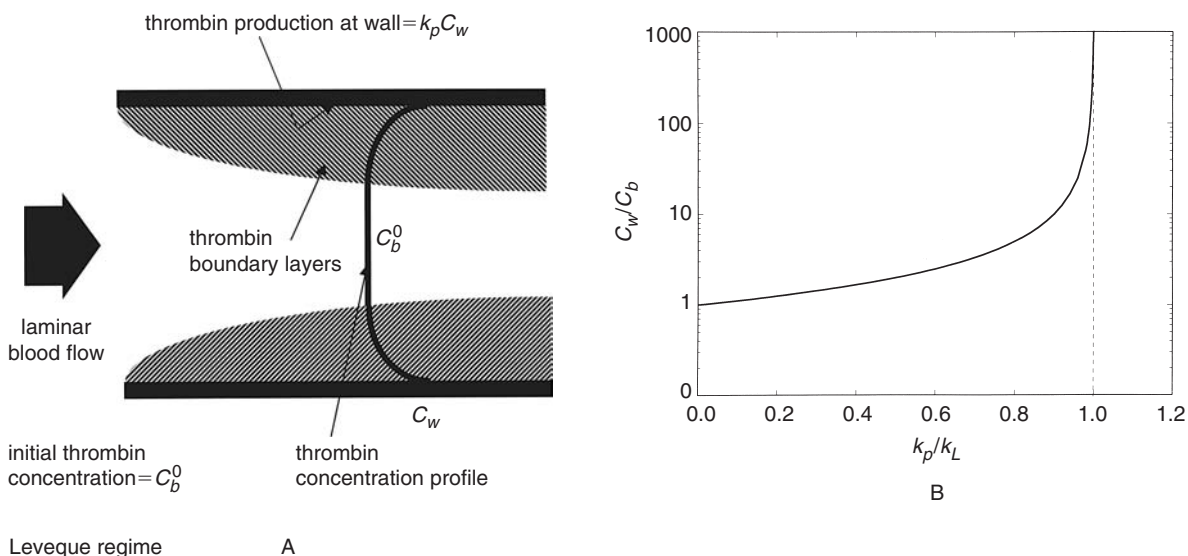

FIG. 1. (A) Model illustrating thrombin production at the surface of a tube as a balance between autoaccelerative production at the surface and mass transfer away from the wall. (B) Schematic illustration of Eq. 2 showing the dramatic increase in wall to bulk concentration ratio as the mass transfer coefficient k_L becomes equal to the first-order autocatalytic production constant (k_p). Since k_L decreases with increasing axial position down a tube, increasing k_p/k_L corresponds to increasing axial distance x . Adapted from Rollason and Sefton (1992).

material or the result of adherent platelet release or even the effect of complement activation is currently unknown. Nevertheless, such an observation suggests that low platelet adhesion is not a sufficient criterion of *in vivo* platelet compatibility. Rather, low thrombogenicity is characterized by both low platelet adhesion and low platelet activation (see Chapter 4.6 for definition of activation); the latter may even be more important than the former. Leukocyte activation (and complement activation) may also be key components in thrombogenicity (see Chapters 4.4 and 4.6); in the future, these too may become critical parameters defining the thrombogenicity of the surface. In an attempt to evaluate more than just platelet adhesion on biomaterials, flow cytometric techniques have been utilized to measure bulk (or circulating) activated platelets, platelet microaggregates and activated leukocytes (Baker *et al.*, 1998; Gemmell *et al.*, 1995). In future, it is hoped that such assays could provide better correlation between *in vitro* and *ex vivo* performances.

INERT (BIOTOLERANT) MATERIALS

Much of the effort in biomaterials research over the past 30 years has been directed toward the development of inert materials that do not react with platelets and coagulation factors. As outlined in Fig. 2, a number of approaches, often conflicting, have been developed. For example, there is still no consensus as to whether a surface should be hydrophilic or hydrophobic. The lack of agreement is largely due to our incomplete understanding of the biological pathways to materials failure and our inability to fully evaluate blood material responses. In developing materials with lower thrombogenicity researchers have primarily focused their efforts on modifying the surfaces of existing polymeric materials,

such as polyurethanes, silicone rubber, and polyethylene. This approach is reasonable since it is only the surface chemistry of a material that should dictate its biological responses; the mechanical characteristics of the material are primarily

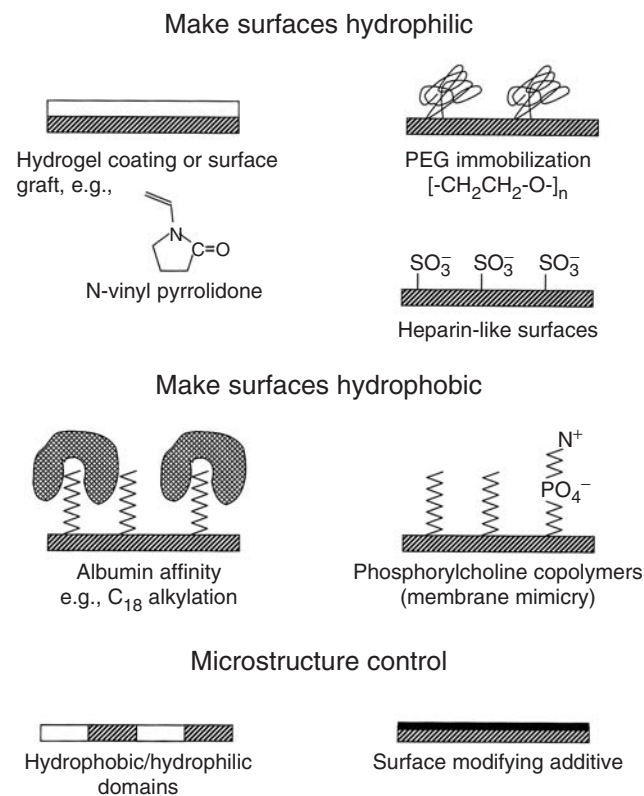

FIG. 2. Potential strategies for preparing inert surfaces with low thrombogenicity.

dictated by bulk chemistry. As illustrated by the following discussion the full range of surface modification strategies outlined in Chapter 2.14 have been used, albeit with limited success. Despite the successes in reducing protein and cellular deposits on some materials, a truly nonthrombogenic surface does not exist.

Hydrogels

A popular method to improve the blood compatibility of biomaterials is to increase surface hydrophilicity by incorporating a hydrogel at the surface. All the commonly used hydrogels (see Chapter 2.5) that can be cast, chemically cross-linked, or surface grafted have been used. By definition, hydrogels permit the retention of large amounts of water without dissolution of the polymer itself. This makes them very similar to biological tissues in that they are permeable to small molecules and possess low interfacial tension. It was Andrade who first postulated that since the interfacial free energy between blood and vascular endothelium was near zero, material surfaces that tend to have an interfacial energy of zero should have minimal thrombogenicity (Andrade *et al.*, 1973). Today, considerable experimental evidence supports the claim that materials with minimal interfacial energy, like hydrogels, do not strongly support cell and/or thrombus adhesion. Unfortunately, such generalizations are always flawed by exceptions. A hydrogel (cellulose) used as a dialysis membrane material (Cellophane) is well recognized as being thrombogenic, possibly because it is also a strong complement activator (see Chapter 4.4). Furthermore low-adhesion (or low protein adsorption) is not the same as low thrombogenicity.

In the early 1980s, a number of polymers were grafted with hydrogel surfaces in an effort to decrease their thrombogenicity. For example, in a large *ex vivo* study (Hanson *et al.*, 1980), a variety of surface-grafted copolymers were prepared and evaluated for platelet consumption in a baboon shunt model of arterial thrombogenesis. Although few platelets were found adherent to the graft surface, the higher the water content, the greater the rate at which the graft tubing caused the destruction of the circulating platelets (Fig. 3). Even though this study concluded that hydrogels do not possess low thrombogenicity, utilization of hydrogels remains a popular approach to lower thrombogenicity. It is likely that platelet consumption will be of concern only in applications with large surface areas. On the other hand, platelet consumption is evidence of platelet activation and the local (as opposed to systemic) consequences of such activation have yet to be defined.

Rather than radiation grafting of hydrogels onto materials, surfaces can also be simply coated with hydrophilic polymers, such as poly(vinyl pyrrolidone), PVP. While coating with PVP is intended to increase lubricity and ease catheter insertion, beneficial effects on thrombogenicity (and bacterial adhesion) have been noted (Francois *et al.*, 1996).

Poly(ethylene glycol) (PEG) Immobilization

Immobilization of the water-soluble synthetic polymer poly(ethylene glycol) (PEG, $-\text{CH}_2\text{CH}_2\text{O}-$) is a very popular

FIG. 3. Rate of cannula platelet consumption per unit area (in baboons) is directly related to the graft water content of shunts grafted with eight acrylic and methacrylic polymers and copolymers. HEMA, hydroxyethyl methacrylate; EMA, ethyl methacrylate; AAm, acrylamide; MAAC, methacrylic acid. Mean values \pm 1 S.E. (from Hanson *et al.*, 1980, with permission).

FIG. 4. Structure of poly(ethylene glycol) (PEG) modified surfaces. (a) At low surface coverage ($D \gg R_F$), molecules assume conformation and size similar to random coil. (b) At high surface coverage ($D \ll R_F$), molecules are more extended chain-like and form a dense brush. Adapted from deGennes (1980).

means of making a biomaterial surface more protein and cell resistant.¹ It also makes the surface hydrogel-like. This approach was promoted by Merrill *et al.*, who recognized the lack of protein binding (hydrogen donor) sites on the PEO molecule (Merrill and Salzman, 1983). A widely recognized theory that helps explain the nonthrombogenicity of PEG containing surfaces was presented by Nagaoka *et al.* (1984). They reasoned that the presence of diffuse hydrophilic polymers, covering a significant portion of a biomaterial surface, would exert a steric repulsion effect toward blood proteins and cells (Fig. 4). The dominance of steric repulsion over the van der Waals attractive forces was hypothesized to be dependent on the extension and flexibility of the polymer chain in the bulk solution. The resulting excluded volume effect results from a loss in configurational entropy of the PEG that in turn results

¹PEG, >10 kDa, is called PEO [poly(ethylene oxide)] reflecting the different monomer and polymerization process used.

from the rise in the local osmotic pressure occurring when PEG chains are compressed when blood elements approach the surface. This effect is dependent on both the chain length (N , monomers/chain) and the surface density of chains (σ , number of chains per unit area). A simple scaling relationship relates these parameters (and a , the monomer size) to the thickness, L , of the polymer layer at the surface, for the case of a good solvent (specifically an athermal solvent) and when the chain density is high (distance between chains, D) is less than the Flory radius, R_F (deGennes, 1980):

$$L \cong Na\sigma^{1/3} \quad (3)$$

Jeon *et al.* (Jeon and Andrade, 1991; Jeon *et al.*, 1991) among others, have theoretically modeled protein-surface interactions in the presence of PEG and concluded that steric repulsion by surface-bound PEG chains was largely responsible for the prevention of protein adsorption on PEG-rich surfaces.

As shown in Fig. 5, a number of approaches have been used to enrich surfaces with PEG. For example, it has been grafted to surfaces via a backbone hydrogel polymer, such as in the preparation of methoxypolyethylene glycol monomethacrylate copolymers (Nagaoka *et al.*, 1984). It has also been covalently bonded directly to substrates via derivatization of its hydroxyl end groups with an active coupling agent or, alternatively, the hydroxyl end groups have been reacted with active coupling agents introduced onto the surface (Tseng and Park, 1992; Desai and Hubbell, 1991a; Chaikof *et al.*, 1992). The availability of a large number of reactive PEG molecules (for example, amino-PEG, tresyl-PEG, *N*-hydroxysuccinimidyl-PEG, e.g., from Shearwater Polymers, Inc, now Nektar Therapeutics) has greatly facilitated the use of covalent immobilization strategies. Unfortunately, it is difficult to achieve the needed high surface coverages by immobilization since the first molecules immobilized sterically repel later molecules that are attached, unless thermodynamically poor solvents are used. The surface fraction may then be too low to completely “mask” the other functional groups that may be present. Pure monolayers of star

PEO have been grafted to surfaces in an attempt to increase surface coverage (Sofia and Merrill, 1998). Other investigators have used block copolymers (e.g., Pluronic) of PEO and PPO [poly(propylene oxide)] by adsorption, by gamma irradiation, or as an additive (McPherson *et al.*, 1997); some have combined PEO with other strategies such as phosphoryl choline (Kim *et al.*, 2000).

PEO has also been incorporated, by both ends, into polyetherpolyurethanes (Merrill *et al.*, 1982; Liu *et al.*, 1989; Okkema *et al.*, 1989). Unfortunately, the results depend on a combined effect of surface microphase separation and the hydrogel effect of the PEO side chains. While some have noted lower thrombogenicity, others have not. For example, Okkema *et al.* (1989) synthesized a series of poly(ether urethanes) based on PEO and poly(tetramethylene oxide)(PTMO) soft segments and noted that the higher PEO-containing polymers were more thrombogenic in a canine *ex vivo* shunt model. Since PEO-containing polyurethanes have a considerable non-PEO phase Chaikof *et al.* (1989) prepared a cross-linked network of PEO chains using only small polysiloxane units.

A number of investigators have noted that the beneficial effect of PEG is molecular weight dependent. To some extent, however, the benefit of high molecular weight PEO is compromised by the crystallizability of long-chain PEO or the benefit may reflect particular process advantages of longer PEO chains. Chaikof *et al.* (1992) with end-linked PEO and Desai and Hubbell (1991b) with physically entrapped PEO found the lowest protein and platelet or cell deposition with high-molecular-weight PEO (>18,000 Da). Nagaoka *et al.* (1984) were among the first to demonstrate that increasing the PEG chain length of hydrogels containing methoxy poly(ethylene glycol) monomethacrylates led to reductions in protein and platelet adhesion (Fig. 6). It is clear that incorporation of PEG results in reduced levels of cell (including platelet) adhesion and protein adsorption, when compared to unmodified and typically hydrophobic substrates. It is far less clear whether the reduced adhesion or adsorption translates to lower material thrombogenicity (Llanos and Sefton, 1993a,b). Further it is not clear whether reduced adhesion/adsorption is due specifically to the thermodynamic effects of poly(ethylene oxide) or to the increase in surface hydrophilicity after its immobilization. While the *in vitro* results have looked very promising, the lack of correlation between the few *in vitro* and *ex vivo* studies is of concern. More recent efforts with plasma-deposited tetraglyme (Shen *et al.*, 2001) have led to surfaces with ultralow adsorbed fibrinogen, suggesting that previous attempts at using PEG modification have not been successful because of the inability to achieve the desired ultralow (<5 ng/cm²) levels of adsorbed protein.

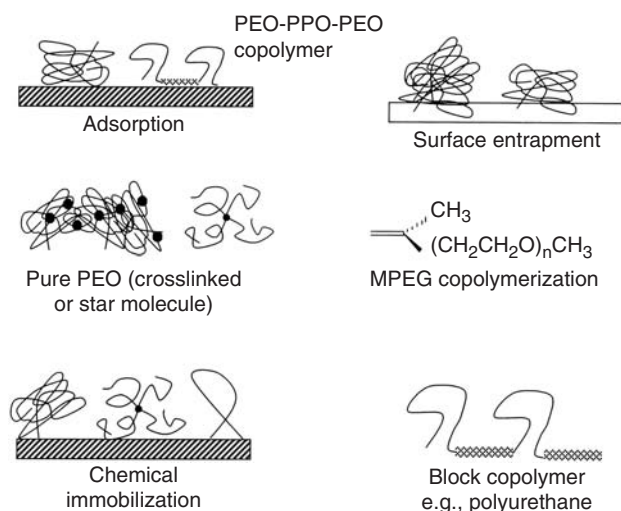

FIG. 5. Methods for incorporating poly(ethylene glycol) (PEG) onto the surfaces of materials.

Albumin Coating and Alkylation

The early observation that surfaces coated with albumin did not support protein adsorption and platelet adhesion (reviewed by Andrade and Hlady, 1986) led many investigators to lower material thrombogenicity by either albumin coating or enhancing the affinity of albumin for surfaces via alkylation. Albumin is an abundant acidic globular plasma protein with

FIG. 6. Effect of PEG (or "POE") chain length (n) on the adhesion of platelets (from activated platelet-rich plasma) and adsorption of plasma proteins (from plasma) onto poly(methyl methacrylate-*co*-methoxypolyethylene glycol methacrylate) gels. Mean values and standard deviation are shown. Both protein adsorption and platelet adhesion were measured by total protein analysis. A relative platelet adhesion value of 0.3 corresponded to an SEM platelet adhesion density of ~ 80 platelets/1000 μm^2 (from Nagaoka *et al.*, 1984, with permission).

high aqueous solubility and stability. It is widely stated that albumin adsorption lowers material thrombogenicity since it does not possess the peptide sequences to enable interaction with cells (platelets and leukocytes) or the enzyme receptors in the coagulation cascade. It adsorbs relatively tightly onto hydrophobic surfaces while having a poor affinity for hydrophilic surfaces. Consequently, utilization of this strategy entails increasing the hydrophobicity of the surface, which is the opposite of the strategies discussed earlier whereby the hydrophilicity of the surface was increased. Albumin coating is consistent with another hypothesis, developed early in the 1970s, that suggested that hydrophobic surfaces with critical surface tensions (conceptually related to surface free energy) around 20–30 dyn/cm would be have a lower thrombogenicity (Baier *et al.*, 1970).

A limitation of relying on albumin coating is that other proteins will adsorb to the surface displacing the albumin thereby limiting the long term effectiveness of this strategy (see Chapter 3.2). Hence an example of coating a surface with albumin involved immersing a Dacron arterial prosthesis in albumin/glutaraldehyde solution followed by quenching of the free aldehyde groups (Kottke-Marchant *et al.*, 1989). The use of glutaraldehyde was expected to reduce the extent of exchange with proteins with higher affinity for the surface than albumin. Covalent immobilization of albumin has also been used for the same purpose (Hoffman *et al.*, 1972; Matsuda and Inoue, 1990). Unfortunately, these strategies do not address the inevitable denaturing of albumin with time.

Since albumin has binding pockets for long alkyl chains, Munro *et al.* (1981) hypothesized and demonstrated that surfaces with long carbon chains (C-16 or C-18) would have

a high affinity for albumin and would provide for a dynamically renewable natural albumin layer. Cellulose membranes were alkylated by grafting 4-vinylpyridine to the surface of Cuprophane and subsequently alkylating with non-fatty-acid-like C10 and fatty-acid-like C16 aliphatic chains (Frautschi *et al.*, 1995). Albumin adsorption (from dilute plasma) was enhanced on the alkylated surfaces. Strzinar and Sefton (1992) reacted a C18 and C4 isocyanate with poly(vinyl alcohol) hydrogel in order to improve the platelet reactivity of the hydrogel. Butylation of PVA dramatically reduced platelet reactivity in a dog shunt suggesting that the reduced reactivity might be independent of chain length and hence more related to the hydrophobicity of the substrate and not to albumin affinity per se. Unfortunately, the incorporation of C18 on the hydrophilic PVA surface was complicated by a nonuniform surface incorporation and this was a limitation of this strategy.

Phospholipid-Mimicking Surfaces

A number of investigators have hypothesized that a surface similar to the external phospholipid membrane of cells should be nonthrombogenic. Since phosphorylcholine, the major lipid head group on the external surface of blood cells, is inert in coagulation assays it has been the choice of investigators for incorporation into surfaces. Upon cellular activation, the negatively charged phospholipids that are preferentially localized on the cytoplasmic face of the plasma membrane flip to the outer membrane, which accelerates blood clotting by enabling assembly of the prothrombinase and tenase complexes.

Various approaches have been used to incorporate the electrically neutral zwitterionic head group into surfaces. Durrani *et al.* (1986) prepared a series of reactive derivatives of phosphorylcholine that were designed to react with surface hydroxyl groups and surface acid chlorides on various materials. Another approach involved coating materials (Campbell *et al.*, 1994; Lewis *et al.*, 2000) or blending a polyurethane (Ishihara *et al.*, 1995, 1996, 1999) with a methacryloylphosphorylcholine (MPC, Fig. 7)/polyacrylate copolymer. Platelet adhesion was significantly reduced on phosphorylcholine-coated expanded polytetrafluoroethylene (ePTFE) grafts at 90 min in dogs, and anastomotic neointimal hyperplasia and neointimal cell proliferation were also reduced (Chen *et al.*, 1998). The modified material's strong affinity for phospholipids due to the phosphorylcholine group is thought to impart

FIG. 7. Chemical structure of poly(2-methacryloyloxyethyl phosphorylcholine).

FIG. 8. General formulation of surface-modifying additive (SMA) block copolymer based on polycaprolactone (PCC) and poly(dimethyl siloxane) (PDMS). Adapted from Tsai *et al.* (1994).

the observed low thrombogenicity, although Ishihara *et al.* (1998) have attributed the low protein adsorption of their phospholipid polymers to the high free-water fraction. The mechanism of action of such materials remains unclear.

Surface-Modifying Additives

The blending of a copolymer, composed of polar and non-polar blocks, to a base polymer appears to be a successful means of lowering material thrombogenicity. The strategy, originally developed by Thoratec Laboratories Corporation, is a way to alter the surface properties of materials without affecting bulk properties (Ward *et al.*, 1984). The copolymers, added in low concentration, migrate to the base polymer surface during and after fabrication and dramatically change the outermost surface molecular layers that form the region that determines biocompatibility (Tsai *et al.*, 1994). The copolymers have a structure which is amphipathic, that is, certain groups or segments will have an attraction for the continuous phase (major polymer component of the blend), while other portions of the molecule will have little attraction for the base polymer and will be of lower polarity (Ward *et al.*, 1984). The generic formulation of a polycaprolactone–polysiloxane block copolymer that has been tested for biocompatibility is shown in Fig. 8. They have been used to lower the thrombogenicity of cardiopulmonary bypass and hemodialysis components by using SMA blended polymers or SMA coated surfaces. A recent clinical evaluation of the effects of SMA on cardiopulmonary bypass circuits demonstrated a reduction in platelet interactions with no effect on complement activation (Gu *et al.*, 1998).

Fluorination

The incorporation of fluorine into materials is also a strategy to lower thrombogenicity. It is believed that the fluorine group's low surface energy inhibits protein adsorption and platelet adhesion/activation. Preparing surfaces with fluorine is often facilitated by the tendency of fluorine-containing functional groups to concentrate on the surface of the polymer during preparation. Fluoroalkyl groups as chain extenders have been used to prepare nonthrombogenic polyurethanes (Kashiwagi *et al.*, 1993). Kiaei *et al.* (1988) found a strong effect of a fluoropolymer plasma on thrombus formation. A number of new fluorinated surface-modifying additives have also been developed (Tang *et al.*, 1996).

Plasma Treatments

Another surface modification technique resulting in a covalently attached coating is plasma deposition or glow discharge deposition (described in Chapter 2.14). This technique enables the rapid polymerization and deposition of organic compounds that cannot be easily polymerized by conventional polymer mechanisms. Active species, generated by energy absorption, react with and covalently bind to the substrate surface. Dacron vascular grafts were treated with tetrafluoroethylene in a radio frequency glow discharge (RFGD) apparatus by Bohnert *et al.* (1990). They demonstrated that while the deposition of fluorocarbon polymers did not lower the adsorption levels of fibrinogen and albumin it did substantially reduce the ability of detergent to elute the adsorbed proteins. The significance of this in terms of thrombogenicity is not clear. A study (Sefton *et al.*, 2001) comparing many such plasma-modified surfaces did not identify a modification chemistry that was superior to the base material in terms of platelet or leukocyte activation.

Heparin-Like Materials

A number of synthetic polymers have been synthesized or modified in order to prepare polymers with chemical similarity to heparin and thus possess heparin-like activities. For example, Fougnot *et al.* (1983) synthesized sulfonate/amino acid sulfamide polystyrene derivatives in order to create insoluble heparin-like materials. Some investigators (e.g., Grasel and Cooper, 1989) only incorporate sulfonate groups in an effort to lower thrombogenicity by surface thrombin inhibition. Enhanced binding and inactivation of thrombin was found suggesting that these weak heparin-like molecules are sufficiently dense so as to lower thrombogenicity. A new approach combines sulfonation and PEG-like materials in the use of sulfonated cyclodextrin polymers (Park *et al.*, 2002).

Self-Assembled Surface Layers

Self-assembled surface layers (Whitesides *et al.*, 1991) have been envisioned as useful templates to nucleate or organize ordered, designed biomaterials (Ratner, 1995). Molecular self-assembly is the spontaneous association of molecules under equilibrium conditions into stable, structurally well-defined aggregates joined by noncovalent bonds (Whitesides *et al.*, 1991). The advantages of self-assembly films are their high order and orientation and well-defined head-group geometry that exposes only one functional group to the outside (Ratner, 1995). This approach remains to be exploited for the

preparation of practical low-thrombogenicity materials. So far, self-assembled monolayers of alkylsilanes supported on oxidized poly(dimethyl siloxane) (PDMS) rubber have been used as a model system (Silver *et al.*, 1999). The authors reported that surfaces grafted with hydrophobic head groups as $-\text{CH}_3$ and CF_3 had significantly lower platelet and fibrinogen deposition than the surfaces composed of hydrophilic head groups in a canine *ex vivo* arteriovenous series shunt model.

ACTIVE (BIOACTIVE) MATERIALS

The limited successes of the various surface treatments for lowering thrombogenicity has encouraged researchers to pursue other strategies. The most popular and the one that started the field is the heparinization of surfaces, although the incorporation of other antithrombotic and antiplatelet agents into materials is gaining popularity (Fig. 9). Currently, the antithrombotic agents utilized have mainly been against thrombin (hirudin, PPACK, [D-phenylalanyl-L-propyl-L-arginine chloromethyl ketone], thrombomodulin). In the future, it is likely that agents against factor Xa (low-molecular-weight heparins, LMWH) or recently developed inhibitors of tissue

factor expression (extrinsic pathway) could also impart a lower degree of thrombogenicity for some devices.

The incorporation of antiplatelet agents into materials has been limited by the instability and complex mechanism of action of many of these agents. The new generation of platelet GPIIb/IIIa antagonists (e.g., ReoPro, Centocor) will likely be more useful given their greater stability and potency. The future use of pharmacological agents could also include agents to inhibit complement. Complement activation is known to occur on biomaterials although the availability of inhibitory agents is limited. A clearer understanding of how activated complement proteins mediate cellular reactivity could provide the impetus for incorporating such agents into materials (Gemmell, 1998).

Heparinization

Heparinization of surfaces continues to be the most popular technique for lowering the thrombogenicity of materials. The heparin-like activity of the microvascular endothelium provides logic to such an approach but it should be appreciated that prostacyclin, a potent platelet inhibitor, also plays a role in maintaining the thromboresistance of the natural endothelium. As illustrated in Fig. 10, heparin is a linear, acidic carbohydrate composed of repeating disaccharide units that are O- and N-sulfated. The molecular weights of heparin chains range from 1200 to 40,000 Da with a mean molecular weight of approximately 10,000. Depending on its molecular weight and structure, heparin is able to inhibit, in association with its cofactor (antithrombin III), the serine proteases: thrombin and factor X. Since thrombin is also a potent platelet activator heparin's presence on a surface should help minimize platelet activation. Investigators have been able to covalently, ionically, and physically attach heparin to various substrates utilizing a number of chemistries given its remarkable stability. The main concern has been that once immobilized, the heparin should be able to assume its native conformation and be able to interact with antithrombin III.

The effectiveness of heparin as an agent capable of increasing synthetic venous graft patencies and reducing downstream anastomotic neointimal hyperplasia and cell proliferation has been demonstrated. Utilizing a novel polytetrafluoroethylene-based local drug delivery device heparin was infused within those blood layers adjacent to the graft wall and at downstream anastomotic sites for 14 days and demonstrated to be highly effective (Chen *et al.*, 1995). Such results continue to motivate researchers to heparinize surfaces.

Ionically Bound Heparin and Controlled Release Systems

If heparin is bound ionically to the surface then heparin will be slowly released over time as a result of exchange with the ionic components of blood. A similar effect is obtained if heparin is dispersed within a hydrophobic polymer. Selected techniques to produce materials that release heparin at biologically significant rates have been discussed in depth by a number of investigators (Kim and Jacobs, 1996; Sefton *et al.*, 1987; Amiji and Park, 1993). Ionic approaches involve binding

FIG. 9. Agents, other than heparin, that have been (or could be) incorporated into biomaterials to actively control thrombogenicity. Hirudin and PPACK are thrombin inhibitors. Prostacyclin (PGI₂) is a natural inhibitor of platelet function while DMP 728 is a small-molecule GPIIb/IIIa antagonist. Thrombomodulin inhibits thrombin by activating protein C.

FIG. 10. (A) Antithrombin III-binding pentasaccharide of heparin. The pentasaccharide sequence is composed of three glucosamine (units 1, 3, and 5), one glucuronic acid (unit 2), and one iduronic acid (unit 4) units. Structural variants are indicated by $-R'$ ($-H$ or $-\text{SO}_3^-$) or $-R''$ ($-\text{COCH}_3$ or $-\text{SO}_3^-$). The 2-*O*-sulfate groups (asterisk), a marker component for the anti-thrombin-binding region, and sulfate groups indicated by (●) are essential for high-affinity binding to antithrombin. (B) The mechanism of action of heparin and antithrombin III. (C) The reducing end of heparin formed by treatment with nitrous acid. (A from Fiore and Deykin, 1995; B from Bauer and Rosenberg, 1995, with permission.)

the highly negatively charged heparin onto a cationic surface through ionic binding. The limitation is that the leaching of heparin will eventually leave the surface unprotected. Certain nonionic approaches are also characterized by high release rates (due to relatively unstable bonds), so that determining heparin release rate (in addition to amount bound) is a primary means of characterizing these surfaces. Limitations of the use of dispersed systems include the loading capacity of heparin, which prevents long-term usage, and the heterogeneity of heparin, leading to the early release of lower molecular weight chains.

The thromboresistance of heparinized materials based on controlled release appears to be due to a microenvironment of heparin in solution at the blood material interface. The relationship between release rate (N , $\text{g}/\text{cm}^2\text{s}$) and surface

concentration (C_s , g/cm^3), for heparin or any other agent released from the inside wall of a tube of radius r_0 is given by (Basmadjian and Sefton, 1983):

$$\frac{C_s}{Nr_0/D} = 1.22 \left[\frac{x/r_0}{\text{ReSc}} \right]^{1/3} \quad (4)$$

where D = diffusivity (cm^2/sec), r_0 = tube radius, x = axial position, Re = Reynolds number = $2r_0v\rho/\mu$, Sc = Schmidt number = $\mu/\rho D$, v = average velocity, ρ = density, μ = viscosity. The diffusivity of heparin is $\sim 7.5 \times 10^{-7} \text{ cm}^2/\text{sec}$ and the critical C_s (minimum therapeutic level) for heparin is $\sim 0.5 \mu\text{g}/\text{ml}$.

Use of tridodecyl methylammonium chloride (TDMAC, Lehninger *et al.*, 1966), a lipophilic hydrocarbon, eliminated

the need for the graphite coating that was part of the original graphite-benzalkonium-heparin (GBH) method (Gott *et al.*, 1963). TDMAC and the many other quaternary ammonium compounds enabled heparin to be ionically bound to a wide range of biomaterials. Unfortunately, such compounds are surfactants with potentially toxic consequences and are known to be eluted from the surfaces within a week.

Quaternizable amino groups have also been incorporated directly into polymers to improve the stability of the ionically bound heparin. Tanzawa *et al.* (1973) synthesized a graft copolymer with a dimethylaminoethyl group by UV-initiated copolymerization of *N,N*-dimethylaminoethyl methacrylate (DMAEM) and methoxypolyethylene glycol methacrylate (MPEG). Use of this technique (Angiocath, Toray Industries) to coat polyurethane catheters indicated that a minimal heparin elution rate of 0.04 $\mu\text{g}/\text{cm}^2$ min was needed to render the catheter thrombus free *in vivo* (Idezuki *et al.*, 1975). This value is consistent with Eq. 4.

A commercial procedure (Baxter Bentley Healthcare Systems, Irvine, CA) to ionically bind heparin (Duraflon II) has been used to coat cardiopulmonary bypass circuits and other devices. While heparin coating of extracorporeal circuits is designed to reduce surface thrombus formation, during clinical trials its effect on complement, contact activation, and inflammation has been unclear and often contradictory (Wildevuur *et al.*, 1997; Fosse *et al.*, 1997).

Covalently Bound Heparin

To impart a degree of activity longer than that possible with ionic linkages, heparin has been covalently immobilized to material surfaces. It is now recognized that the conformation of the attached heparin and the point of attachment (end

point versus multipoint) are critical factors determining the catalytic efficiency of the immobilized heparin. Lindhout *et al.* (1995) studied the antithrombin activity of surface-bound heparin under flow conditions. They demonstrated that the rate of thrombin inactivation of the antithrombin-heparin surface equals the maximal rate of transport of thrombin toward the surface when the surface coverage of antithrombin exceeds 10 pmol/cm^2 , thus indicating that a higher intrinsic catalytic efficiency of a surface does not necessarily result in a higher antithrombin activity.

Many of the coupling methods listed in Chapter 2.16 have been used for heparin; see also Fig. 3 in Chapter 2.16. For example, Heyman *et al.* (1985) attached 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide-activated heparin covalently onto chemically modified poly(ether urethane) catheters through a diaminoalkane spacer. The immobilized heparin retained its ability to bind and inactivate thrombin and factor Xa. Unfortunately, carbodiimides (Fig. 11) are recognized as less than ideal activating agents for immobilizing heparin since the acidic conditions used can result in a loss of anticoagulant activity.

Larm *et al.* (1983) developed a technique by which heparin can be covalently end-point-attached (commercialized as the Carmeda Bioactive Surface, Stockholm, Sweden) to the surface of plastics as well as glass and steel. Heparin is first partially depolymerized by deaminative cleavage using nitrous acid to produce heparin fragments terminating in an aldehyde group (Fig. 10C). The heparin is then covalently linked to the primary amino groups of polyethyleneimine (PEI) (Fig. 12). This technique results in a highly stable, low-thrombogenicity coating that has been demonstrated to retain its efficacy *in vivo* for 4 months in dogs (Arnander *et al.*, 1987) and during patient treatment with an artificial lung (Bindslev *et al.*, 1987).

FIG. 11. One step carbodiimide activation of carboxyl groups of heparin for binding to aminated Sepharose. For EDC, R = (CH₂)₃N(CH₃)₂. For a carboxylated substrate (e.g., hydrolyzed polymethyl acrylate) its carboxyl groups may be activated by carbodiimide in a separate step for subsequent reaction with the free amine groups of heparin.

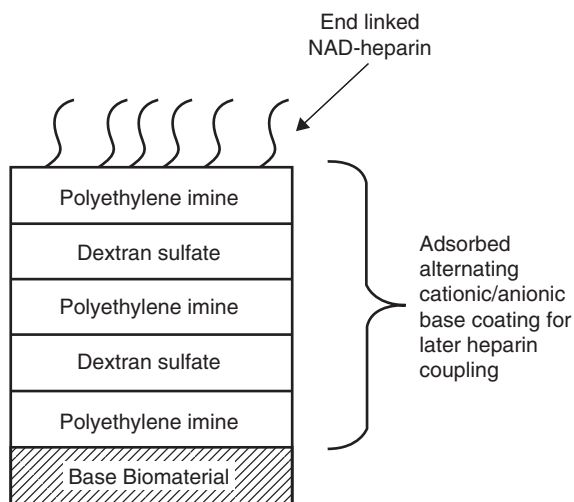

FIG. 12. CARMEDA method for immobilizing nitrous acid treated heparin (end-linked heparin) to dextran sulfate and polyethyleneimine-treated surface.

There was also a beneficial effect on *in vivo* bacterial colonization of treated polyurethane central venous catheters (Appelgren *et al.*, 1996).

Heparin has also been covalently immobilized via its terminal serine at the end of the protein-carbohydrate linkage region to poly(vinyl alcohol) hydrogel. The heparin is bound during the Lewis acid-catalyzed cross-linking of poly(vinyl alcohol) chains with glutaraldehyde. The heparinized poly(vinyl alcohol) hydrogel possessed significant anticoagulant activity although the platelet incompatibility of the hydrogel substrate led to significant platelet consumption in an *ex vivo* canine shunt model (Cholakis *et al.*, 1989).

Park *et al.* (1988) have covalently bound heparin to a polyurethane using PEO spacer groups. The increasingly mobile nature of the longer hydrophilic spacer chains were considered to have increased the observed bioactivity of immobilized heparin by providing a more bulk-like environment for the heparin. An intravascular oxygenator and carbon dioxide removal device (IVOX; CardioPulmonics, Salt Lake City, UT) also uses covalent heparin bound to a PEG spacer. The PEG is grafted onto a plasma-polymerized polysiloxane on a base material after plasma amination of the surface.

Thrombin Inhibition without Heparin

Recognizing the importance of inhibiting material-induced thrombin generation, agents other than heparin have been used to inhibit thrombin and thereby lower the thrombogenicity of the material. For example, hirudin, a potent thrombin inhibitor, has been covalently bound to biomaterials. Compared with heparin, hirudin is advantageous because it has no influence on platelet function, has no immune-mediated platelet-activating activity, and, most importantly, does not require the presence of endogenous cofactors such as antithrombin III. Thus the polypeptide hirudin is thought

able to block clot-bound thrombin that is inaccessible to inhibition by a heparin/antithrombin III complex. On the other hand, heparin functions as a catalyst. That is immobilized heparin, if not blocked by adsorbed protein, can continually accelerate the inactivation of thrombin by antithrombin III. It is unclear how long a covalently immobilized hirudin surface would remain effective and even whether an immobilized hirudin could gain access to the clot-bound thrombin. Nevertheless Ito *et al.* (1991) used heterobifunctional cross-linking reagents to derivatize hirudin to form covalent cross-links between hirudin and albumin, producing active conjugates for immobilization to surfaces (Ito *et al.*, 1991), and others have immobilized hirudin to a polylactide-glycolide copolymer (Seifert *et al.*, 1997). Another group has exploited controlled release of hirudin for this purpose (Kim *et al.*, 1998). Small-molecule thrombin inhibitors such as PPACK and others under development may prove useful as alternatives.

Another approach involves immobilizing thrombomodulin, an endothelial cell-associated protein that inhibits thrombin by activating protein C. Using a small-scale dialyzer it was demonstrated that immobilized human thrombomodulin (on cellulose) still had coenzyme activity for activation of protein C and anticoagulant activity (Kishida *et al.*, 1995). An amino-terminated silane was used to couple thrombomodulin to glass, and the authors reported both anticoagulant activity and reduced platelet adhesion (Han *et al.*, 2001). Further work is needed to appreciate the potential of such surfaces.

Immobilization of Anti-Platelet Agents

There has been considerable interest in incorporating anti-platelet agents into materials to lower material thrombogenicity, especially given the inevitable presence of platelets on biomaterials. The fact that the natural vessel wall helps prevent thrombus formation through a potent yet unstable anti-platelet agent, prostacyclin (to elevate platelet cyclic AMP levels, Fig. 9), supports such an approach. Efforts to maintain the biological activity of the agent during immobilization coupled with concern for the ability of bulk platelets to be affected by the immobilized agent has limited the enthusiasm for this approach. A simpler approach for a number of these agents would be to incorporate them into materials for release. Unfortunately, the inability to load sufficient drug into materials for release will limit the materials' life span. It remains to be seen whether suppression of initial blood/material interactions is sufficient for sustained biocompatibility.

Despite the challenges, anti-platelet agents have been incorporated into surfaces. For example, Ebert *et al.* (1982) immobilized prostaglandin $F_{2\alpha}$, which was subsequently converted to the unstable prostacyclin using a diamindodecane spacer arm. The benefits of spacer arms are described elsewhere (Chapter 2.16). A related approach is to add an anti-platelet agent such as PGE_1 , in addition to heparin, into a polymer. A PGE_1 -heparin compound was synthesized and incorporated into a polyurethane (Jacobs *et al.*, 1985). Also, prostacyclin has been incorporated into polymer matrices for controlled release (McRea and Kim, 1978). Aspirin, capable of inhibiting

the generation of the platelet activator thromboxane A₂, has also been incorporated into poly(vinyl alcohol) membranes used in hemodialysis (Paul and Sharma, and 1997), and a dipyrimidole (Persantin) derivative was photoimmobilized on a polyurethane (Aldenhoff *et al.*, 1997). A novel approach was to exploit endogenous *S*-nitrosoproteins in plasma to produce NO from immobilized cysteine to minimize platelet adhesion on a polyurethane and a poly(ethylene terephthalate) (Duan and Lewis, 2002).

An exciting new generation of anti-platelet agents based on inhibiting fibrinogen binding to activated platelet GPIIb/IIIa receptors offers a fresh approach to lowering the thrombogenicity of surfaces via drug release. These agents, from blocking monoclonal antibodies to small peptides and compounds (e.g., DMP728, Fig. 9), not only block platelet aggregation but will also likely block platelet adhesion to artificial surfaces. Some have already been incorporated into stents for release (see Section IV).

Immobilization of Fibrinolytic Agents

Some investigators have sought to promote fibrinolysis on artificial surfaces by promoting the surface generation of plasmin. Clot lysis is achieved by the action of plasmin on fibrin, after the former's formation from plasminogen. Whether the action of such surfaces is "too little too late" is unknown. Sugitachi and Takagi (1978) immobilized urokinase, a fibrinolytic enzyme that acts on plasminogen, on various materials. The long-term enzymatic stability of such agents (typically large proteins) after immobilization is of concern. A slightly different approach, recently pursued, is to immobilize plasminogen and then convert it to plasmin so as to impart fibrinolytic activity to a surface (Marconi *et al.*, 1996). A disadvantage of utilizing streptokinase and urokinase to cleave plasminogen to plasmin is that these agents activate both circulating and fibrin-bound plasminogen. This contrast with the action of tissue plasminogen activator (tPA), an endogenous serine protease that converts only fibrin-bound plasminogen to plasmin.

A nonpharmacological approach to developing fibrinolytic surfaces for blood-contacting applications was the preparation of lysine-derivatized polyurethane surfaces (Woodhouse and Brash, 1992). The expectation is that these surfaces exhibit fibrinolytic activity because the lysine residues promote the selective adsorption of plasminogen from plasma through the lysine-binding sites in the plasminogen molecule. In the presence of tissue plasminogen activator, adsorbed plasminogen was cleaved twice as fast on the lysinized material as opposed to the precursor sulfonated material (Woodhouse *et al.*, 1996).

USE OF ENDOTHELIAL CELLS AND RGD PEPTIDES

It is intuitive to believe that the ideal nonthrombogenic surface for vascular grafts/artificial hearts will consist of an intact luminal endothelial cell layer. Herring *et al.* (1984) seeded Dacron and e-PTFE grafts with endothelial cells in a preliminary clotting step with blood and endothelial cells.

Encouraging results have always been obtained in dogs although there are a number of issues that exist regarding the use of endothelial cells for vascular grafting. A full discussion of this subject is presented elsewhere (Zilla *et al.*, 1999). Some attempt has been made to modify materials to give them a higher affinity for endothelial cell attachment. Sipehia (1990) used an anhydrous ammonia gaseous plasma technique to modify polystyrene and PTFE surfaces. The modified surfaces contained amide and amine groups and it was concluded that they facilitated the attachment of endothelial cells. Another approach is to precoat them with substances that promote endothelial cell adhesion (Bos *et al.*, 1999). Van Wachem *et al.* (1987) noted that surfaces precoated with fibrinogen or fibronectin resulted in higher numbers of adhering cells. The most elegant approach has been that of Hubbell (Massia and Hubbell, 1990), who has utilized immobilized RGD peptides (see Chapter 2.16) to encourage endothelial cell attachment. This approach has been adopted by many others, although there is a concern that bare spots would lead to enhanced platelet and thrombus deposition.

STRATEGIES TO LOWER THE THROMBOGENICITY OF METALS

The recent deployment of stents (Chapter 7.3) for the purpose of maintaining patency in coronary arteries after angioplasty introduces metallic surfaces to the circulatory system. The minimal surface area of the device coupled with the concern over smooth-muscle cell proliferation led many investigators to hypothesize that thrombus formation would not be of great concern. On the other hand, anti-platelet therapy has led to reduced restenosis rates and lower platelet adhesion values and for a time there was great interest in heparin-coated stents. This early work has now been supplanted by rapamycin-eluting stents, which have the dramatic effect of eliminating in-stent restenosis for at least 6 months after deployment (Morice *et al.*, 2002). Rapamycin (Sirolimus) is a macrolide antibiotic that was previously used as an immunosuppressant. The drug was blended in a proprietary mixture of nonerodible polymers and coated onto the surface of a stainless steel balloon-expandable stent. The use of this and other therapeutic agents (e.g., taxol) in polymer-coated stents is rapidly becoming standard in interventional cardiology.

Prior to the success with rapamycin, other strategies to lower stent thrombogenicity had been reported. For example, tantalum stents were polymer coated with poly(ether urethane) and parylene to reduce platelet adhesion density (Fontaine *et al.*, 1996) and *N*-vinylpyrrolidone (NVP) has been gamma radiation grafted onto plasma-treated stainless steel stents (Seeger *et al.*, 1995). Hyaluronic acid coating also reduced platelet thrombus formation on stainless steel stents and tubes in a primate thrombosis model (Verheye *et al.*, 2000). In another study, metal/polymer composite stents loaded (40% by weight, >90% elution in 89 hours) with a potent anti-platelet agent (GPIIb/IIIa antagonist) were demonstrated to reduce, by almost a factor of 2, platelet adhesion in dogs 2 hours after stent deployment (Santos *et al.*, 1998).

SUMMARY

It is an axiom that the interactions between materials and blood are complex. Hence it is no surprise that developing low-thrombogenicity materials (let alone materials with zero thrombogenicity) is very difficult. Medical device manufacturers relying on elegant device designs and systemic pharmacological agents have done wonders with existing materials. Adverse effects are minimized and existing devices, if not risk free, provide sufficient benefit to outweigh the risks. The focus of research in biomaterials is to make better materials that have fewer risks and greater benefits. Stents that “actively” prevent restenosis are a great example of how modifying a material can have a dramatic clinical effect. Using a less thrombogenic material so that catheters that did not occlude due to thrombosis would be highly desirable as well.

Inert materials, such as those with immobilized PEG, can resist protein and platelet deposition, but these may only be at best surrogate markers for thromboembolic phenomena. On the other hand, incorporating anticoagulants such as heparin can be an effective means of reducing thrombin production rates below critical values (e.g., $k_p < 10^{-4}$ cm/sec), but this may not be sufficient to prevent platelet activation and consumption. Many strategies for lowering thrombogenicity have been identified, and they all show a beneficial effect in at least one assay of thrombogenicity. However, few if any have made the transition from a one parameter benefit to multiple benefits or from *in vitro* to *in vivo*. These issues are discussed more fully in Chapter 4.6.

Which approach will ultimately be successful is impossible to predict. Certainly there is much activity in biomembrane mimicry and immobilizing PEG. Creating stable self-assembled monolayers may enable more sophisticated designer surfaces. There are many new anticoagulants and antithrombotics under development and few have yet to be incorporated into material surfaces. Combining approaches to address thrombin production and platelet activation simultaneously may lead to new opportunities. Finally, as new hypotheses are developed to understand cardiovascular material failure, new approaches will be identified for inhibiting particular pathways of failure. Perhaps the failure to produce the ideal nonthrombogenic material, despite 30 years of research, has merely reflected our limited understanding of blood-materials interaction. Perhaps, the right strategy for producing a nonthrombogenic material will have little to do with controlling platelets or thrombin, but will be directed toward leukocytes or complement (Gemmell, 1998; Wetterö *et al.*, 2003). Further research throughout the world is expected to improve the blood interactions of materials used in medicine.

7.3 CARDIOVASCULAR MEDICAL DEVICES

Robert F. Padera, Jr., and Frederick J. Schoen

INTRODUCTION

In no area of medicine have biomaterials played a more critical role in the life-saving treatment of patients than in the cardiovascular system. Blood oxygenators used in cardiopulmonary bypass have made possible open heart surgeries such as coronary artery bypass surgery, valve replacement, and repair of congenital or acquired structural cardiac defects. Heart-valve prostheses, both mechanical and bioprosthetic, are used to replace dysfunctional natural valves with substantial enhancement of both survival and quality of life. In this situation, the benefit is substantial and has been well documented. Specifically, the mortality of unrepaired critical aortic stenosis is 50% at 2–3 years, a natural history more severe than many cancers. In contrast, survival following valve replacement is 50–70% at 10–15 years (Rahimtoolla, 2003). Although this intervention represents a tremendous improvement, patients with artificial valves still do not fare as well as similarly aged individuals without valve disease; complications related to the device are a major reason (Fig. 1). Metallic cylindrical mesh stents, inserted via catheters and without surgery during percutaneous transluminal coronary angioplasty (also known as PTCA, in which a balloon is threaded into a diseased vessel and inflated, thereby deforming the atherosclerotic plaque and partially relieving the obstruction to blood flow), have revolutionized the treatment of coronary artery disease and myocardial infarction. These interventions have markedly increased the longevity of hundreds of thousands of patients suffering from atherosclerotic vascular disease, the major cause of mortality in the developed world (ACC/AHA, 2001; Schoen, 1999a; Al Suwaidi *et al.*, 2000). More than one million PTCA procedures are performed annually worldwide, the majority of which employ intracoronary stenting. Synthetic vascular grafts used to repair weakened vessels or bypass blockages primarily in the abdomen and lower extremities have saved countless individuals from massive bleeding from ruptured degenerated aortas and have resulted in enhanced blood flow to and salvage of severely ischemic (i.e., blood-starved) organs and limbs, and are also used to obtain vascular access for hemodialysis treatment of patients with chronic renal failure. Devices to aid or replace the pumping function of the heart include intraaortic balloon pumps, ventricular assist devices, and total implantable artificial hearts. Pacemakers and automatic internal cardioverter defibrillators (AICDs) are used widely to override or correct aberrant life-threatening cardiac arrhythmias.

Most of these devices either alleviate the conditions for which they were implanted or provide otherwise enhanced function and serve the patients who receive them well and for extended periods. Nevertheless, device failure and/or other tissue–biomaterials interactions frequently cause clinically observable complications and necessitate reoperation or cause death. These deleterious outcomes may follow many years of uneventful benefit to the patient. Thus, precipitous or progressive “failure” can follow long-term “success.”

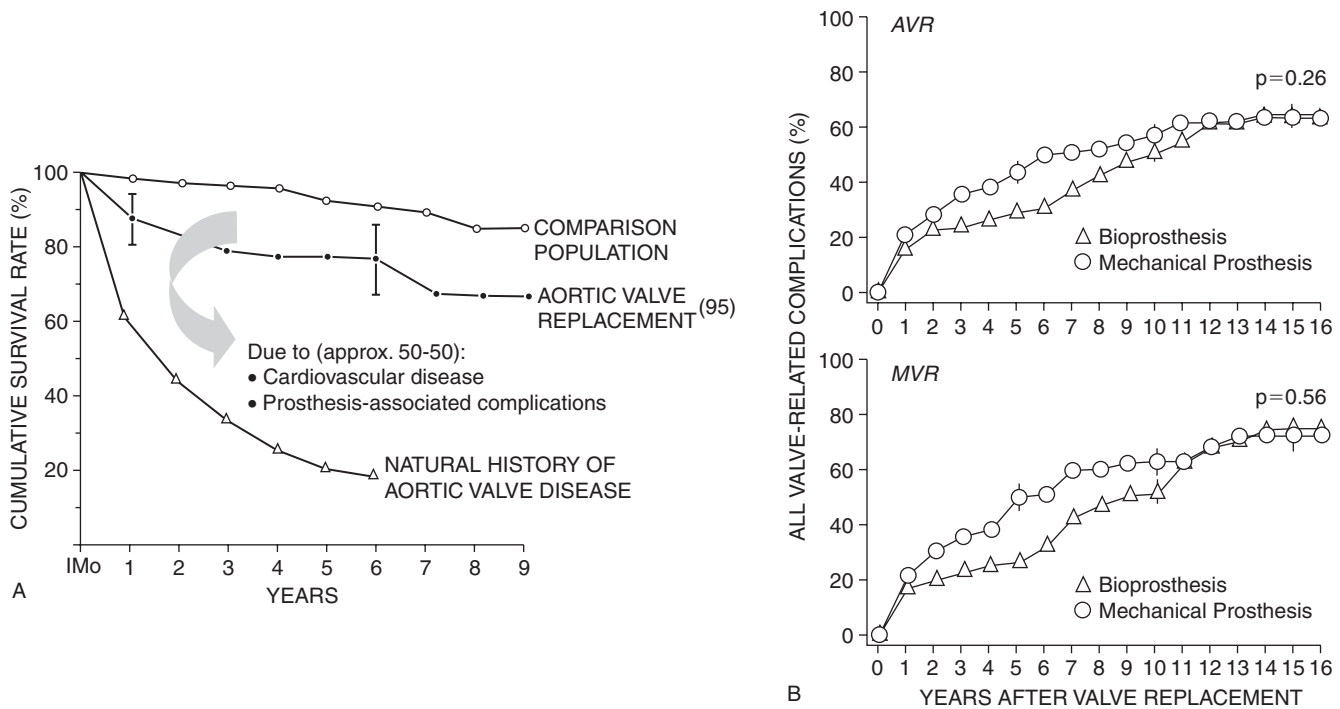

FIG. 1. Outcome following cardiac valve replacement. (A) Survival curves for patients with untreated aortic valve stenosis (natural history of valve disease) and aortic valve stenosis corrected by valve replacement, as compared with an age-matched control population without a history of aortic valve stenosis. The numbers presented in this figure for survival following valve replacement nearly 4 decades ago remain accurate today. This reflects the fact that improvements in valve substitutes and patient management have been balanced by a progressive trend toward operations on older and sicker patients with associated medical illnesses. Modified by permission from Roberts, L., *et al.* (1976). Long-term survival following aortic valve replacement. *Am. Heart J.* 91: 311–317. (B) Frequency of valve-related complications for mechanical and tissue valves following mitral valve replacement (MVR) and aortic valve replacement (AVR). Reproduced by permission from Hammermeister, K., *et al.* (2000). Outcomes 15 years after valve replacement with a mechanical versus a bioprosthetic valve: final report of the Veterans Affairs Randomized Trial. *J. Am. Coll. Cardiol.* 36: 1152–1158.

TABLE 1 Complications of Cardiovascular Devices

Heart valve prostheses	Vascular grafts	Circulatory assist devices
Thrombosis/thromboembolism	Thrombosis/thromboembolism	Thrombosis/thromboembolism
Anticoagulant-related hemorrhage	Infection	Endocarditis
Prosthetic valve endocarditis	Erosion into adjacent structures	Extraluminal infection
Intrinsic structural deterioration (wear, fracture, poppet escape, cuspal tear, calcification)	Perigraft seroma (Anastomotic) false aneurysm	System component fractures
Nonstructural dysfunction (pannus overgrowth, tissue or suture entrapment, paravalvular leak, inappropriate sizing, hemolytic anemia, noise)	(Anastomotic) intimal fibrous hyperplasia Mechanical failure	Bladder/valve calcification
		Hemolysis
		Mechanical failure

Some important mechanisms of tissue–biomaterials interaction are similar across device types, and several generic types of device-related complications can occur in recipients of nearly all cardiovascular implants. These complications, which will be discussed in detail later, include thromboembolic complications, infection, dysfunction owing to materials degeneration, and abnormal healing, either too much or too little. The clinical

manifestations and relative frequencies of these prosthesis-associated problems vary among different device types; additionally some problems are unique to specific applications and models (Table 1).

This chapter will discuss the most widely used cardiovascular medical devices from three perspectives: descriptions of the devices, the diverse pathologies for which they are indicated,

and complications that may arise from their use. Cardiovascular devices that are described in detail elsewhere in this volume (see Chapters 7.4 and 7.6), will only be briefly covered here.

SUBSTITUTE HEART VALVES (FOR VALVULAR HEART DISEASE)

The four valves in the human heart play a critical role in assuring the forward blood flow that is critical to proper cardiac function. The tricuspid valve allows flow from the right atrium to the right ventricle, the pulmonary valve from the right ventricle to the pulmonary artery, the mitral valve from the left atrium to the left ventricle, and the aortic from the left

ventricle to the aorta. Disorders of these valves can cause stenosis (i.e., obstruction to flow), regurgitation (i.e., reverse flow across the valve), or a combination of both stenosis and regurgitation. Some disease processes such as infective endocarditis (i.e., infection of a heart valve) can cause rapid destruction of the affected valve and can lead to abrupt heart failure and death; others such as degenerative calcific aortic stenosis can take many decades to develop (during which the disease is inapparent) before clinical manifestations appear.

There are several major forms of valvular heart disease (Fig. 2). The most common indication for valve replacement overall is calcific aortic stenosis—obstruction at the aortic valve secondary to wear-and-tear induced calcific degeneration of the cusps of a previously normal tricuspid (i.e., with

FIG. 2. Heart valve disease. (A) Severe degenerative calcification of a previously anatomically normal aortic valve, the predominant cause of aortic stenosis. (B) Chronic rheumatic heart disease, manifest as mitral stenosis, viewed from the left atrium. (C) Myxomatous degeneration of the mitral valve, demonstrating hoarding with prolapse of the posterior mitral leaflet into the left atrium (arrow). A, B: Reproduced by permission from Schoen, F. J., and Edwards, W. D. (2001). Valvular heart disease: General principles and stenosis. in *Cardiovascular Pathology*, 3rd ed. Silver, M. D., Gotlieb, A. I., and Schoen, F. J., eds. Churchill Livingstone, New York. C: Reproduced by permission from Schoen, F. J. (1999). The heart. in *Robbins Pathologic Basis of Disease*, 6th ed., R. S. Cotran, V. Kumar, T. Collins, eds. W.B. Saunders, Philadelphia. (See color plate)

three cusps) aortic valve (Fig. 2A). This condition typically produces symptoms in the eighth decade of life. Calcification of the valve cusps does not allow them to fully open, causing pressure overload and resultant hypertrophy (enlargement) of the mass of the left ventricle. Patients who have congenitally (i.e., are born with) abnormal valves develop valve dysfunction and thereby symptoms at younger ages—for example approximately 15 years earlier when they are among the 1–2% of all individuals who are born with a bicuspid (i.e., with two cusps) aortic valve. Aortic regurgitation (also known as insufficiency) is most often caused by dilation of the aortic root, preventing closing of the cusps and allowing backflow across the valve. This leads to volume overload of the left ventricle. Mitral stenosis (Fig. 2B) is most often caused by chronic rheumatic heart disease that leads to scarring and stiffening of the mitral leaflets, usually many years following a bout of acute rheumatic fever suffered in childhood. Rheumatic fever is a complication of streptococcal pharyngitis (a common form of childhood throat infection) in a small percentage of individuals. Mitral regurgitation results from many different conditions; the most frequent include myxomatous degeneration (also known as floppy mitral valve, in which the strength of the mitral valve tissue is deficient and causing the leaflets to deform excessively) (Fig. 2C), conditions in which the left ventricle is abnormal and consequently the valve is not supported properly, and infective endocarditis. Diseases of the tricuspid and pulmonic valves are much less common and often do not require surgical intervention. The major complication of valvular heart disease is cardiac failure secondary to changes in the myocardium induced by pressure or volume overload of the chambers upstream or downstream of the diseased valve.

The surgical treatments available for valvular heart disease include repair and valve replacement. Reconstructive procedures to eliminate mitral insufficiency of various etiologies and to minimize the severity of rheumatic mitral stenosis are now highly effective and commonplace, accounting presently for over 70% of mitral valve operations (Bolling, 2001). Repairs are generally preferable, if they can be done. The advantages of repair over replacement relate to the elimination of both the risk of prosthesis-related complications and the need for

chronic anticoagulation (which will be discussed later) that is required in many patients with substitute valves, and to a lower rate of postoperative valve-related infection (infective endocarditis). In conjunction with valve repair, the annulus (valve ring) is stabilized with or without a prosthetic annuloplasty ring.

In the many cases of valve disease in which repair cannot be done, severe symptomatic valvular heart disease is treated by excision of part or all of the diseased valve and replacement by a functional substitute (Isom, 2002). Since the early 1960s, following the first aortic valve replacements by Dwight Harken and mitral valve replacements by Albert Starr with caged ball valves, nearly 100 models of prosthetic heart valves have been developed and used (Harken *et al.*, 1960; Starr and Edwards, 1961). Today, more than 80,000 valve replacement procedures are performed each year in the United States and more than 275,000 per year worldwide. From a design standpoint, the ideal replacement valve would be nonthrombogenic, nonhemolytic, infection resistant, chemically inert, durable, and easily inserted. It would open fully and close quickly and completely, would heal appropriately in place, and would not be noticed by the patient (noise-free) (Harken *et al.*, 1962; Sapirstein and Smith, 2001). Cardiac valvular substitutes are of two generic types, mechanical and biological tissue (Vongpatanasin *et al.*, 1996; Schoen, 1995a; Korossis *et al.*, 2000). It is estimated that slightly more than half of all valves implanted in the present era are mechanical, the remainder are tissue.

Mechanical valves (Fig. 3) are composed of nonphysiologic biomaterials that employ a rigid, mobile occluder (usually a pyrolytic carbon disk) in a metallic cage (cobalt-chrome or titanium alloy) as in the Bjork-Shiley, Hall-Medtronic, and OmniScience valves, or two carbon hemidisks in a carbon housing as in the St. Jude Medical, or CarboMedics CPHV, the Medical Carbon Research Institute or On-X prostheses. Pyrolytic carbon is a material that has high strength, fatigue and wear resistance, and exceptional biocompatibility including thromboresistance (Cao, 1995). The sewing cuff, which anchors the valve into the native orifice, is composed of expanded polytetrafluoroethylene (ePTFE), Dacron, or other

fabric to allow suturing and subsequently tissue integration into the host tissue. The opening and closing of the valve is purely a passive phenomenon, with the moving parts [occluder or disk(s)] responding to changes in pressure and blood flow within the chambers of the heart and great vessels. Patients receiving mechanical valves must be treated with lifelong anticoagulation to reduce the risk of thrombosis and thromboembolic events.

Tissue valves (Fig. 4) are anatomically more similar to natural valves than are mechanical prostheses. Most tissue valves are composed of three cusps of tissue derived from animals—most frequently either porcine (pig) aortic valve or bovine (cow) pericardium—treated with glutaraldehyde. This fixation preserves the tissue, kills the cells within the valve, and decreases the immunological reactivity of the tissue, so that no immunosuppression is required for these xenografts as is required for kidney or heart transplants. However, since these valves no longer contain viable cells, the cusps themselves cannot remodel or respond to injury as does normal tissue. These cusps are mounted on a metal or plastic stent with three posts (or struts) to simulate the geometry of a native valve. The base ring is covered by a Dacron- or ePTFE-covered sewing cuff to facilitate surgical implantation and healing. The most commonly used bioprosthetic valves are the Hancock porcine and Carpentier-Edwards porcine and Carpentier-Edwards pericardial tissue valves. The major advantages of tissue valves compared to mechanical prostheses are their pseudoanatomic central flow and relative nonthrombogenicity; patients with tissue valves usually do not require anticoagulant therapy. As reflected in overall heart valve substitution industry data, innovations in tissue valve technologies and design have stimulated this segment of the market to grow disproportionately in the past decade by expanding indications for tissue valve use (Fig. 5) (Rahimtoolla, 2003; Fann and Burdon, 2001).

Tissue valves derived from human cadaveric aortic or pulmonary valves (allografts) with or without the associated vascular conduit have exceptionally good hemodynamic profiles,

FIG. 5. Comparison of total number of mechanical and tissue valve replacements (and repairs) in the United States and the world in the year 2000. Reproduced by permission from Schoen, F. a low incidence of thromboembolic complications without chronic anticoagulation, and a low reinfection rate following valve replacement for endocarditis (O'Brien *et al.*, 2001). Early allografts sterilized and/or preserved with chemicals or irradiation suffered a high rate of leaflet calcification and rupture. Nevertheless, subsequent technical developments have led to cryopreserved allografts, in which freezing is performed with protection from crystallization by dimethylsulfoxide; storage until valve use is carried out at -196°C in liquid nitrogen. Contemporary allograft valves yield freedom from degeneration and failure equal to or better than those of conventional porcine bioprosthetic valves, but are limited by availability, difficulty in obtaining the proper size, and a more complex surgical procedure.

A and D: Reproduced by permission from Schoen, F. J., Levy, R. J., and Piehler, H. R. (1992). Pathological considerations in replacement cardiac valves. *Cardiovasc. Pathol.* 1: 29. (See color plate)

Valve prosthesis reliability and host–tissue interactions play a major role in patient outcome. Four categories of valve-related complications (Fig. 6) are most important: thrombosis and thromboembolism, infection, structural dysfunction (i.e., failure or degeneration of the biomaterials making up a prosthesis), and nonstructural dysfunction (i.e., miscellaneous complications and modes of failure not encompassed in the previous groups). (Rahimtoolla, 2003; Vongpatanasin *et al.*, 1996; Schoen, 1995b; Schoen and Levy, 1999).

Thromboembolic complications are the major cause of mortality and morbidity after cardiac valve replacement with mechanical valves, and patients with them require chronic therapeutic anticoagulation with warfarin derivatives (Height and Smith, 1999). Thrombotic deposits that form on valve prostheses can immobilize the occluder or shed emboli (Fig. 6A,B). Tissue valves are less thrombogenic than mechanical valves, with most patients not requiring long-term anticoagulation unless they have atrial fibrillation or another specific propensity

to thrombose the valve. Nevertheless, the rate of thromboembolism in patients with mechanical valves on anticoagulation is not widely different from that in patients with bioprosthetic valves without anticoagulation (2–4% per year). Chronic oral anticoagulation also increases the risk of hemorrhage.

Prosthetic valve infection (endocarditis) occurs in 3–6% of recipients of substitute valves (Fig. 6C) and often involves the prosthesis–tissue junction at the sewing ring with accompanying tissue destruction in this area (Piper *et al.*, 2001; Mylonakis and Calderwood, 2001). This complication can occur at any time following valve implantation. The microbial etiology of early (less than 60 days postoperatively) prosthetic valve endocarditis is dominated by the staphylococcal species *S. epidermidis* and *S. aureus*, even though prophylactic antibiotic regimens used today are targeted against these microorganisms. The clinical course of early prosthetic valve endocarditis tends to be fulminant. In late endocarditis, a probable source of infection can be found in 25–80% of patients,

the most frequent initiators being dental procedures, urologic infections and interventions, and indwelling catheters. The most common organisms in these late infections are *S. epidermidis*, *S. aureus*, *Streptococcus viridans*, and enterococci. Surgical reintervention is often required. Rates of infection of bioprostheses and mechanical valves are similar, but previous endocarditis markedly increases the risk.

Prosthetic valve dysfunction owing to materials degradation can necessitate reoperation or cause prosthesis-associated death. Durability considerations vary widely for mechanical valves and bioprostheses, for specific types of each, for different models of a particular prosthesis utilizing different materials or having different design features (e.g., different generations of a valve model such as Starr–Edwards caged ball valve (Schoen, 1995b; Schoen, 2001) or Bjork–Shiley tilting disk valves (Schoen, 1995b; Schoen, 2001)), and even for the same model prosthesis placed in the aortic rather than the mitral site (e.g., Braunwald–Cutter valve in the aortic but not the mitral site failing frequently (Schoen, 1995b; Schoen, 2001)). Fractures of metallic or carbon valve components occur rarely, but are catastrophic and life threatening (Fig. 6D) (Watarida *et al.*, 2001). In contrast, structural dysfunction is the major cause of failure of the most widely used bioprostheses (Fig. 6E), resulting in slowly progressive symptomatic deterioration and usually requiring reoperation (Sacks, 2001; Butany and Leask, 2001; Schoen and Levy, 1999; Schoen, 1999b). Within 15 years following implantation, 30–50% of porcine aortic valves implanted as either mitral or aortic valve replacements require replacement because of primary tissue failure. Cuspal mineralization is the major responsible pathologic process with regurgitation through tears the most frequent failure mode in porcine valves. Calcification is markedly accelerated in younger patients, with children and adolescents having an especially accelerated course. Bovine pericardial valves also suffer primarily design-related tearing, with calcification frequent but less limiting.

Paravalvular defects usually caused by inadequate healing may be clinically inconsequential or may aggravate hemolysis (destruction of red blood cells) or cause heart failure through regurgitation. Hemolysis owing to turbulent flow and blood–material surface interactions is an ever-present risk. Although severe hemolytic anemia is unusual with contemporary valves, paravalvular leaks or dysfunction owing to materials degeneration may induce clinically important hemolysis.

Methods are being actively studied and some are being used clinically to prevent calcification in bioprosthetic valves (Vyahavare *et al.*, 2000; Schoen and Levy, 1999; Levy *et al.*, 2003). Other approaches to provide improved valves include modifications of bioprosthetic valve stent design and tissue mounting techniques to reduce cuspal stresses, tissue treatment modifying or alternative to conventional glutaraldehyde pretreatment to enhance durability and postimplantation biocompatibility, nonstented porcine valves, minimally cross-linked autologous pericardial valves, flexible trileaflet polymeric (polyurethane) prostheses, and mechanical and tissue valves with novel design features to improve hemodynamics, enhance durability, and reduce thromboembolism. Some investigators are designing valves that could potentially be securely and safely inserted by a catheter rather than a major surgical

procedure (Cribier *et al.*, 2002). Tissue engineering, in which a functional, viable valve replacement is grown *in vitro* prior to implantation, is an important emerging field that may also lead to improved outcomes for patients with valvular disease (Rabkin and Schoen, 2002).

STENTS AND GRAFTS (FOR ATHEROSCLEROTIC VASCULAR DISEASE)

Atherosclerosis is a chronic, progressive, multifocal disease of the vessel wall intima of which the atheromatous plaque is the characteristic lesion. Atherosclerosis primarily affects the large elastic arteries and large and medium-sized muscular arteries of the systemic circulation, particularly at points of branches, sharp curvatures, and bifurcations. Atherosclerosis of native coronary arteries generally is limited to the large superficial epicardial vessels before they give off branches that bring blood to the heart muscle. Mature atherosclerotic plaques consist of a central core of lipid and cholesterol crystals and cells such as macrophages, smooth muscle cells and foam cells along with necrotic debris, proteins and degenerating blood elements (Fig. 7A) (Schoen and Cotran, 1999; Libby, 2000; Ross, 1999). This core is separated from the lumen by a fibrous cap rich in collagen. The major complications of atherosclerosis result from progressive obstruction of a vascular lumen, disruption of a plaque followed by thrombus formation (Fig. 7B), or destruction of the underlying vascular wall. The most important complication is myocardial infarction, which is permanent injury to heart muscle initiated by complete thrombotic occlusion following rupture of an atherosclerotic plaque that previously was only partially obstructive. The natural history of atheromatous plaque and the efficacy and safety of interventional therapies depend in part on relative plaque composition, the spatial distribution of the constituents and the integrity of the fibrous cap, which largely determines plaque stability (Kolodgie *et al.*, 2001; Huang *et al.*, 2001). Plaque mechanical properties can determine the propensity to complications as well as influence the success rate of interventions such as percutaneous transluminal coronary angioplasty (PTCA). Risk factors for atherosclerosis and coronary artery disease include diabetes, systemic arterial hypertension, hypercholesterolemia, and smoking.

Coronary Artery Stents

PTCA is used in patients with stable angina, unstable angina, or acute myocardial infarction to restore blood flow through a diseased portion of the coronary circulation obstructed by atherosclerotic plaque and/or thrombotic deposits (Fig. 8A) (Landau *et al.*, 1994). In this procedure developed and implemented first by Andreas Gruntzig in the late 1970s, a long catheter is passed retrograde from the femoral artery up the aorta to the openings of the coronary arteries that arise from the aorta immediately distal to the aortic valve cusps. Using radioopaque dye and fluoroscopy, areas of stenosis can be identified. A deflated balloon is passed over a guidewire to a site of stenosis, where the balloon is inflated using progressive and substantial expansile force (~10 atm). Enlargement of the

lumen and increased blood flow occurs by plaque reduction via compression, embolization, or redistribution of the plaque contents and by overall mechanical expansion of the vessel wall (Virmani *et al.*, 1994).

Short-term failure of this procedure (*i.e.*, closure of the treated vessel within hours to days) can occur via several mechanisms, including elastic recoil of the vessel wall, acute thrombosis at the site of angioplasty, and acute dissection (*i.e.*, blood within the wall itself) of the vessel beyond the area of angioplasty. The major problem is that the long-term success of PTCA is limited by the development of progressive, proliferative restenosis, which occurs in 30–40% of patients, most frequently within the first 4–6 months (Haudenschild, 1993). The usual process causing restenosis after PTCA is fibrous tissue formation in the lumen, owing to excessive medial smooth muscle proliferation as an exaggerated response to angioplasty-induced injury, similar to features of atherosclerosis itself and vascular graft healing (see later discussion). Locally delivered pharmacologic and molecular therapies have not effectively mitigated restenosis after PTCA (Riessen and Isner, 1994; Kibbe *et al.*, 2000).

Stents (Fig. 8B) are expandable tubes of metallic mesh that have been developed to address these negative sequelae of balloon angioplasty. Stents have been used in patients since the late 1980s; today, the majority of patients undergoing PTCA will also receive a stent. Stents preserve luminal patency and provide a larger and more regular lumen by acting as a scaffold to support the disrupted vascular wall and minimize thrombus formation following PTCA and thereby reduce the impact of postangioplasty restenosis (Serruys *et al.*, 1994).

Stent technologies have undergone a rapid evolution. The majority of stents in use today are composed of balloon-expandable 316L stainless steel or nitinol mesh tubes that range from 8 to 38 mm and from 2.5 to 4.0 mm in diameter. Development has focused on permitting stents to become more flexible and more easily delivered and deployed, allowing the treatment of a greater number and variety of lesions. The choice of stent is based on several factors, including the characteristics of a given plaque, such as its diameter, length, and location within the coronary anatomy, and the experience of the interventional cardiologist with a particular stent.

Stenting has been shown to be superior to angioplasty alone in several lesions and situations, including in vessels greater than 3 mm in diameter, in chronic total occlusions, in stenotic vein grafts, in restenotic lesions after angioplasty alone, and in patients with myocardial infarction (Stone *et al.*, 2002). The early complications of stenting generally involve subacute stent thrombosis that occurs in 1 to 3% of patients within 7 to 10 days of the procedure (Fig. 8C). This complication has largely been overcome by aggressive multidrug treatment with antiplatelet agents such as clopidogrel, aspirin, and glycoprotein IIb/IIIa inhibitors. The major long-term complication of stenting is in-stent restenosis, which occurs within 6 months in 50% of patients who are stented (Fig. 8D). Tissue interactions with an implanted stent are complex (Welt and Rogers, 2002). There is early damage to the endothelial lining and stretching of the vessel wall, stimulating adherence and accumulation of platelets and leukocytes. Covered initially by a variable platelet–fibrin coating, stent wires may eventually

become completely covered by a endothelium-lined neointima, with the wires embedded in a layer of intimal thickening consisting of smooth muscle cells in a collagen matrix (Farb *et al.*, 1999). This tissue may thicken secondary to the release of growth factors, chemotactic factors, and inflammatory mediators from platelets and other inflammatory cells that result in increased migration and proliferation of smooth muscle cells, and increased production of extracellular matrix molecules, narrowing the lumen and resulting in restenosis (Virmani and Farb, 1999).

Many approaches have been used in an attempt to reduce in-stent restenosis. Intracoronary radiotherapy is a procedure in which a beta or gamma source is brought into close proximity to the stent to deliver local radiation. This is thought to block cell proliferation, induce cell death, and inhibit migration of smooth muscle cells in the area of the stent to reduce neointimal accumulation. Several studies have shown promising initial results in reducing the restenosis rate, but have also shown some long-term complications including late thrombosis, increased restenosis at the edge of the treated field, and damage to the wall (Salame *et al.*, 2001).

The most promising results have been attained with polymer-coated drug-eluting stents (Fig. 9) (Fattori and Piva, 2003; Sousa *et al.*, 2003a,b). Two of the drugs currently in clinical trials are rapamycin (sirolimus) (Sousa *et al.*, 2003c) and paclitaxel (Park *et al.*, 2003). Rapamycin, a drug used for immunosuppression in solid-organ transplant recipients, also inhibits proliferation, migration, and growth of smooth muscle cells and extracellular matrix synthesis. Along with its anti-inflammatory properties, this drug targets the major mechanisms of restenosis discussed above. Paclitaxel, a drug used in the chemotherapeutic regimens for several types of cancer, also has similar anti-smooth muscle cell activities. These drugs are embedded in a polymer matrix (such as a copolymer of poly-*n*-butyl methacrylate and polyethylene–vinyl acetate or a gelatin–chondroitin sulfate coacervate film) that is coated onto the stent. The drug is released by diffusion and/or polymer

FIG. 9. Cumulative distribution of the percentage of stenosis in the high-dose and control groups. The distributions were similar at baseline (about 80%) and immediately after stent placement (about 0%). At 6 months follow-up, the distribution in the high-dose group remained similar to the distribution immediately after stenting, whereas the control group suffered greater restenosis (about 40%). Reproduced by permission from Park, S. J., *et al.* (2003). A paclitaxel-eluting stent for the prevention of coronary restenosis. *N. Engl. J. Med.* 348: 1537–1545.

degradation over varying periods of time that can be engineered by the specifics of the polymer–drug system. These coated stents have had excellent initial success, virtually eliminating restenosis over time periods of 2 years and longer, and are felt to represent a major breakthrough in the treatment of coronary artery disease. Drug eluting stents are commercially available and most PTCA procedures will likely employ them (Poon *et al.*, 2002).

Peripheral Stents and Stent Grafts

Peripheral vascular disease results mainly from narrowing of the aorta and its branches secondary to atherosclerosis, the same accumulation of plaque within the arterial wall described above in coronary artery disease (Schoen, 1999b). As the degree of stenosis increases, blood flow to the distal tissues is impeded, causing ischemia in the tissues served by the diseased artery. Occlusions often occur in the abdominal aorta or the iliac arteries, which are the arteries serving the legs. When this occurs, pain is felt in the legs (especially the calf), buttocks, or hips during times of exertion; the pain usually diminishes with rest. In severe cases of vascular compromise, healing of even minor injuries can be inefficient leading to gangrene and requiring amputation of the affected limb. The treatment for many patients with peripheral vascular disease involves using a vascular graft to perform a bypass around the area of blockage to restore ample blood flow. Aneurysms (i.e., ballooning of the vessel due to the weakness of its wall), especially of the abdominal aorta, may result from atherosclerosis and are at risk of rupture once they reach a certain size. Aneurysms are also repaired with synthetic vascular grafts.

Surgical procedures such as open abdominal aortic aneurysm repair and aorto-femoral bypass grafting can have significant associated complications in certain patient populations. A minimally invasive approach such as that afforded by PTA with or without stenting is appropriate in these settings. Stents and stent grafts can be employed in the peripheral circulation to increase lumen size in a similar fashion to their use in the coronary circulation (Faries *et al.*, 2002; Ramaswami and Marin, 1999).

Stents for treatment of peripheral vascular disease are generally constructed of stainless steel or nitinol and may be coated with compounds such as ePTFE. Stent grafts (Fig. 10) are composed of a metallic frame covered by a fabric tube and combine the features of stents and vascular grafts; they can be deployed endovascularly. Stent grafts are used to treat aortic aneurysms, where the aortic wall has been weakened and threatens to rupture, as well as stenosis of other arterial sites. The graft portion, usually composed of polyester or ePTFE, can sit on either the luminal or abluminal (outside) aspect of the metallic stent and is intended to provide a mechanical barrier to prevent intravascular pressure from being transmitted to the weakened wall of the aneurysm, thus excluding the aneurysm from the flow of blood. These stents and stent grafts are deployed in a similar manner to those in the coronary circulation, either as self-expanding units or over an inflatable balloon. The stent used for a given application is selected by diameter, length, and geometry of the lesion and location of side branches or branch points.

Stent and stent grafts have been especially successful in treating subtotally occluded short (5–10 cm) segments of the iliac artery that can cause significant chronic lower extremity ischemia, and in the treatment of stenosis of the renal arteries and the smaller arteries of the lower extremity (femoral, popliteal, and tibial arteries), the carotid arteries, the celiac artery, and the superior mesenteric artery. Stents and stent grafts in these sites suffer mechanical failure at a greater rate than those in the coronary circulation (Jacobs *et al.*, 2003). Fracture of the struts that make up the stent, fabric erosion, and device fatigue are modes of failure of these devices.

Vascular Grafts

The concept of using synthetic material as a conduit in the vascular system dates back to the early 1900s when animal experiments were carried out using aluminum, silver, glass, and Lucite tubes as vascular replacements. Fabrics such as Vinyon N, a cloth used in parachutes, were employed in the mid-1900s as vascular conduits that could be fashioned from commercially available textiles. Current synthetic vascular grafts are typically fabricated from poly(ethylene terephthalate) (Dacron) or expanded polytetrafluoroethylene (ePTFE), with the Dacron grafts being used for larger vessel applications and the ePTFE to bypass smaller vessels. These grafts can be made porous to enhance healing but they are then impregnated with connective tissue proteins to aid clotting, reduce the blood loss through the pores of the graft upon implantation, and stimulate tissue ingrowth, and with antibiotics to reduce the risk of infection of the graft. Loosely woven or porous synthetic grafts that are not impregnated need to be preclotted with the patient's own blood for this same purpose.

Synthetic grafts (Fig. 11A) perform well in large-diameter, high-flow, low-resistance locations such as the aorta and the iliac and proximal femoral arteries, with grafts used for aortofemoral bypass having 5- to 10-year patency rates of 90% (Clagett, 2002). In contrast, synthetic small-diameter vascular grafts (<6 to 8 mm in diameter) generally perform less well with 5-year patency less than 50%. In general, the longer the interposition or bypass graft, and the smaller the recipient vessel, with a corresponding increase in resistance to flow, the less favorable are both short- and long-term patency rates. For this reason, a major superficial vein in the leg, the saphenous vein, is typically removed surgically and moved to the site needed to bypass blockages in the coronary circulation (for coronary artery bypass grafting) and in the distal extremities (e.g., for femoropopliteal bypass grafting) when an adequate length of disease-free vein segment can be harvested for the given application (Fig. 11B). Other natural vessels such as the internal mammary artery in the coronary circulation may be used.

When a synthetic graft is implanted, the luminal surface of the graft becomes coated with a film of plasma proteins, primarily fibrinogen. This layer develops over time into a platelet–fibrin aggregate termed a pseudointima. When endothelial cells cover this layer simulating the inner layer of a native blood vessel and serving as a nonthrombogenic surface, it is termed a neointima. Humans have a limited ability to endothelialize vascular grafts, resulting in confluent

endothelium covering only a 10- to 15-mm zone adjacent to the anastomosis. Thus, except adjacent to an anastomosis (the sutured connection of the graft to the native artery), a compacted platelet–fibrin pseudointima comprises the inner lining of clinical fabric grafts, even after long-term implantation (Fig. 12A). Because firm adherence of such linings to the underlying graft may be impossible, dislodgment of the lining leading to distal embolization or formation of a flap-valve can occur and cause acute obstruction.

Tissue lining the inner wall of a vascular graft has three possible sources: (1) overgrowth from the host vessel across anastomotic sites, (2) tissue ingrowth through fabric interstices,

and (3) deposition of functional endothelial cells and/or multipotential stem cells from the circulating blood (Fig. 12B). In a graft with interstices large enough to permit ingrowth of fibrovascular elements, endothelial cells can arise from capillaries extending from outside to inside the graft and migrate to the luminal surface at a large distance from the anastomosis. However, since most clinical vascular grafts are impervious in order to obviate hemorrhage, existing grafts and other fabrics used as cardiovascular implants heal primarily by ingrowth of endothelium and smooth muscle cells from the cut edges of the adjacent artery or other tissue. Although there is considerable current interest in harnessing the potential of

(1989). *Interventional and Surgical Cardiovascular Pathology: Clinical Correlations and Basic Principles*. W.B. Saunders, Philadelphia.

circulating endothelial cell precursors to cover grafts, this has not yet been realized (Rafii, 2000).

An implanted graft becomes encapsulated in the surrounding connective tissue and elicits a typical foreign-body reaction. The tissue covering the graft on its exterior surface, separating it from normal tissue, consists of a foreign-body inflammatory reaction containing giant cells adjacent to the material, covered by collagen, fibroblasts, blood vessels, and other cellular and extracellular connective tissue elements. This foreign-body capsule extends from the outside graft surface to the surrounding undisturbed body tissues. Graft interstices may be filled with fibrin or connective tissue elements, including cells and extracellular matrix and, where ingrowth has occurred, blood vessels.

The major complications of vascular grafts are thrombosis/thromboembolism, infection, periprosthetic fluid collection, pseudoaneurysm (i.e., an extravascular hematoma that communicates with the intravascular space), intimal hyperplasia, and structural degeneration. Failure of small-diameter vascular prostheses is most frequently due to occlusion by thrombus formation or generalized or anastomotic fibrous hyperplasia. As in any cardiovascular site, "Virchow's triad" of surface thrombogenicity, hypercoagulability, and locally static or low blood flow largely predicts the propensity toward thrombus formation. This predicts thrombosis in small-diameter synthetic grafts where there can be low flow states due to poor flow out of the end of the graft (termed runoff) from atherosclerosis beyond the anastomosis. In larger vessels with higher blood flow such as the aorta, the surface thrombogenicity of the graft is overcome by brisk flow.

Prophylactic perioperative systemic antibiotics limit infection of implanted vascular prostheses to 6% of patients or less. Early infections typically are related to the surgical procedure or to perioperative complications such as wound infection. Late infections usually occur secondary to seeding from the blood of the synthetic material in patients with low-grade bacteremia, often secondary to dental or gastrointestinal procedures. Since the anastomotic suture line is usually involved, an infected vascular graft usually has a partially disrupted connection to the natural artery; thus, rupture with hemorrhage at the graft site may bring the patient to clinical attention. Surgical removal of an infected graft is usually necessary to cure the infection.

The healing of synthetic vascular grafts can yield exuberant fibrous tissue at the anastomotic site as an overactive physiologic repair response (Fig. 13). Late failure of clinical and experimental vascular grafts, especially in those less than 8 mm in diameter, is frequently due to diffuse fibrous thickening of the inner capsule. This intimal hyperplasia results primarily from smooth muscle cell migration, proliferation, and extracellular matrix elaboration following and possibly mediated by acute or ongoing endothelial cell injury. Contributing factors include (1) surface thrombogenesis, (2) delayed or incomplete endothelialization of the fabric, (3) disturbed flow across the anastomosis, and (4) mechanical factors at the junction of implant and host tissues. In vein grafts, intimal hyperplasia is often diffuse, leading to progressive luminal reduction of the entire graft, but focal lesions can cause isolated stenoses at anastomoses. In contrast, synthetic vascular prostheses tend to develop intimal hyperplasia predominantly at or near anastomoses, particularly at the distal site.

Progressive deterioration of a synthetic vascular graft can cause mechanical failure at the anastomotic site or in the body of the prosthesis leading to aneurysm formation or the formation of an external collection of blood due to rupture (false aneurysm). The incidence of long-term graft deterioration is unknown. The causes of delayed failure of a synthetic prosthesis include chemical, thermal, or mechanical damage to polymeric yarn materials during manufacture, fabric defects induced during manufacture (e.g., dropped stitches) or during insertion (even “atraumatic” vascular clamps can damage yarn fibers), and postoperative biodegradation of graft material.

In light of the complications associated with vascular grafts, current research has focused on improvement of synthetic vascular grafts and on alternatives such as tissue-engineered blood vessels. Attempts have been made to covalently modify the luminal surface of the grafts in order to (1) prevent coagulation, (2) prevent platelet adhesion/aggregation, (3) promote fibrinolysis, (4) inhibit smooth muscle cell adhesion/proliferation, and (5) promote endothelial cell adhesion and proliferation. Endothelialization of the entire graft would improve the thrombogenicity of the graft and may also help prevent bacterial attachment to the graft and subsequent infection. Attempts to seed the luminal surface with unmodified or genetically modified endothelial cells are also underway. Engineering an artery using biodegradable polymer matrices seeded with smooth muscle and endothelial cells is a promising approach to solving the problem of developing an adequate small-diameter vascular graft (Consigny, 2000; Seifalian *et al.*, 2001).

PACEMAKERS AND ICDS (FOR CARDIAC ARRHYTHMIAS)

The normal cardiac electrical cycle (Fig. 14A) begins with an impulse initiated by the sinoatrial (SA) node, which is located in the right atrium near its junction with the superior vena cava. The impulse spreads through both left and right atria, causing depolarization of the cardiac myocytes resulting in atrial contraction. The impulse arrives at the atrioventricular (AV) node, located in the posterior right atrium near the intraatrial septum, the ostium of the coronary sinus, and the tricuspid valve. After a short delay, the impulse passes through the AV node to the bundle of His and into the left and right bundle branches, located in the intraventricular septum. The impulse spreads through the right and left ventricles causing myocyte depolarization and coordinated ventricular contraction.

Cardiac arrhythmias reflect disturbances of either impulse initiation or impulse conduction (Huikuri *et al.*, 2001). Abnormal foci of impulse-generating (automatic) cells outside the SA node, called ectopic foci, may initiate propagated cardiac impulses that generate suboptimal ventricular contractions. Intrinsic SA node dysfunction also can account for disturbances of impulse initiation. Disturbances of impulse conduction mainly consist of conduction blocks or reentry. Conduction blocks constitute a failure of propagation of the usual impulse as a result of a disease process (such as ischemia or inflammation) or a drug. Blocks can be complete (no impulse propagation) or incomplete (impulse propagates

more slowly than normal or intermittently) and can be permanent or transient. Reentry is said to occur when a cardiac impulse traverses a loop of cardiac fibers and reexcites previously excited tissue without a second impulse from the SA node. For patients in whom these cardiac arrhythmias cannot be controlled by pharmacological therapy (i.e., antiarrhythmic drugs), two therapeutic options are available: (1) electrical therapy to control the cardiac rhythm (i.e., direct current cardioversion, implantable electrical devices such as pacemakers and implantable cardioverter-defibrillators), and (2) interventional/surgical therapy to remove the affected tissue or interrupt the abnormal pathway (i.e., endocardial resection, cryoablation, and other ablative techniques).

Cardiac Pacemakers

The implantation of the first cardiac pacemaker was performed in 1958 and since then, cardiac pacing has become a well-established therapeutic tool (Atlee and Bernstein, 2001). More than 500,000 patients in the United States currently have pacemakers (Fig. 14B,C) and more than 150,000 new permanent pacemakers are implanted each year; pacemaker placement, revision, or removal is a commonly performed procedure. Permanent cardiac pacing is used for various types of conduction block. These commonly lead to bradycardia (abnormally low heart rate) resulting in inadequate cardiac output. Most cardiac pacemakers are implanted in patients older than 60 years but they are also used in children, including infants, when necessary.

Modern cardiac pacing (Kusumoto and Goldschlager, 2002) is achieved by a system of interconnected components consisting of (1) a pulse generator which includes a power source and electric circuitry to initiate the electric stimulus and to sense normal activity; (2) one or more electrically insulated conductors leading from the pulse generator to the heart muscle, with a bipolar electrode at the distal end of each; and (3) a tissue, or blood and tissue, interface between electrode and adjacent stimulatable myocardial cells.

Pacemakers are powered by lithium-iodide batteries and have an expected service life of 5–12 years. The first pacemakers were large (40–200 cm³) by today’s standards (9–45 cm³) and contained few of the features that characterize current devices. The pacemaker delivers a small current (2–4 mA) to the myocardium via the electrodes, resulting in depolarization and contraction of the heart. A single-chamber pacemaker delivers a stimulus based on a programmed timing interval. The pacemaker also senses intrinsic cardiac activity and can be inhibited from providing unnecessary or inappropriate stimuli. This “demand” pacing is valuable in a patient whose problem is intermittent. A dual-chamber pacemaker with electrodes in both the atrium and ventricle delivers the sequential atrial and ventricular signals to approximate the timing of the normal heartbeat. This device also senses intrinsic atrial and ventricular depolarizations and delivers stimuli at the appropriate time to maintain proper synchrony of the chambers.

Cardiac pacing may be either permanent or temporary. Permanent cardiac pacing involves long-term implantation of both pulse generator and electrode leads. The generator is

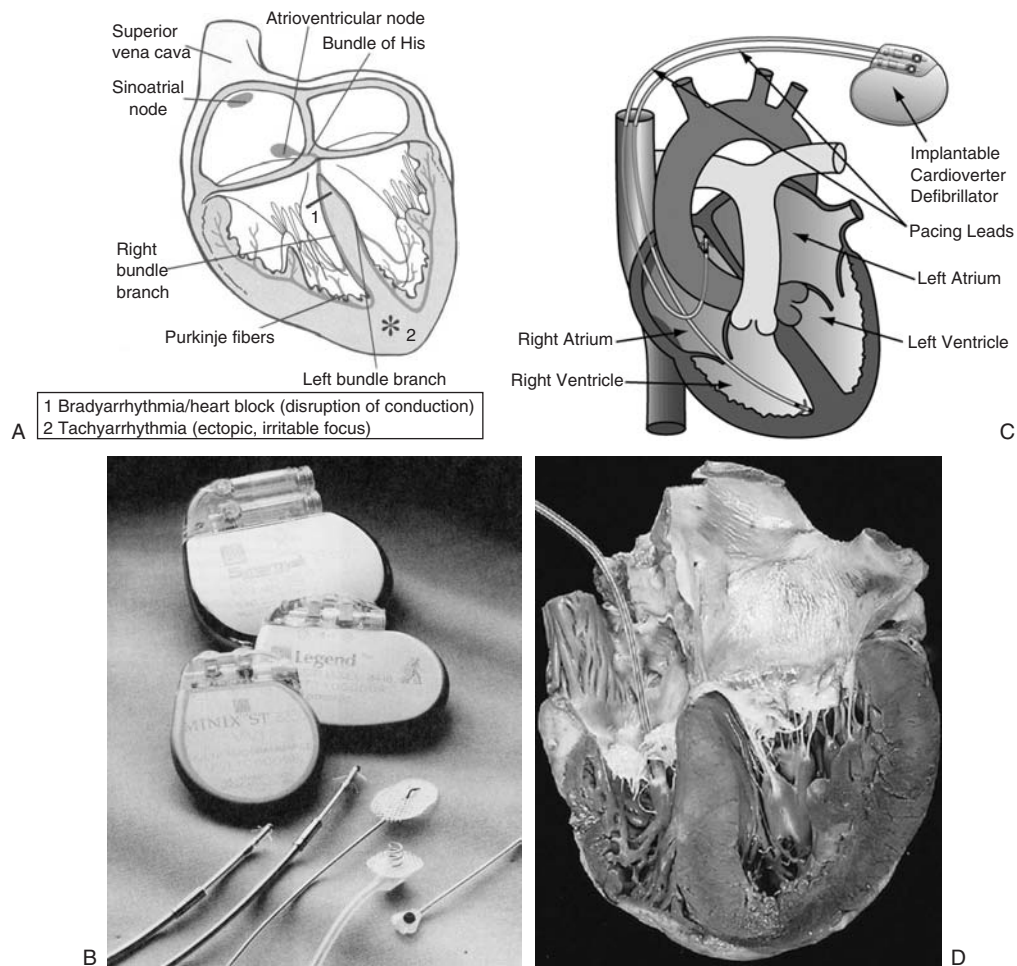

FIG. 14. (A) The normal cardiac electrical pathways showing schematically both conduction blocks and ectopic foci of impulse generation. (B) Two bipolar pulse generators: the dual chamber Synergist II, the rate-responsive Legend ST miniature ventricular device. Left to right are two pipolar urethane-insulated tined endocardial leads and three myocardial leads; a stab-in, urethane-insulated lead with silicone sewing pad and Dacron mesh disk; a screw-in lead, insulated with silicone; and an epicardial urethane-insulated lead with a silicone sewing pad. (C) Schematic demonstrating ICD lead placement in right ventricle. (D) Transvenous pacing lead placed in right ventricle demonstrating fibrosis of the distal portion of the lead (arrow). B: Courtesy of Arthur J. Coury, Medtronic, Inc., Minneapolis, MN. (now Genzyme, Inc., Cambridge, MA) D: Reproduced by permission from Schoen, F. J., and Cotran, R. S. (1999). placed in a tissue pocket beneath the skin on the anterior chest with the leads advanced transvenously through the left subclavian vein (which runs under the left clavicle) with the electrodes terminating at the endocardial surface of the heart. The tips of the electrodes are typically placed within the right atrium and/or right ventricle depending on the pacing modality.

Temporary pacing is most frequently used for the patients with acute myocardial infarction complicated by cardiac conduction system disturbances that could progress to complete heart block. Leads for temporary cardiac pacing are generally directed transvenously into the apex of the right ventricle and the pulse generator is located outside the body. In the context of cardiac surgery when the surface of the heart (epicardium) is already exposed, temporary pacing is achieved

by placing insulated wires with bare ends to the epicardial surfaces of the atria or ventricles with the leads emerging transthoracically from the anterior chest to permit easy withdrawal. Ultimately, the temporary pacemaker is either replaced by a permanent device or discontinued.

The interface between the electrode and depolarizable myocardial tissue is of critical importance in the proper functioning of the pacemaker (Fig. 14D). Typically, a layer of nonexcitable fibrous tissue induced by the electrode forms around the tip of the electrode. This nonexcitable tissue is undesirable as it increases the strength of the threshold pacing stimulus required to initiate myocyte depolarization. Fibrosis between the lead and the heart muscle can be reduced with improved lead designs and the use of slow, local release of

corticosteroid drugs (Cornacchia *et al.*, 2000). The practical point is that, if pulse generator output is not set sufficiently high in the early postimplantation phase, loss of pacing with potentially fatal consequences can result. By contrast, maintaining output at such high levels once thresholds have stabilized greatly shortens battery life. Thus, pacemakers with adjustable variations in output have been developed.

An ideal endocardial pacing lead should provide stable fixation immediately from the time of implantation, achieve and maintain a minimal threshold for stimulation, maximize sensing, and function reliably for many years. Electrode fixation to the inside heart surface (endocardium) may be active or passive. In active fixation, the electrode is designed to grasp the endocardial surface to achieve immediate fixation at implantation. A very effective aid to passive fixation is the addition of projecting tines, or fins, in the region of the electrode tip. A different approach to improving fixation has been the development of electrodes with porous metal surfaces. An endocardial pacemaker lead may require a special design if it is implanted at a particular site. One example is the J-shaped atrial lead, which is curved to facilitate placing the electrode tip in the right atrial appendage, inherently the most stable site for fixation.

The complications of pacemaker leads and electrodes include infection, electrode dislodgment, lead fracture, thrombosis and thromboembolism, myocardial penetration or perforation, electrode corrosion and insulation failure, and an unduly high pacing threshold. Complications related to pacing leads may be related to the body of the lead, as distinct from the lead–pacemaker pack interface or the electrodes. Pacing lead improvements over the years have included helical coil and multifilament designs to decrease electrical resistance and enhance flexibility and durability.

Infection is a dreaded complication of the pacemaker leads and pulse generator (Voet *et al.*, 1999). The infection may originate in the pacemaker pocket and track along the lead, which acts as a contaminated foreign body. Alternatively, it may occur by implantation of bacteria on traumatized endocardium or thrombus contiguous with the lead. The most common organism cultured is *Staphylococcus epidermidis*. Septicemia may develop and septic pulmonary emboli have occurred. The fundamental therapeutic principle in pacemaker-related endocarditis is removal of at least the lead and, when the pacemaker pocket is involved, the entire pacing system. Most leads can be removed by prolonged gentle traction, but recourse to cardiotomy with cardiopulmonary bypass may be needed if the lead is incarcerated in fibrous tissue.

The most common complications related to the pulse generator are erosion due to pressure necrosis of the skin overlying the pulse generator, infection of the pacemaker pocket, and migration or rotation of the pacemaker pack. Under extreme circumstances, the entire pacemaker pack may extrude from the wound, causing a loss of pacing. Perhaps the most obvious complication related to the pacemaker is loss of the stimulus for pacing attributable either to failure of an electronic component or, more commonly, to battery depletion. In the past, many reports appeared on interference with pacemaker function by devices ranging from electric razors, toothbrushes, and microwave ovens at home to electrosurgical and diathermy

apparatus in the hospital. Fortunately, recent generations of cardiac pacemakers have been greatly improved with regard to their resistance to electromagnetic interference.

Implantable Cardioverter-Defibrillator (ICD)

The first implantable cardioverter-defibrillator was placed in 1980 (Jacobs *et al.*, 2003); currently more than 30,000 ICDs are implanted annually in the United States. The goal of ICDs is to prevent sudden death in patients with certain life-threatening arrhythmias. ICDs have been shown to revert sustained ventricular tachycardia (abnormally high ventricular rate, which often initiates sudden death) and ventricular fibrillation (uncoordinated electrical/myocardial activity) in multiple prospective clinical trials. Benefit in overall mortality has been documented (AVID, 1997).

ICDs consist of similar components to a pacemaker, namely a pulse generator and leads for tachyarrhythmia detection and therapy. The pulse generator is a self-powered, self-contained computer with one or two 3.2-V lithium–silver vanadium oxide batteries used to power all components of the system including aluminum electrolytic storage capacitors. The devices have a service life of 5–8 years. The lead is generally placed in the right ventricle through a transvenous approach. The ICD constantly monitors the ventricular rate and, when the rate exceeds a certain value, provides therapy. Current devices will initially provide a short burst of rapid ventricular pacing that terminates some types of ventricular tachyarrhythmias without providing a large shock. This approach can terminate up to 96% of episodes of ventricular tachycardia without the need for a shock. If this pacing fails to break the arrhythmia, the ICD delivers a shock of 10–30 joules between the electrode in the right ventricle and the surface of the pulse generator to terminate the dysrhythmic episode. These devices also keep a running record of arrhythmias and treatment results. ICDs are indicated in patients at high risk for ventricular arrhythmias (primary prevention) and in patients who have already had an episode of sudden cardiac death from which they have been resuscitated (secondary prevention).

Implantable cardioverter–defibrillators are subject to many of the same complications described earlier for implantable pacing systems. However, the more extensive hardware of the ICD system may contribute an increased frequency of complications relative to pacemakers, such as infection and late accumulation of pleural fluid. Several additional considerations are specific to ICDs. The consequences of repeated defibrillations can cause the following effects: (1) direct effect of repeated discharges on the myocardium and vascular structures, and (2) possible thrombotic potential of the indwelling intravascular electrodes. Another major complication of ICDs from the standpoint of the patient, other than the inability to sense or terminate an arrhythmia leading to sudden death, is an inappropriate shock. In addition to being startling and quite painful at the time of the shock, patients receiving multiple inappropriate shocks have been known to develop posttraumatic stress disorder symptoms.

CARDIAC ASSIST AND REPLACEMENT DEVICES (FOR HEART FAILURE)

Congestive heart failure constitutes a deficiency of the pump function of the cardiac muscle, the myocardium, and is an extremely common condition (Jessup and Brozena, 2003). Each year in the United States, congestive heart failure is the principal cause of death in 40,000 individuals, a contributing factor in more than 200,000 deaths, diagnosed in 400,000 individuals, and the primary diagnosis in more than 900,000 hospitalizations. Cardiac transplantation cannot be the solution in most such individuals. The increasing discrepancy between the number of available donor hearts (only 3000 per year) and the large number of patients who might benefit from cardiac transplantation (estimated at 30,000–100,000 per year) has prompted efforts toward the development of mechanical devices to augment or replace cardiac function (Hunt and Frazier, 1998; Goldstein *et al.*, 1998; Jessup, 2001).

Congestive heart failure is the final common pathway of many cardiac conditions, including valvular heart disease, coronary artery atherosclerosis with resultant ischemic heart disease, and diseases that affect the cardiac muscle directly (often called cardiomyopathy). Heart failure can occur precipitously, as in myocardial infarction or myocarditis induced by viruses, or it can be a slow, progressive worsening of exercise tolerance and shortness of breath over many months or years owing to slow, progressive deterioration of the heart muscle. It can manifest itself in the postoperative period after both cardiac surgery (e.g., valve replacement, cardiac transplantation) and noncardiac surgery (e.g., abdominal aortic aneurysm repair).

As one might expect, therefore, the natural history of heart failure depends on the cause and progression of the underlying disease process. For example, patients with heart failure after cardiac surgery (called postcardiotomy shock) often recover the vast majority of their cardiac function after a short period of time if they are otherwise supported by mechanical support. In contrast, patients with a chronic cardiomyopathy, one of the most common reasons for cardiac transplantation, often need long-term mechanical support; studies have shown that at least 50% of such individuals would die in 3–5 years from their disease without it. One must take these clinical considerations into account when designing mechanical support systems, as different devices may best serve patients with different problems (DiGiorgi *et al.*, 2003).

Cardiopulmonary Bypass

First used in 1953 by John Gibbon, cardiopulmonary bypass devices pump blood external to the body and thereby permit complex cardiac surgical procedures to be done safely and effectively. Bypass machines are useful in extracorporeal membrane oxygenation (ECMO) to assist in the transport of oxygen and carbon dioxide for patients (especially neonates and infants) with pulmonary diseases such as respiratory distress syndrome (Alpard and Zwischenberger, 2002).

The basic operating principles of the current heart–lung machines are quite straightforward and have changed little

in the past half century. Deoxygenated blood returning from the systemic circulation into the right atrium is withdrawn by gravity siphon into a cardiotomy reservoir and is then pumped into an oxygenator. The most common type of oxygenator is a membrane oxygenator, where oxygen is passed through the tube side of a shell-and-tube type device while the blood passes through the shell side. Oxygen and carbon dioxide are exchanged via diffusion through synthetic membranes (usually polypropylene or silicone) with high permeability to these respiratory gases. The oxygenated blood is then passed through a heat exchanger to adjust the temperature of the blood and the blood is returned to the systemic circulation via the aorta. At the beginning of the procedure, the patient is anticoagulated with heparin to reduce the risk of thrombosis within the device; as the patient is weaned from bypass, the anticoagulation can be quickly reversed by the use of a drug called protamine. The heat exchanger lowers the temperature of the blood and therefore the core body temperature during the operation, decreasing the metabolic requirements of the body and protecting the organs (including the heart) against ischemic damage. At the end of the operation, the blood can be warmed to normal physiologic temperature as the patient is weaned from the bypass machine. During the surgical procedure, a specially trained perfusionist controls the operation of the heart–lung machine, allowing the surgeon and anesthesiologist to concentrate on their respective tasks. This device, therefore, provides the function of both the heart (maintaining systemic blood flow and pressure) and the lungs (oxygenating blood and removing carbon dioxide), allowing the heart to be effectively stopped for delicate surgical procedures that would be next-to-impossible to perform on a beating, moving heart.

Many improvements to the original design of cardiopulmonary bypass machines have been made since their inception. One of the problems with the original heart–lung machines was the trauma that they would cause to the blood, including red blood cells (hemolysis) leading to functional anemia and thrombocytopenia (low numbers of or dysfunctional platelets), leading to bleeding problems. This problem has been largely overcome with advanced pump designs and the use of the membrane oxygenators. Roller pumps and centrifugal pumps are commonly used because they cause a lesser degree of hemolysis and shear forces; it is important in the design of these pumps to determine the optimum balance between pumping function and hemolysis/shear stress to the formed blood elements. Bubble oxygenators, which directly pass bubbles of oxygen gas through the blood, cause more hemolysis, protein denaturation, and platelet dysfunction than membrane oxygenators and are currently less frequently used. In addition, newer devices allow blood that has escaped the circulation within the sterile operating field around the heart to be processed and returned to the patient, reducing the need for blood transfusion during the procedure.

Cardiopulmonary bypass can result in many pathophysiologic changes, including complement activation from the prolonged interaction of blood with synthetic surfaces (see Chapter 4.4), platelet and neutrophil activation and aggregation, changes in systemic vascular resistance, and expression of other proinflammatory mediators (Levy and Tanaka, 2003). When these changes are severe, the use of the heart–lung

machine can result in confusion, renal insufficiency, pulmonary dysfunction, low-grade hepatic dysfunction, and increased susceptibility to infection. Together, these manifestations are termed the postperfusion syndrome. Current research is aimed at reducing these changes through the use of novel materials with improved biocompatibility, shortened and “off pump” surgeries, and certain therapeutic strategies to reduce the systemic effects of the proinflammatory mediators.

Intraaortic Balloon Pump

Since the original use of the intraaortic balloon pump (IABP) in 1968 by Adrian Kantrowitz, the basic design and function of the current device has remained relatively similar during the ensuing decades, but the indications for IABP have increased. IABPs (Fig. 15) are catheter-based polyethylene or polyurethane balloons with volumes of 30–50 ml, although smaller devices are used in the pediatric population. Helium is used as the inflating gas; its low viscosity allows for rapid inflation and deflation and it is rapidly dissolved in the bloodstream in the event of inadvertent balloon rupture.

IABPs (Baskett *et al.*, 2002; Nanas and Mouloupoulos, 1994) are generally positioned under fluoroscopic guidance in the descending thoracic aorta after percutaneous insertion via the femoral artery. They are timed to inflate during diastole (ventricular relaxation) and deflate during systole (ventricular contraction) using the patient’s electrocardiogram or arterial pressure curve for synchronization. This is counterpulsation, which is out of phase with the patient’s heartbeat and causes volume displacement of blood proximally and distally within the aorta. Several beneficial effects serve to improve cardiac function. Coronary blood flow (the majority of which occurs in diastole) is increased by the rise in diastolic pressure, delivering more oxygenated blood to the myocardium. In addition, left ventricular afterload (the pressure the myocardium must attain to pump blood into the aorta) is decreased, reducing the workload and therefore the oxygen requirement of the myocardium. The combination of these two hemodynamic factors therefore improves the balance between myocardial oxygen supply and demand and results in improved cardiac performance. The device also directly improves systemic circulation, but only to a modest degree (approximately 10%), in contrast to other cardiac assist modalities.

IABP (Torchiana *et al.*, 1997) therapy permits the heart to rest and recover enough function to support adequate circulation after the device has been removed, usually after only a few days. The major contraindications for IABP use include aortic valve regurgitation and aortic dissection. Complications, which occur in 11–33% of patients with IABPs, include limb ischemia from problems at the insertion site requiring early balloon removal or vascular surgery, aortic dissection, balloon rupture, hematoma, and sepsis.

Ventricular Assist Devices

Ventricular assist devices and artificial hearts have been used primarily in two settings: (1) for potentially reversible heart

FIG. 15. Percutaneous intra-aortic balloon pump. Left, balloon deflated for insertion. Right, balloon inflated. (Courtesy S. Volvek, Datascope Corp., Oakland, NJ.)

failure, in which cardiac function is likely to recover with cardiac rest (e.g., postcardiotomy shock); and (2) for end-stage cardiac failure not likely to recover and where mechanical support will provide a bridge to transplantation. Left ventricular assist devices (LVADs) also provide long-term cardiac support with survival and quality-of-life improvements over optimal medical therapy for patients with end-stage congestive heart failure who are not transplant candidates (Rose *et al.*, 2001). These devices represent life-sustaining “destination therapy” for heart failure patients with contraindications to transplantation such as metastatic cancer. LVADs are also being investigated as a “bridge-to-recovery” in patients with congestive heart failure to induce ventricular changes that might improve cardiac function and eventually allow device

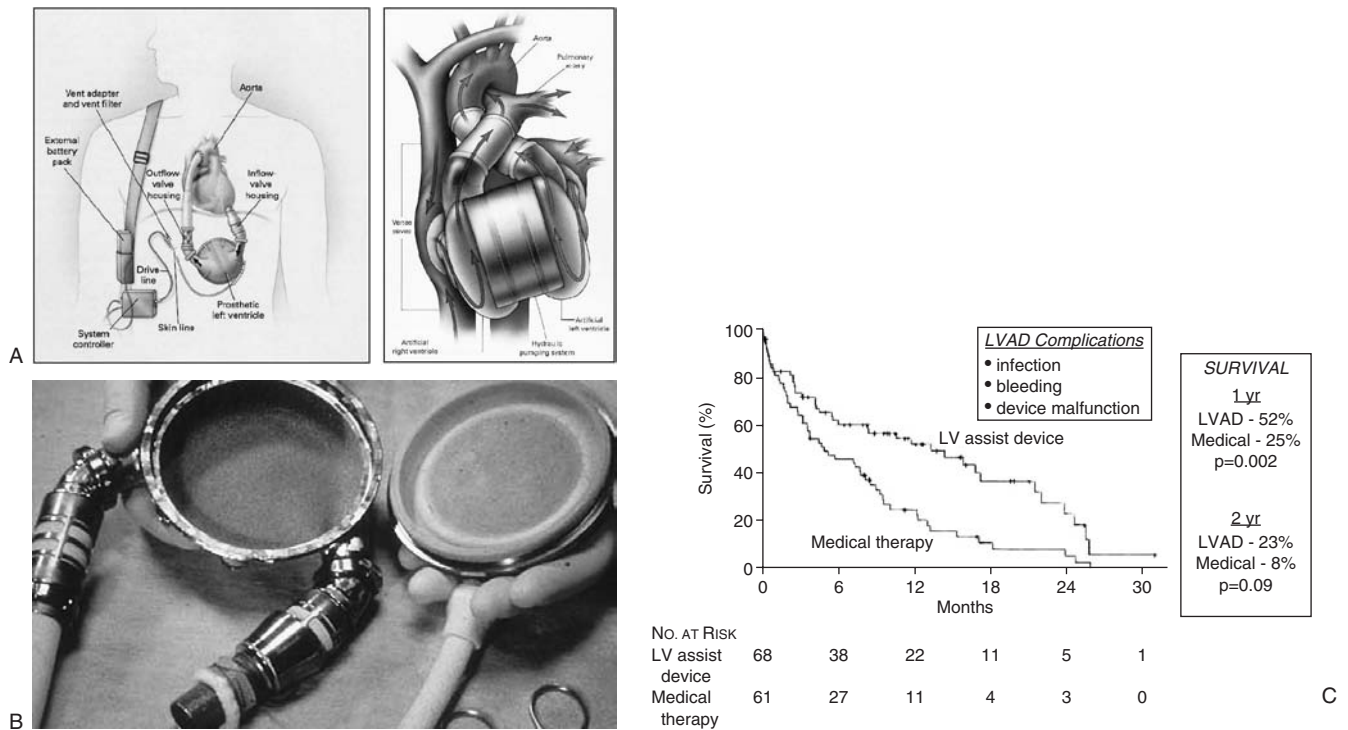

FIG. 16. Left ventricular assist device (LVAD) and total artificial heart. (A) Schematic representation of Thoratec HeartMate LVAD and Abiomed Total Implantable Artificial Heart. Long-term use of a left ventricular assist device for patients with end-stage heart failure. *N. Engl. J. Med.* 345: 1435–1443. B: Reproduced by permission from Schoen, F. J., and Edwards, W. D. (2001). Pathology of cardiovascular interventions. in *Cardiovascular Pathology*, 3rd ed., M. D. Silver, A. I. Gotlieb, and F. J. Schoen, eds. Churchill Livingstone, New York.

removal. Research in this area focuses on the mechanisms of cardiac recovery, identification of patients who could achieve recovery, and specifics such as the timing and duration of therapy (Kumpati *et al.*, 2001; Young, 2001).

Ventricular assist devices, first successfully employed by Michael DeBakey in 1963, can replace ventricular function for extended periods, in contrast to the short-term duration of cardiopulmonary bypass or IABP use. The heart remains in place with the VAD inflow connected to the atrium or ventricle and the VAD outflow connected to the aorta or pulmonary artery (Fig. 16A). In contrast, an artificial heart is composed of two pumping chambers that together replace the heart, analogous to heart transplantation. FDA-approved VADs include univentricular (used as a left or right ventricular assist device) and biventricular extracorporeal and implantable pulsatile devices. These pumps have mechanical or bioprosthetic valves to ensure unidirectional flow, fabric and metal conduits, and a blood-containing chamber with an elastomeric moving bladder/membrane in a rigid housing. Some devices are pneumatically driven by pulses of air generated by an external pneumatic unit and transmitted through tubes to the pumping unit, whereas others are electrically driven. The pumps themselves can be extracorporeal or implanted in the abdominal cavity. Some component of the system traverses the skin in most types of devices; the blood-containing conduits traverse

the skin as they pass between the heart/aorta and the device in extracorporeal systems, while the tubing containing the pneumatic driveline or the electrical cord and air vent passes through the skin in implantable devices. The goal is to eliminate all through-the-skin connections and to transmit electrical energy via radio frequency across intact skin.

The Abiomed BVS 5000 is an extracorporeal, uni- or biventricular VAD that is one of the most commonly used devices for short-term mechanical support. The Thoratec VAD is an extracorporeal uni- or biventricular VAD that uses a pneumatic pusher-plate pump and is often used to provide long-term biventricular support as a bridge-to-transplant. The Novacor N1000PC is an LVAD system with an implantable pump and externalized vent tube, controller, and batteries that employs smooth polyurethane blood-contacting surfaces. These three devices require the patient to be on long-term anticoagulation to lower the risk of thrombosis and thromboembolic events. The Thoratec HeartMate system has both pneumatic and electrical models and consists of an implantable, long-term univentricular support system that was the first VAD to be approved as a bridge-to-transplant. This device (Fig. 16B) has a textured polyurethane-coated diaphragm surface along with a metallic surface covered with titanium beads, both of which encourage the deposition of circulating cells and coagulation proteins to form a stable pseudointima that minimizes

additional thrombus formation and thromboemboli even without long-term anticoagulation. A recently published clinical trial (REMATCH) indicated both the efficacy of chronic VAD support in enhancing the survival of patients with otherwise refractory heart failure, and the safety of the pump surface design in preventing thromboembolism (Fig. 16C). Three classes of advanced devices are under development, including (1) pneumatic devices that are wrapped around the heart and thus do not directly contact blood, (2) compact intracardiac axial-flow pumps (Goldstein, 2003), and (3) a total implantable artificial heart.

Total Implantable Artificial Heart

The Jarvik-7 heart has served as a long-term mechanical cardiac replacement in several individuals since the first implantation of this device in 1982; this and several other types of replacement devices have been used as a bridge to transplantation. The first total artificial heart implants in the United States since the mid-1980s are currently being evaluated (AbioCor, Abiomed Corp.) (Marshalls, 2002).

The Jarvik-7 total artificial heart consisted of two pneumatically powered polyurethane sac-type blood pumps, each with either a 70 or 100 ml stroke volume and powered by separate power units, which provided both systemic and pulmonary circulations. Tilting-disk-type prosthetic inflow and outflow valves provided unidirectional blood flow in the two ventricles. Air tubes from the external pneumatic power unit traveled to the device through the skin via infection-resistant skin buttons. Air pulses entered the space between the cases to compress and expand the sac, providing cardiac output of 4–8 liters per minute. Each ventricle was attached to the native remnant atrium with an atrial suture cuff, while the outlet port was attached to the aorta or pulmonary artery by a conventional vascular graft. Clinical studies showed that the available artificial hearts would fit in the chest of an appropriately sized patient, would provide an adequate cardiac output, and could maintain cardiovascular pressures within a physiologic range. Infection and thromboembolism were frequent complications in these already critically ill patients, and ultimately resulted in withdrawal of this device from the commercial market. Implant retrieval and evaluation studies of these devices demonstrated that transitions of materials and geometries within the pumps were the most vulnerable sites for thrombus formation (Fyfe and Schoen, 1993).

The AbioCor implantable replacement heart (Fig. 16A) is designed to fully sustain the circulatory system and to mimic the function of the human heart while being a completely implantable system with no wires or ports traversing the skin. The internal thoracic unit, weighing 1 kilogram and about the size of a grapefruit, consists of two ventricles with artificial valves and a motorized hydraulic pumping system. In addition, there is an internal rechargeable battery, a miniaturized electronics package, and an external battery pack. The electronics package allows the control and monitoring of the heart rate based on the physiologic requirements of the patient at any given time. The external battery pack continually transmits energy to the internal battery transcutaneously, eliminating the

problem of device infection via percutaneous lines. The internal lithium battery can hold enough power for about 30 minutes of use, allowing the patient to be free of the external pack for short periods of time. The internal moving parts of the device are fabricated from proprietary polyurethane (AngioFlex) that is designed to be a smooth biocompatible blood-contacting surface and to have flexibility and durability to withstand many years of continuous use. To implant the device, most of the native heart is removed; the left and right ventricular inflows are attached to the remnants of the left and right atria, with the outflows attached to the remnant aorta and pulmonary artery, respectively.

Complications of Cardiac Assist Devices

The major complications of cardiac assist devices are hemorrhage, thrombosis/thromboembolism, and infection. Additional common complications include hemolysis, pannus formation around anastomotic sites, and device failure. Device failure can occur secondary to fracture or tear of one of the prosthetic valves within the device conduits as this application provides a particularly severe test of valve durability (Fig. 17A), or can occur secondary to damage to the pumping bladder.

Hemorrhage (Fig. 17B) continues to be a problem in device recipients, although the risk of major hemorrhage has been decreasing with improved therapies and methods. Many factors predispose to perioperative hemorrhage, including (1) coagulopathy secondary to liver dysfunction, poor nutritional status, and anticoagulation therapy, (2) platelet dysfunction secondary to contact of blood with synthetic surfaces, and (3) the extensive nature of the required surgery. Hemorrhage is also a complication of anticoagulation in general, even in the absence of a medical device.

Nonthrombogenic blood-contacting surfaces and appropriate blood flow characteristics are essential for a clinically useful cardiac assist device or artificial heart. Thrombi form primarily in association with crevices and voids, especially in areas of disturbed blood flow such as connections of conduits and other components to each other and to the natural heart. Many pumps have used smooth polymeric pumping bladders; these are frequently associated with thromboembolic complications. One approach discussed earlier (Thoratec HeartMate) is the use of textured surfaces, which accumulate a controlled layer of thrombotic material that seems to be resistant to both further thrombus and thromboemboli (Long, 2001).

Infectious complications (Fig. 17C) have been a major limiting factor in the prolonged use of cardiac assist devices. Infection can occur within the device but may also be associated with the percutaneous pneumatic or electrical lines. Susceptibility to infection is potentiated not only by the usual prosthesis-associated factors, but also by the multisystem organ damage from the underlying disease, by the periprosthetic culture medium provided by postoperative hemorrhage, and by prolonged hospitalization with the associated risk of nosocomial infections. These infections are a significant cause of morbidity and mortality and are often resistant to antibiotic therapy and host defenses.

MISCELLANEOUS CARDIOVASCULAR DEVICES

Closure Devices: Atrial Septal Defect and Patent Ductus Arteriosus

In prenatal life, the circulation is different than it is in postnatal life (Schoen, 1999a). The lungs of the fetus are not expanding and oxygenation of fetal blood is provided via the placenta and maternal circulation. This requires two important shunts to be present that close immediately after birth. The foramen ovale, a hole in the fetal intraatrial septum, allows oxygenated blood returning to the right atrium from the placenta to preferentially pass into the left atrium. This blood passes through the mitral valve into the left ventricle and is pumped out through the aorta into the systemic circulation. The ductus arteriosus, present between the pulmonary artery and aorta, allows deoxygenated blood pumped from

the right ventricle to bypass the lungs and directly reenter the systemic circulation, as the prenatal pulmonary circulation has a high vascular resistance (owing to the nonexpanded lungs). After birth, these functional shunts should close to completely separate the right and left circulations; failure to do so results in an atrial septal defect (ASD) or patent ductus arteriosus (PDA) that can allow inappropriate shunting of blood in the postnatal circulation. ASDs or ventricular septal defects (VSDs) can also result from abnormal formation of the muscle of the atrial septum or ventricular septum.

Although these defects can be closed via an open surgical procedure (sutures and/or fabric patches for ASD or VSD, simple ligation for PDA), efforts have been made to allow closure of these defects using a minimally invasive approach (Hornung *et al.*, 2002). The decision to close an ASD, VSD, or PDA depends on the size of the shunt and the symptoms, if any, of the patient. The first catheter-based closure of a PDA

was performed in 1967 by Porstmann using an Ivalon plug placed in the PDA to occlude flow. Of the many PDA closure devices that have been developed over the years, most are metal-based devices that work by causing thrombosis of the PDA with subsequent organization and fibrosis, permanently preventing flow through the residual ductus arteriosus. Mills and King reported the first transcatheter closure of an ASD in 1976 using a double umbrella device that covered the opening from both the right and left atrial sides. Their occlusion device consisted of a skeleton of ePTFE-coated wire supporting an occluder of Dacron fabric delivered through a catheter. Improvements over the years include better device fixation methods and smaller caliber introducers. Several ASD closure devices are being evaluated in clinical trials. Advantages of nonsurgical closure devices include shorter hospital stay, more rapid recovery, and no residual thoracotomy scar. As experience is gained in the transcatheter closure of PDAs and ASDs, this technology is being extended to the closure of VSDs, particularly in high-risk patients thought to be poor operative risks.

Inferior Vena Cava Filters: Deep Venous Thrombosis and Pulmonary Embolus

Venous thromboembolic disease is a significant cause of morbidity and mortality, largely due to the complication of pulmonary embolism (PE). The most common scenario is for a thrombus to form in the deep venous system of the lower extremities (so-called deep venous thrombus or DVT), become detached from the wall of the vein, travel through the inferior vena cava to the right side of the heart, and lodge as an embolus in one of the large branches of the pulmonary artery. Therapy for patients with DVT or PE usually involves anticoagulation with warfarin and/or low-molecular-weight heparin. However, when anticoagulation is contraindicated because of active or threatened bleeding, or when there is recurrent DVT/PE despite adequate anticoagulation, placement of an inferior vena cava (IVC) filter is indicated.

The concept of placing a barrier to catch DVTs destined for the pulmonary circulation dates back to Trousseau in the 1860s, but such filters did not become clinical reality until the late 1960s (Greenfield and Michna, 1988). Prior to the development of these devices, surgical ligation of the IVC during an open abdominal operation was performed. Interventional radiologists began to place filters using a minimally invasive percutaneous approach in the 1980s. There are five types of filters commonly used in current clinical practice whose common design elements include metallic wires in a configuration to catch emboli in the bloodstream, a mechanism to anchor the device securely to the wall of the IVC, and an ability to be deployed through a catheter percutaneously. These devices (Streiff, 2000; Greenfield and Proctor, 2000) (Fig. 18) include the two Greenfield-style filters (one titanium and one stainless steel), the bird's-nest filter (stainless steel), the Simon nitinol filter (nickel-titanium alloy with thermal memory properties), and the Vena Tech filter (alloy of cobalt, chromium, iron, nickel, molybdenum, magnesium, carbon, and beryllium). Complications of these devices include thrombosis at the

insertion site, thrombi forming on the filter itself (Fig. 18B), thrombosis and obstruction of the IVC, migration or tilting of the device, and penetration of the IVC wall. Many of these complications are rare and/or without clinical consequence. As these devices have become safer and more effective, the indications for their use have expanded. Current research involves creating devices with a lower profile to make insertion easier and reduce insertion site thrombosis, designing removable devices, and continuing to evolve the devices with the goal of catching potentially lethal emboli while maintaining adequate vena caval blood flow.

CONCLUSION

Cardiovascular medical devices have been used for more than a half-century for myriad applications that save, prolong, and enhance the quality of life for countless individuals. Still, complications from these devices can cause significant morbidity and mortality for individual patients, even years after implantation. Ongoing research aims to improve existing devices, reduce the frequency and severity of complications and develop novel approaches to the treatment of cardiovascular disease.

7.4 IMPLANTABLE CARDIAC ASSIST DEVICES

William R. Wagner, Harvey S. Borovetz,
and Bartley P. Griffith

CLINICAL NEED AND APPLICATIONS

Heart failure results in more than 43,000 deaths per year in the United States and contributes to the death of another 220,000 individuals. There are approximately 400,000 new cases diagnosed annually and those diagnosed with this condition have a mortality rate of about 50% at 5 years (American Heart Association, 1999). When the severity of heart failure is graded, those in the sickest class (New York Heart Association class IV) have an even poorer prognosis, with a survival rate of only about 25% at 2 years (Schocken *et al.*, 1992). For these end-stage patients heart transplantation has become an effective treatment over the past 20 years, largely as a result of the introduction of successful immune suppression drugs such as cyclosporine. Actuarial survival rates for heart transplant

patients are currently 75% at 3 years (United Network for Organ Sharing, 1999).

The success of heart transplantation is limited, however, by an inadequate and stagnant donor supply. Although 35,000–64,000 patients could potentially benefit from heart transplantation annually (Funk, 1991), in 2003, only 2055 cardiac transplants were performed in the United States. While waiting for scarce donor organs to become available, approximately 20% of individuals listed for heart transplantation die annually (United Network for Organ Sharing, 1999). To address the need to support the circulation in patients with end-stage heart failure a wide variety of mechanical devices have been developed over the past several decades. Current devices that are widely used for the purpose of bridge-to-cardiac transplantation will be discussed in this chapter, as will circulatory support devices that may enter the market in the near future.

Roles for Ventricular Assist Devices

Three devices are currently approved by the FDA for the provision of circulatory support while patients await a donor heart. These devices do not replace the patient's heart (as would a total artificial heart), but rather work as ventricular assist devices (VADs). The general concept behind a VAD can be seen in Fig. 1. The inflow conduit of the device is connected to the apex of the left ventricle. Blood from the patient's ventricle enters the VAD conduit and flows toward a unidirectional valve that directs flow into a pumping sac. The pumping sac

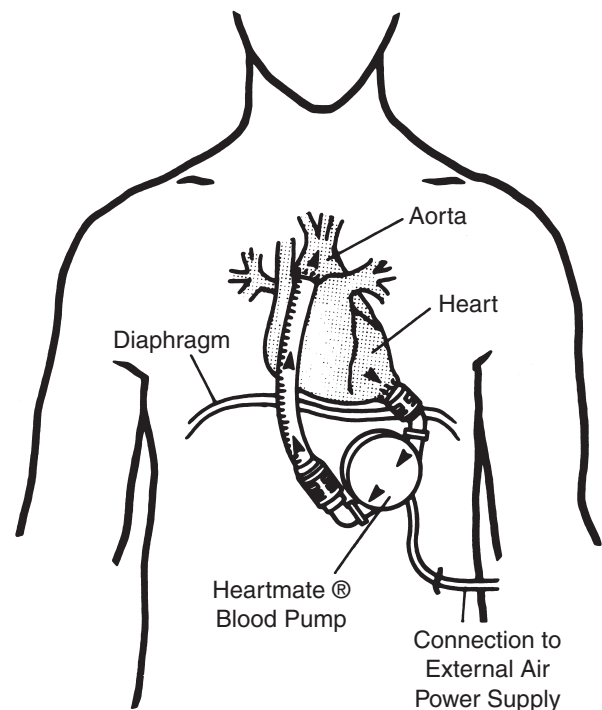

FIG. 1. ThermoCardiosystems HeartMate VAD demonstrating anatomical placement and blood flow. (Reprinted from F. A. Arabia, R. G. Smith, D. S. Rose, D. A. Arzouman, G. K. Sethi, and J. G. Copeland, *ASAIO J.* 42: M542–M546, 1996.)

can be triggered to compress by several methods: sensing pump filling, compressing at a constant frequency, or triggering off the patient's electrocardiogram. Upon compression the inflow valve is closed and the outflow valve opens, permitting blood flow through the outflow conduit toward the patient's ascending aorta. The VAD thus "unloads" the left ventricle of the heart and provides the necessary work to periodically propel blood into the arterial tree.

As a bridge-to-cardiac transplantation, VADs have provided circulatory support to end-stage heart failure patients who otherwise would have a low likelihood of surviving until a donor organ became available. Nearly 70% of patients undergoing VAD support have survived until heart transplantation (Mehta *et al.*, 1995). Patients undergoing VAD "bridging" generally do not undergo further deterioration in their condition and, in fact, demonstrate markedly improved end-organ function and an improvement in their health status due to improved perfusion (Frazier *et al.*, 1994). Ironically, the success of VAD bridging has been implicated in intensifying the donor shortage by including recipients who would otherwise have not survived until transplantation (Massad *et al.*, 1996). A second result of this trend is the need for increasingly extended periods of VAD support prior to organ availability.

The improvement in end organ function generally associated with extended circulatory support has led investigators to evaluate whether the heart muscle itself may undergo recovery from the disease process of heart failure during the support period. A variety of recent studies in VAD-supported patients have shown a reduction in the inflammatory mediators associated with heart failure as well as decreased myocyte necrosis and apoptosis, improved myocyte contractility, and indications of improved function in the left ventricle (Mann and Willerson, 1998). These reports have led to the investigation of VAD support as a "bridge to recovery" where patients are weaned after extended periods of circulatory support. The attractiveness in bridging to recovery lies in freedom from transplantation and immunosuppressive therapy for the patient and an increased donor organ supply for the community. Early clinical experience with this procedure indicates that, although success can be achieved, patients must be carefully screened for this procedure and the majority of VAD patients are unlikely to meet selection criteria (Loebe *et al.*, 1999).

Another result of the increasingly positive experience of supporting patients until transplantation with VADs is the concept of using VADs as a permanent source of circulatory support or as a "destination therapy." A number of permanent VAD implants have occurred in Europe in the past several years and a randomized trial comparing VAD implantation with medical therapy in patients who require, but are ineligible for heart transplantation, has been initiated in the United States with support from the National Heart, Lung, and Blood Institute (Rose *et al.*, 1999). A number of factors have led to the consideration and investigation of permanent support: the limited donor organ supply, a significant patient population that fails to meet age and medical eligibility requirements for transplant listing, and improved quality of life with recent portable VAD designs. Major concerns regarding this option focus primarily on the complications that remain associated with VAD support. As one might expect, biomaterial performance and

device biocompatibility are central to the perceived limits of utilizing VADs as alternatives to transplant in end-stage heart failure patients.

In looking back on the history of mechanical circulatory support, it is interesting that the field has returned to the challenge that was taken up in the early to mid-1980s with the first implants of the Jarvik-7 total artificial heart (TAH) intended for permanent support (DeVries *et al.*, 1984). Medical complications such as infection and thromboembolism, as well as manufacturing concerns, led to the discontinuation of TAH use as permanent support. Also at this time the success of immunosuppressive therapies was being reported, raising heart transplantation to the role of preferred therapy for end-stage heart failure. The TAH was subsequently transferred to a different corporate sponsor (CardioWest, Tucson, AZ) and utilized in the bridge to transplant role (Guy, 1998). In the meantime VADs were being used as investigational devices for bridging patients to transplantation with demonstrated success. In the 1990s several VADs received FDA approval for use as a bridge to cardiac transplantation. Supported primarily by the National Institutes of Health, research and development of TAHs is ongoing; however, clinical circulatory support is accomplished almost exclusively by VADs. This is not to say, however, that the TAH is not currently used in the bridge-to-cardiac-transplantation role. The CardioWest TAH has been implanted in 150 patients since 1993 and has a success rate of bridging patients to transplantation comparable to that of the more widely utilized VADs (Arabia *et al.*, 1999; Copeland *et al.*, 1997).

This chapter will focus only on current VAD designs widely utilized in the bridge-to-cardiac-transplantation role when discussing biomaterials and biocompatibility considerations.

VENTRICULAR ASSIST DEVICE DESIGN AND BLOOD CONTACTING MATERIALS

Thoratec

The Thoratec VAD (Thoratec Laboratories, Pleasanton, CA) is based upon the Pierce-Donachy VAD originally developed in the mid-1970s at Pennsylvania State University and currently has been implanted in over 1000 patients. In Fig. 2 the interface of this VAD with the circulatory system is presented. Of particular note is the paracorporeal nature of this device. Both inflow and outflow conduits cross the skin and the pumping sac rests on the lower abdomen. One advantage of this type of design is the potential to implant smaller patients. While the other commonly utilized VADs are often incompatible in terms of size with smaller, often female patients, the Thoratec device has been implanted in patients ranging in weight from 37 to 317 pounds. Also of note is the potential for this device to be used in a biventricular support mode with two devices implanted in tandem as shown in Fig. 2. Although it has been found that the majority of patients experiencing end-stage heart failure require only left ventricular assistance (Kormos *et al.*, 1996), for those who require support of the right ventricle, the Thoratec pump can be placed in conjunction with another Thoratec pump or other VAD supporting the left ventricle.

FIG. 2. Thoratec VADs utilized for biventricular support. The right ventricular assist device (RVAD) draws blood from the right atrium, while the left ventricular assist device (LVAD) is connected to the apex of the left ventricle. Both pumping sacs rest outside of the body with inflow and outflow conduits crossing the skin. (Reprinted from S. A. Hunt and O. H. Frazier, *Circulation* 97: 2079–2090, 1998.)

The Thoratec VAD has the potential to draw blood from cannulas designed to interface with the ventricle or atrium, with the former being more commonly utilized for extended left ventricular support. The inflow cannula and the pumping sac are composed of Thoralon, a proprietary polyurethane elastomer blended with a surface-modifying agent. The surface-modifying agent is designed to increase the potential for surface molecular rearrangement and reduce thrombogenicity (Farrar *et al.*, 1988). The outflow cannula is composed proximally of Thoralon polyurethane that fuses distally with a Dacron graft, to allow suturing to the ascending aorta. The Dacron graft is preclotted with patient blood and thrombin or cryoprecipitate and thrombin prior to implantation to seal the graft pores. Where the cannulas cross the skin, polyester velour is present on external surfaces of the Thoralon to encourage tissue integration. The opposing valves controlling flow into the pumping sac are tilting disk mechanical valves (Bjork–Shiley Monostrut). Compression of the full pumping sac produces a stroke volume of approximately 65 ml and is accomplished pneumatically, requiring connection to a controller providing positive and negative air pressure. Although a portable pneumatic system is in clinical trials, many current Thoratec patients

FIG. 3. Novacor VAD with wearable power pack and controller. 1, Pump/drive unit; 2, valved conduits; 3, inflow conduit; 4, outflow conduit; 5, percutaneous line; 6, filter; 7, compact controller; 8, primary power pack; 9, reserve power pack. (Reprinted from A. El-Banayosy, M. Deng, D. Y. Loisanche, H. Vetter, E. Gronda, M. Loebe, and M. Vigano, *Eur. J. Cardiothorac. Surg.* 15: 835–841, 1999.)

are tethered to a rather large drive console that limits mobility and the potential for discharge to home.

Novacor

The Novacor Left Ventricular Assist System shown in Fig. 3 is a VAD designed exclusively for left-sided support of the heart. Developed by Peer Portner and colleagues in the 1970s (Portner *et al.*, 1978) the Novacor system has undergone design refinement over the past two decades and has now been implanted in almost 1000 patients worldwide. Unlike the Thoratec device, the Novacor VAD rests predominantly within the body cavity with only a single percutaneous line to transmit power, provide pump control, and vent air displaced by pumping sac compression and relaxation. Compression of the pumping sac is accomplished electrically with a pulsed-solenoid energy converter coupled to pusher plates on opposing sides of the sac by a flat spring mechanism. The controller and power pack have been reduced in size such that patients can wear these units on a belt. The reduced size of the complete system allows great patient mobility and, in many instances, discharge to home while the patient awaits word of donor organ availability. The impact of such discharge on the economics of supporting patients with end-stage heart failure is great (i.e., intensive care unit daily charges versus negligible costs for patients at home). Such portable systems also offer quality of life improvements that have led to the implantation of the Novacor system as an alternative to transplantation in Europe (Dew *et al.*, 1999; El-Banayosy *et al.*, 1999a).

The inflow and outflow conduits of the Novacor VAD are 22-mm-diameter low porosity, gelatin-sealed woven polyester grafts (Sulzer Vascutek). Since the grafts are sealed, no preclotting is required in the operating room. The inflow conduit is nonconvoluted, while the outflow is crimped. To protect against conduit kinking, external polypropylene supports are present on the external surfaces of the conduits. A sewing ring at the proximal end of the inflow conduit allows suturing to the apex of the left ventricle. The inflow conduit connects distally to a valved Dacron conduit housing a 22-mm porcine xenograft valve. This valved conduit connects to the smooth Biomer polyurethane pumping sac that has a maximum stroke volume of 70 ml. The outflow valved conduit and outflow conduit are similar to the inflow conduits with the exception that the distal section of the outflow conduit is not protected with polypropylene support. This allows sizing of the outflow graft to the patient.

The percutaneous lead of the Novacor, also known as the driveline, has a Dacron coating that begins at the pump and extends 34 cm distally. This Dacron coating is intended to encourage tissue integration, particularly at the skin exit site. At approximately 1 week after implantation granulation tissue is expected to adhere to the driveline to reduce the potential for bacterial entry along this biomaterial surface. Driveline infections have the potential to become life threatening if bacteria migrate up the line in the patient to colonize the exterior surfaces of VAD. This potential complication is common to all circulatory support devices that must physically communicate across the patient's skin.

HeartMate

The HeartMate VAD (developed by ThermoCardiosystems [Woburn, MA] and now produced by Thoratec) is similar to the Novacor in that the inflow and outflow conduits as well as the pumping sac reside entirely within the patient as seen in Fig. 1. Two designs of this VAD have been widely applied clinically. The older pneumatic model utilizes an external air pump to compress the pumping sac in a fashion akin to that of the Thoratec device, while the more recent vented electric design uses an integral electric motor powered by an external battery pack. The pneumatic model provides for some patient mobility with a portable 8.5-kg pneumatic console, but patient mobility is much improved in the electric model with wearable battery pack. From a blood-contacting materials perspective, both models are identical. The HeartMate VAD is the most widely utilized VAD design to date with more than 2000 patients having been implanted worldwide.

From a materials perspective, the HeartMate design departs substantially from the Thoratec and Novacor VADs. The inflow from the apex of the left ventricle occurs through a titanium alloy (Ti-6Al-4V) cannula attached to a low-porosity Dacron graft. The blood and tissue contacting surfaces of the titanium cannula are surface coated with sintered titanium microspheres 50–75 μm in diameter, as seen in Fig. 4A. The Dacron portion of the inflow conduit houses a 25-mm porcine xenograft valve (Medtronic). The outflow conduit is also a valved Dacron conduit with an identical opposing valve at the exit of the pumping sac. The pumping sac is composed

FIG. 4. (A) Blood-contacting surface of the rigid housing in the HeartMate VAD with sintered titanium microspheres (spheres are 50–75 μm in diameter). (B) Integrally textured polyurethane surface of the flexible diaphragm (fibrils are approximately 18 μm in diameter). (Reprinted from M. J. Menconi, S. Pockwinse, T. A. Owen, K. A. Dasse, G. S. Stein, and J. B. Lian, *J. Cell. Biochem.* 57: 557–573, 1995.)

on one side of a titanium alloy surface with sintered titanium microspheres. On the opposing side the flexible pusher plate diaphragm is made of Biomer polyurethane that has been textured on its blood-contacting surface with surface integral fibrils approximately 18 μm in diameter and 300 μm in length, as seen in Fig. 4B (Menconi *et al.*, 1995). The maximum stroke volume of the pumping sac is 83 ml.

The implication of having textured surfaces contacting the blood in the HeartMate VAD is that these surfaces rapidly clot upon device placement. While this may seem like a negative scenario for the interior surfaces of a VAD, the concept behind the design is that while clots rapidly form on these surfaces, these thrombi are densely adherent and do not appear to embolize into the bloodstream in a clinically relevant manner. Over time additional blood cell interaction occurs, similar to an inflammatory reaction (see Chapter 4.2). A heterogeneous surface containing platelets, monocytes, macrophages, foreign-body giant cells, lymphocytes, and pluripotent hematopoietic cells is deposited. It is postulated that pluripotent hematopoietic cells differentiate into fibroblasts, myofibroblasts, and in some cases endothelial cells, that are reported to populate the surface (Rafii *et al.*, 1995; Spanier *et al.*, 1999; Frazier *et al.*, 1993). The fibroblastic cells may then secrete extracellular matrix components such as collagen, which is routinely found on textured VAD surfaces following extended implants. Unlike the inflammatory response associated with porous cardiovascular biomaterial surfaces, the cells populating the interior HeartMate VAD surface are likely derived entirely from the passing blood. Cellular migration from tissue onto these surfaces in the time frame that the cellular deposits are observed is considered unlikely. The blood-contacting biological interface that develops from the initial surface coagulum after approximately 1 week is referred to as the pseudointimal layer (Fig. 5) and

has been shown not to grow in thickness exceeding 150 μm over periods of implantation on the order of 1 year (Menconi *et al.*, 1995).

COMPLICATIONS AND VAD BIOCOMPATIBILITY ISSUES

Complications associated with the implantation and operation of VADs include those that may be related to biomaterial-centered processes discussed earlier in this text, including thromboembolism, infection, and bleeding. It is worth noting, however, that the mechanisms behind these complications vary among patients and are multifactorial. Many of the processes contributing to the complication may be independent of the biomaterial implant. Of particular relevance here is the health status of the patient at the time of device implantation. Patients in end-stage heart failure suffer from a variety of conditions secondary to the poor perfusion of their organs. They undergo a variety of invasive treatments and monitoring that precede VAD insertion and have often spent extended periods sedentary in the hospital environment.

Independent of VAD implantation end-stage heart failure patients are at risk for infection due to poor perfusion, compromised immune function, extended exposure to nosocomial infections, and invasive monitoring devices. Thromboembolism can occur in this patient group as a result of ventricular arrhythmia and ventricular mural thrombi, poor distal hemodynamics, and systemic vascular disease. Bleeding risks are elevated as a result of compromised liver function secondary to poor organ perfusion, and invasive monitoring and therapy short of VAD implantation. With these considerations in mind, there is certainly a relationship between the

FIG. 5. Pseudointima developed on the interior textured surfaces of the HeartMate VAD after an implantation period of 243 days. On the left is the titanium surface with sintered microspheres and on the right is the textured polyurethane surface. (Reprinted from V. L. Poirier, *Thorac. Cardiovasc. Surg.* 47(suppl): 316–320, 1999.)

extensive biomaterial surface implantation of a VAD and the above complications. The blood-contacting surface areas of the VADs discussed above are in the 400–500 cm² range—a substantial implantation. These major complications will be discussed next.

Thromboembolism

Thromboembolic rates for VAD support vary widely among the specific devices studied and the reporting centers. Rates can vary simply due to the average implant period of the VAD, the health of the patients selected for support, and the patient medical management routine. Thromboembolism can be defined in a conservative manner to include only obvious neurologic events (strokes) lasting for more than 24 hours that are coupled with imaging evidence of a recent cerebral infarction and that cannot be explained as originating from a source other than the VAD. Alternatively, the definition can be liberalized to include suspected neurologic events such as blurred vision, weakness on one side, compromised field of view, and other events that are transient in nature, that may or may not be followed up with diagnostic imaging, and that may potentially be explained by some other risk factor. It is also possible to investigate peripheral embolization with imaging techniques that would not likely be employed in the majority of clinical centers (Schmid *et al.*, 1998). Finally, although not generally included in reported thromboembolic rates, tissue infarcts attributable to VAD support can be quantified at the time of autopsy in patients who die while on the device. With these limitations to reported thromboembolic rates in mind, the rates generally tend to be in the 10–30% range for the Thoratec and Novacor VADs and considerably less at approximately 5% for the HeartMate VAD (Mehta *et al.*, 1995; El-Banayosy *et al.*, 1999a; DeRose *et al.*, 1997).

To explain the principal mechanisms of thromboembolism in VAD patients one needs to recall the mechanisms of thrombosis on artificial surfaces discussed in Chapter 4.6 and consider the role of flow in this thrombotic process as discussed in Chapter 5.4. Low pump volumetric outputs have been directly associated with thrombotic deposition on the valves of an earlier design of the Novacor VAD (Wagner *et al.*, 1993). This design was subsequently altered to reduce the potential for low blood velocities to develop within the pumping sac and valve system. With all VAD designs, excessively low volumetric flow is considered to be a risk factor for thromboembolism.

The hemostatic system is affected with the implantation of all types of VADs. With the HeartMate device it has been shown that platelets, coagulation, and fibrinolysis are all activated early in the implant period at 2 hours after the operation (Livingston *et al.*, 1996). This activation is in excess of the marked elevations resulting from the extensive biomaterial contact involved in cardiopulmonary bypass for the implant surgery. The textured, prothrombotic surfaces of this VAD likely contribute to this effect. Longer-term elevations in hemostatic markers have also been reported for all VAD designs. Ongoing elevations in platelet activation, coagulation, and fibrinolysis have been reported for all three VADs discussed, suggesting that the device surfaces remain active during the

implant period in bridge-to-transplantation patients (Dewald *et al.*, 1997; Wilhelm *et al.*, 1999; Spanier *et al.*, 1996).

Attempting to relate activation of coagulation, platelets, or fibrinolysis with the risk for thromboembolism remains difficult for VAD patients. Although thromboembolic events are uncomfortably common, most centers do not have the numbers of patients to collect the number of observations necessary to statistically relate specific hemostatic alterations to thromboembolic events. As a result, markers of thromboembolism that do not result in an obvious clinical event (e.g., stroke) have been utilized to relate to measurable thrombotic markers in the blood (as discussed in Chapter 5.4). Microembolic signals detected in the cerebral arteries of VAD patients using ultrasound techniques have been explored as a potential indicator of stroke risk in VAD patients. Some reports have suggested that microembolic signals increase on days when patients experience a clinically obvious thromboembolic event (Schmid *et al.*, 1998). Others have shown that thrombin generation increases on days when large numbers of microemboli are detected in the cerebral arteries (Wilhelm *et al.*, 1999).

As with all cardiovascular devices, anticoagulation and antiplatelet therapy are options to control the reactions at the device–blood interface. A variety of specific anticoagulation and antiplatelet drug and monitoring regimens have been developed for VAD patients. Most commonly patients with Novacor and Thoratec devices are managed acutely with heparin and chronically with oral anticoagulants (i.e., warfarin) and antiplatelet agents. Anticoagulation is monitored with measurement of the activated partial thromboplastin time during heparin therapy and with the prothrombin time or international normalized ratio during oral anticoagulation. For the HeartMate VAD patients generally are not given chronic anticoagulation, and in only a fraction of the patient population are antiplatelet agents administered.

The fact that HeartMate VAD patients do not require chronic anticoagulation, yet still appear to have a markedly lower rate for thromboembolic complications merits discussion and has important ramifications for our definition of material biocompatibility in this setting. In much of the clinical literature the lower rate for thromboembolic complications in HeartMate VAD patients is attributed to the textured surfaces discussed earlier which lead to the formation of a biological pseudointima. This concept of encouraging well-anchored clot formation as a means of ultimately encouraging a biological lining goes back to the mid-1960s and earlier when Sharp, Hall, and other investigators researched this concept (Sharp *et al.*, 1964; Hall *et al.*, 1967).

There are few reports to date regarding the mechanisms through which the HeartMate pseudointima might act to reduce thromboembolism. Recent investigations have shown the mature surface to be dominated by inflammatory and fibroblastic cell lineages expressing tissue factor, inflammatory cytokines, and laying down matrices that include type I collagen (Spanier *et al.*, 1999; Menconi *et al.*, 1995). Such a surface would not appear to have antithrombotic properties. Indeed, Spanier *et al.* (1999) have suggested that such a surface may work by creating a sustained prothrombotic and potentially proinflammatory environment that triggers ongoing coagulation through the tissue factor pathway. The

FIG. 6. Incidence of infectious organisms grouped by site. Cultures were performed of driveline exit site infection, pump pocket infection, and blood (septicemia) in a group of 118 Novacor VAD patients. The number of patients with infection for each site are presented above each pie chart as is the percentage of total patients experiencing infection at this site. (Reprinted from A. El-Banayosy, M. Deng, D. Y. Loisanca, H. Vetter, E. Gronda, M. Loebe, and M. Vigano, *Eur. J. Cardiothorac. Surg.* 15: 835–841, 1999.)

body's extended fibrinolytic response to the ongoing coagulation on this surface may serve as autoanticoagulation to prevent large potential thromboemboli from developing. Alternative explanations for the HeartMate VAD's impressive clinical results should also be considered. The development of small thrombi on the surface of the pump may occur with regularity throughout the implant period, but these thrombi may have a much lower likelihood of embolizing because of stronger adhesion to the extracellular matrix present on the surface. Deposition of the pseudointima may also act to "smooth" discontinuities in pump surfaces that otherwise would serve as a nidus for thrombi formation. The macroscopic flow patterns within the pumping chamber should also be considered. This VAD has been designed to have a "wandering vortex" that may act to minimize the size of thromboemboli generated from pumping-chamber surfaces (Slater *et al.*, 1996).

Infection

Infection is considered by many physicians and investigators to be the most serious complication facing VAD patients and a major obstacle to the implementation of current VAD designs as permanent implants to treat end-stage heart failure. As implant periods for bridge-to-transplant patients increase, the primary cause of death becomes infection (El-Banayosy *et al.*, 1999a). As with thromboembolism, the reported infection rates in VAD patients vary widely between centers because of the criteria selected to classify this complication as well as patient selection and medical management differences. Infection rates can be reported in a very general sense to include all patient infections, usually defined as clinical evidence of infection reflected by elevated leukocyte count, fever, or both in the presence of a positive culture. With this general definition, infection rates generally fall near 50% for all three aforementioned types of VADs (Sun *et al.*, 1999; McBride *et al.*, 1999; El-Banayosy *et al.*, 1999a). Alternatively, only device-related

infections may be reported. These infections can be classified as positive cultures from percutaneous drivelines and cannulas, and from the VAD pocket or mediastinum. With this definition the infection rates tend to fall in the 20–30% range.

Infection is directly responsible for the death of 10–15% of bridge-to-transplant VAD patients (Holman *et al.*, 1999; El-Banayosy *et al.*, 1999a). The seriousness of the infection is largely related to its location. Infections of the blood-contacting interior surfaces of the VAD, confirmed at device explant, are associated with high rates of mortality (~50%). Infection may also contribute to embolic damage and death by the generation of septic emboli, or through enhancement of the thromboembolic process. Patient infections not directly related to the device are not as serious, with the exception of positive blood cultures, which may indicate interior VAD surface vegetations. As discussed in Chapter 4.8, there are distinct bacterial and fungal species that tend to infect biomaterial surfaces and often these infections include multiple organisms. In Fig. 6 the composition of infections in a recent multicenter study are presented in terms of the infected site. Common skin bacteria that are traditionally associated with biomaterial infections dominate the VAD-infecting strains.

Management of infection in patients can be accomplished to a reasonable degree with antibiotics and antifungal agents. It is fortunate that the patient population remains dominated by individuals awaiting device removal at the time of transplantation. Surprisingly, a history of infection during VAD support is not a counterindication for heart transplantation, and studies have shown that, despite the use of antirejection drugs in the posttransplant period, these patients do well (Argenziano *et al.*, 1997). For those patients with suspected infection of the interior VAD surfaces, it has been suggested that device replacement may be an effective method of treatment if transplant is not a short-term option (Argenziano *et al.*, 1997). In Fig. 7 a bioprosthetic inflow valve removed from a Novacor VAD patient suffering from a *Candida albicans* infection is seen. With the extent of this growth, alteration in pump function

FIG. 7. *Candida albicans* vegetations partially obstructing the inflow valve of a Novacor VAD patient at the time of valve replacement. (Kindly provided by R. L. Kormos, M. D., Director, and S. Winowich of the University of Pittsburgh Medical Center Mechanical Circulatory Support Program.)

was apparent and a procedure was performed to replace the infected valves. The patient recovered from this procedure and was successfully transplanted.

Prevention of infection is a primary goal during device implantation and later patient medical management. Prophylactic antibiotics and, in some instances, antifungal agents are utilized in the perioperative period. Careful cleaning and attention to the percutaneous driveline and cannula sites are also of primary importance. From a biomaterials perspective two important design issues arise. First, it is critical for the exterior surfaces of the drivelines and cannulas to rapidly encourage tissue healing and to discourage bacterial colonization. Second, the mechanical properties of the percutaneous lines are of relevance in that large mismatches in stiffness between the skin and lines places stress at the biomaterial-tissue interface. The resulting abrasion may prevent or retard adequate wound healing. The VAD design improvement most likely to affect infection rates will be the introduction of transcutaneous power transmission and control systems, and elimination of the percutaneous line. Systems involving this technology are currently undergoing animal testing (Weiss *et al.*, 1999) and, as of this writing, one device (the LionHeart VAD produced by Arrow International) has been implanted clinically for the first time in two patients

in Germany. Such devices should greatly reduce VAD-related infections and improve quality of life. The totally implantable VAD systems will be of particular interest in the permanent VAD setting.

Bleeding

Bleeding remains a potentially lethal complication associated with VAD implantation, but one that generally occurs in the early postoperative period, when numerous wound sites exist. Reported bleeding rates fall in the 30–35% range (McBride *et al.*, 1999; El-Banayosy *et al.*, 1999b). Bleeding can be defined in terms of the administration of blood products, chest tube drainage after surgery, or surgical interventions to treat hemorrhage. Subsequent trips to the operating room to address bleeding place patients at risk for bacterial and fungal colonization, linking this complication to infection risk. Also of concern in this patient population is the exposure and sensitization of transplant candidates to human antigens associated with blood products (Massad *et al.*, 1997). The use of leukocyte-filtered products has been utilized to address this latter concern.

A number of mechanisms contribute to hemorrhage in VAD patients. As mentioned previously, VAD implantation surgery

is associated with consumption and activation of patients' platelets and coagulation system, as well as activation of the fibrinolytic pathway (Livingston *et al.*, 1996). End-stage heart failure patients undergoing VAD implantation have deficiencies in coagulation factors even in the absence of obvious liver dysfunction (Wang *et al.*, 1995). After postoperative stabilization, Thoratec and Novacor patients are placed on chronic anticoagulation therapy, which carries an ongoing risk for over-anticoagulation (and possible bleeding). Of particular concern in the extended support setting are cerebral bleeds leading to neurologic complications. Anticoagulation in these VAD patients is thus carefully monitored throughout the implant period. To reduce the incidence of bleeding in the perioperative period, antifibrinolytic drugs, such as aprotinin, are now routinely utilized and have had marked effects in reducing blood loss and perioperative mortality (Goldstein *et al.*, 1995).

Mechanical Failure

In the extensive clinical experience with VADs over the past decade there have been very few reported incidents of mechanical failure related to material issues. This is likely due to the long development phases through which all three aforementioned FDA approved devices have passed. The pulsatile VAD systems subject internal diaphragms, cams, bearings, and springs to cyclic loads that would likely lead to more wear-associated failure were these devices asked to perform beyond their design specifications. In bridge-to-transplant implantations, bearing wear has been reported but has not led to catastrophic failure (Sun *et al.*, 1999). Other complications reported involve tearing of Dacron inflow conduits in the HeartMate device as seen in Fig. 8 (Scheld *et al.*, 1997). This complication was likely due to wear from the metal support cage rubbing on the graft surface, and the design has since been altered to constrain cage motion.

As pulsatile VADs move into the area of permanent support, it will be important to develop diagnostic techniques to noninvasively assess the wear process in implanted electrical and mechanical components. Acoustic and power consumption monitoring have been reported as innovative methods for evaluating wear in a patient with a permanent Novacor VAD on device support for more than 1000 days (Dohmen *et al.*, 1999). Durability and reliability testing *in vitro* will continue to be essential for discovering the typical time course of electromechanical failure modes and to provide the opportunity to develop such diagnostic methods. As an example of this, a report on *in vitro* reliability and durability testing with the Novacor VAD has demonstrated a single failure mode in test periods up to approximately 5 years (Lee *et al.*, 1999). This failure can be readily detected and may thus prevent unnecessary replacement of devices at fixed implant periods, while allowing detection of failure and remediation in those devices that may develop early signs of this wear. With knowledge of the failure mode engineers are provided a focal point to work on redesign of the device, leading to further improvements in long-term durability and reliability.

ROTARY BLOOD PUMPS FOR CHRONIC CIRCULATORY SUPPORT

In 1994 the National Heart, Lung and Blood Institute (NHLBI) issued a request for proposals (RFP) entitled, "Innovative Ventricular Assist Systems—IVAS" (NHLBI-HV-94-25). Some of the features desired in these innovative mechanical circulatory support devices were:

- Five year operation with 90% reliability
- Totally implantable with no external venting
- Size and weight characteristics suitable for implantation in both males and females between 18 and 70 years of age
- Demonstrated biocompatibility including avoidance of clinically significant thromboembolism, bleeding, tissue overgrowth, infection, tissue heating, and leakage of device fluids into surrounding tissues

FIG. 8. Ruptured Dacron inflow conduit of a HeartMate VAD that lead to sudden blood loss after 22 days of pump implantation. (Reprinted from H. H. Scheld, R. Soeparwata, C. Schmid, M. Loick, M. Weyand, and D. Hammel, *J. Thorac. Cardiovasc. Surg.* 114: 287–289, 1997.)

- Acceptably low levels of audible noise and mechanical vibration
- Flow capacity of 3–7 L/min against a mean arterial pressure of 90 mm Hg (when operating as a VAD in support of the left ventricle)
- Capability for transmission of energy from outside to inside the body, and diagnostics into and out of the implantable VAD

Of the six proposals funded by the National Institutes of Health in response to this RFP, three involved rotary pump designs. As discussed next, these pumps are fundamentally different from the VADs described earlier in this chapter.

Rotary blood pumps have a number of advantages over the VADs currently used clinically, which generate pulsatile flow. A continuous-flow pump requires no bladder to create a stroke volume comparable to the native ventricle; rather, flow is accomplished with an impeller, in either an axial-flow (straight through) or centrifugal (center to tangential edge) configuration. The rotary pumps are significantly smaller, have fewer moving parts, and are free from valves and cyclic actuators. This simplified design should lead to an increase in overall reliability and durability. Lower overall volumes of implanted materials will make these systems applicable to patients generally excluded from current implantable VADs, e.g., smaller women and children. Also, with the smaller pump size, less of a pocket needs to be created in the body for implantation and this may reduce bleeding and infection rates. Without valves and the compression of a pumping sac, the rotary pumps are also much quieter than current pulsatile-flow generating devices.

As noted above, for permanent circulatory support a fully implantable system is desirable to reduce infection risk and improve quality of life. Both pulsatile-flow VADs and rotary blood pumps can avoid the need for percutaneous power and control wires by utilizing transcutaneous energy transmission systems. With pulsatile bladder pumps such as the three VADs described earlier, another constraint arises regarding complete implantability. The air displaced in the compression and expansion of the pumping sac must shuttle to another location within the body. Current VADs address this need by venting air to and from the device through the percutaneous lines that also serve to supply power and control VAD operation. Completely implantable systems must utilize a compliance chamber that expands and contracts counter to the pumping sac. A number of concerns arise with the implantation of a compliance chamber intended for extended VAD support. First, the foreign-body response (as described in Chapter 4.2) ultimately leads to fibrotic tissue deposition around these sacs and inhibits elastic deformation. This elasticity change alters the forces involved in pump filling and emptying. Second, it is difficult to create polymers that simultaneously exhibit low gas permeability and high elasticity. Current compliance-chamber designs leak gas slowly across the compliance-chamber wall, which if not accounted for, would ultimately lead to altered blood filling and pumping in the VAD. To address this problem the compliance chamber is periodically refilled with gas every 4–6 weeks through a subcutaneous infusion port (Weiss *et al.*, 1999).

By their mode of operation, rotary blood pumps do not require a compliance chamber.

Although free from some of the shortcomings of VADs that generate pulsatile flow, rotary pumps introduce some unique biocompatibility concerns. The high revolutions per minute (RPM) required of rotors to generate flows in these pumps (~5000–10,000 RPM) subjects blood to high shear stresses not encountered physiologically. Although these stresses are of very short duration, concerns arise regarding hemolysis and platelet activation due to this exposure. Biocompatibility testing with rotary blood pumps invariably involves assessment of hemolytic indices, evaluation of thrombotic deposition, and, in animal studies, assessment of potential end-organ embolic damage. To minimize shear-related effects fluid flow over turbine-blade designs is often visualized or modeled in an effort to minimize regions of flow turbulence or stagnation (Kerrigan *et al.*, 1996; Burgreen *et al.*, 1999). A second flow-related concern regards the reduced pulsatility of blood flow that occurs when a continuous-flow, rotary pump is connected to empty the left ventricle and pump blood to the aorta. The chronic effects of diminished pulsatility on long-term patient health are not known, although the use of continuous-flow pumps for cardiopulmonary bypass and acute circulatory support have not led to major physiologic complications, and large-animal implants appear to tolerate this type of circulation for periods beyond 6 months. The current data on this topic have been reviewed by Jett (1999).

The mechanical requirements inherent in small rotary blood pumps have resulted in the selection of metals, primarily titanium alloys, as the material of choice for impellers, flow straighteners, and pump housings. In some current rotary systems inflow and outflow cannulas do not differ remarkably in design and materials selection from those used with current VADs, whereas in others the departure is significant, illustrated by designs wherein the pump is moved into the ventricle (Westaby *et al.*, 1998; Wampler *et al.*, 1999). Design and control concerns arise in association with the inflow orifice of rotary pumps. When ventricular pressures are reduced, the ventricular septum has the potential to be drawn into or around the inflow orifice, obstructing flow and potentially damaging the ventricular wall (Amin *et al.*, 1998). Such concerns do not arise with the passive-filling, pulsatile-flow-generating VADs currently used clinically.

The design of inflow and outflow pump bearings (which support the spinning rotor and resist axial and radial thrust loads) represents a major challenge for rotary blood-pump designers. The bearings used in this setting must effectively dissipate heat, exhibit acceptably low wear, support radial and axial loads, and be readily machined to very high tolerances. Bearing designs currently under investigation utilize magnetic suspension, blood lubrication, or lubrication provided by a purge fluid. Since sliding contact may occur during transients in pressure and flow, starts and stops, and unexpected patient acceleration and deceleration, it is important that bearing materials be wear-resistant. With blood or plasma contact, it is also important that these bearings exhibit appropriate blood biocompatibility. Current reported materials that have been evaluated for rotary pump bearings include zirconium–niobium alloy (Zr-2.5Nb) and titanium–zirconium–niobium

alloy (Ti-13Zr-13Nb), as well as carbon coating techniques (Golding *et al.*, 1998).

Rotary blood pumps currently in development include those described by Butler *et al.* (1997) seen in Fig. 9, DeBakey (1999) illustrated in cross-section in Fig. 10, Golding *et al.*

(1998), Wampler *et al.* (1999), and Westaby *et al.* (1998). One pump, the DeBakey VAD produced by MicroMed Technology (Houston, TX), has entered Phase I clinical trials in Europe. At the time of this writing the DeBakey VAD had been implanted in 18 patients with at least six recipients

supported for over 60 days. This VAD prototype is currently not completely implantable, having a percutaneous line for power transmission, pump monitoring, and speed (RPM) control. Implants to date have been for bridge to cardiac transplantation.

CONCLUSIONS

Major advances have occurred in mechanical circulatory support technology over the past three decades. Bridging patients to cardiac transplantation has now become routine with three devices currently approved by the FDA to fill this role in the United States. This success has set the stage for the application of VADs as alternatives to cardiac transplantation in the transplant-ineligible population. As one would expect with an extensive blood-contacting biomaterial implantation accompanied by percutaneous drivelines, thromboembolism, infection, and bleeding remain complications of primary concern in VAD patients. Completely implantable VADs and innovative rotary blood pumps may serve to reduce these complications and improve device durability and reliability. In the next decade the challenges associated with supporting patients for years, as opposed to months, will be faced. Biomaterial and biocompatibility issues will likely be central to the problems and solutions that arise as mechanical circulatory support devices continue to evolve.

Acknowledgments

The authors thank Dr. Robert L. Kormos, Director of the University of Pittsburgh Medical Center Mechanical Circulatory Support Program, for his expert guidance and innumerable insights on circulatory support issues, as well as the engineers and staff of this program for their assistance on this manuscript. Special thanks must be extended to our VAD patients and their loved ones who have always encouraged us to better understand the challenges and opportunities of implantable circulatory assist devices.

7.5 ARTIFICIAL RED BLOOD CELL SUBSTITUTES

Thomas Ming Sui Chang

INTRODUCTION

The potential presence of HIV in donor blood in the 1980s was the main stimulus leading to serious development of the idea of modified hemoglobin started many years ago (Chang, 1957, 1964, 1965; Bunn and Jandl, 1968). Much progress has been made in the past 10 years leading to the final phase of phase III clinical trials before routine clinical application. The present modified hemoglobin can replace the plasma component and red blood cell component of blood. However, it cannot replace the platelets or the leukocytes of blood. During this period, much experience has been gained and much has been learned (Chang, 1997a). This chapter is a brief overview of this very large area. The readers are referred to much detailed description in the references (Chang, 1997a, 2000, 2002), which is updated on the Web site (www.artcell.mcgill.ca).

HEMOGLOBIN

Hemoglobin is the protein in red blood cells that is responsible for the transport of oxygen from the lung to the other tissues. When hemoglobin is extracted from red blood cells, it can be ultrafiltered and sterilized to remove and inactivate bacteria, viruses and other microorganisms. Thus unlike red blood cells, potential problems related to HIV, hepatitis viruses, parasites, and others could be eliminated. However, hemoglobin extracted from red blood cells cannot be used as a blood substitute for the following reasons. Each hemoglobin molecule is a tetramer consisting of four subunits—two alpha subunits and two beta subunits (Perutz, 1980) (Fig. 1). There is a requirement for 2,3-diphosphoglycerate (2,3-DPG) to be present in the 2,3-DPG pocket of the hemoglobin molecule. This is to decrease the affinity of hemoglobin for oxygen, thus allowing it to release oxygen properly. When infused into the body, there is little or no 2,3-DPG in the plasma to bind to the 2,3-DPG pocket. This results in hemoglobin with high affinity for oxygen, preventing oxygen from being easily released as required to the tissue. What is even more of a problem is that when free in the circulating blood, each hemoglobin molecule breaks down into potentially toxic half-molecules, dimers. The dimers are highly toxic especially their renal toxicity (Savitsky *et al.*, 1978). There are also other problems related to hemoglobin in free solution. The challenge is therefore to modify the basic biomaterial, hemoglobin, before it can be used as a blood substitute.

FIG. 1. Inside the red blood cell, hemoglobin stays as a tetramer. The red blood cell membrane retains 2,3DPG in the cell to bind to hemoglobin. This allows hemoglobin to release oxygen as needed by the tissues with P_{50} of about 28 mm Hg. In 1957 Chang prepared artificial red blood cells by removing the red blood cell membrane and replacing it with artificial membrane. Reprinted with permission from Chang, T. M. S. (1992). *Biomaterials, Artificial Cells and Immobilization Biotechnology* 20: 154–174, courtesy of Marcel Dekker, Inc.

MODIFIED HEMOGLOBIN

Polyhemoglobin

The first modified hemoglobin was formed by removing the biological cell membranes of red blood cells and replacing them with artificial membranes (Fig. 1) (Chang, 1957, 1964, 1965). These early artificial red blood cells can readily bind and release oxygen since 2,3-DPG is retained inside the artificial cells (Chang, 1957). However, although they are about the same size as red blood cells, they are not sufficiently flexible to allow them to survive for a long time after infusion. A number of approaches were used to change the surface properties of these artificial red blood cells (Chang, 1964, 1965, 1972). This includes surface modification to result in changes in surface charge, surface composition and membrane composition. Since hemoglobin has many surface and internal amino groups, Chang (1964, 1965, 1972) studied the use of a bifunctional agent, sebacyl chloride, to cross-link hemoglobin molecules into a cross-linked hemoglobin artificial red blood cell membrane. By decreasing the diameter, all the hemoglobin in the artificial red blood cells could be cross-linked into polyhemoglobin (Fig. 2). The reaction is as follows:

In 1971, Chang reported the use of another bifunctional agent, glutaraldehyde, to cross-link hemoglobin and a red blood cell

FIG. 2. Cross-linking the hemoglobin molecules together prevents their breakdown into dimers. Following the use of sebacyl chloride (Chang, 1964, 1965) the same author reported (Chang, 1971) the use of glutaraldehyde as another cross-linker. Since then, many other investigators have extended and improved this, resulting in glutaraldehyde cross-linked polyhemoglobin, now in phase III clinical trial. Benesch uses pyridoxal phosphate to replace the 2,3-DPG required for human polyhemoglobin. Reprinted with permission from Chang, T. M. S. (1992). *Biomaterials, Artificial Cells and Immobilization Biotechnology* 20: 154–174, courtesy of Marcel Dekker, Inc.

enzyme, catalase, into soluble polyhemoglobin (Fig. 2). The reaction is as follows:

Cross-linking hemoglobin into soluble hemoglobin prevents the breakdown of hemoglobin into dimers. Furthermore, when infusing modified hemoglobin, their colloid osmotic pressure should normally be about the same as that of plasma proteins. This means that only about 7 g/dl of hemoglobin can be infused. Now, colloid osmotic pressure depends on the number of solute particles more than on the total amount of protein in solution. Polyhemoglobin is formed from the cross-linking of an average of four or five hemoglobin molecules together into a soluble macromolecular complex. This way, 15 g/dl of polyhemoglobin would have about the same colloid osmotic pressure as 7 g/dl of hemoglobin (Chang, 1997a). This means that a much larger amount of hemoglobin can be used when in the form of polyhemoglobin. However, there is no 2,3-DPG in the polyhemoglobin to allow them to have lower affinity for oxygen so that they can release oxygen to the tissue as required. Benesch *et al.* in 1975 made the important finding that the addition of a 2,3DPG analog, pyridoxal phosphate, to hemoglobin can also decrease oxygen affinity (Fig. 2). This is therefore added to cross-linked hemoglobin hemoglobin. The 1971 glutaraldehyde approach of Chang has been combined with Benesch's 1975 use of pyridoxal phosphate and developed into pyridoxalated human polyhemoglobin blood substitutes by Dudziak and Bonhard in 1976; Moss' group (Sehgal *et al.*) in 1980; DeVenuto and Zegna in 1982; and Chang's group (Keipert *et al.*) in 1982. The Northfield group of Gould *et al.* (1998) has developed this very extensively to its

present refined state. At present, Gould's group has completed phase II clinical trial and showed in control studies that this is effective in replacing blood loss in surgical patients. They are now in phase III clinical trial in trauma surgery using replacement of up to 10,000 ml which is equal to twice the total blood volume of a patient (Gould *et al.*, 1998). This approach has also been developed extensively by the Biopure group (Pearce and Gawryl, 1998) using bovine hemoglobin to form bovine polyhemoglobin. Since hemoglobin from cows does not need 2,3-DPG to decrease the affinity for oxygen, pyridoxal phosphate is not required. They have completed their phase II clinical trial in patients and have started phase III clinical trial using as much as 11,000 ml in individual patients'. Biopure's veterinary product has been approved by the FDA for routine use in canine veterinary medicine. Clinical trials on the Biopure Polyhemoglobin (Sprung *et al.*, 2002; LaMuraglia *et al.*, 2000) have led to its being approved for routine clinical uses in South Africa (Lok, 2001) and awaiting approval in the United States. Hsia (1991) originated a dialdehyde prepared from open ring sugars to form polyhemoglobin. This cross-linker also modified the 2,3-DPG pocket so that the resulting polyhemoglobin does not require 2,3-DPG or pyridoxal phosphate. This has been developed and extended by Hemosol (Adamson and Moore, 1998).

Other Types of Soluble Modified Hemoglobin

Bunn and Jandl (1968) cross-linked hemoglobin intramolecularly and found that this prevents the loss of hemoglobin through the kidney and serves to decrease renal toxicity. Walder *et al.* in 1979 reported the use of a 2,3-DPG pocket modifier, bis (3,5-dibromosalicyl) fumarate (DBBF) to intramolecularly cross-link the two α subunits of the hemoglobin molecule forming tetrameric hemoglobin. This prevents dimer formation and improves P_{50} . P_{50} is the ease with which oxyhemoglobin releases its oxygen and is measured by the oxygen tension at which 50% of the oxygen is released from oxyhemoglobin. Unlike polyhemoglobin, cross-linked tetrameric hemoglobin is a single hemoglobin molecule. Although its molecular weight is comparable to that of albumin, hemoglobin has much less surface negative charge. As a result, it can cross the intercellular junction of the endothelial cells lining the vasculature much more readily (Fig. 3). This may have resulted in the removal of nitric oxide. Nitric oxide decreases the contraction of smooth muscles including those in vasculature. This may explain the increase in esophageal and intestinal contraction and increase in blood pressure when using these types of cross-linked tetrameric hemoglobin. Baxter has extensively developed this (Nelson, 1998), but the results of their clinical trials have led them to discontinue this approach and to look at another approach.

Another very exciting area is the use of recombinant technology to produce recombinant human hemoglobin from *Escherichia coli* (Hoffman *et al.*, 1990). This results in the fusing of the alpha subunits of the hemoglobin molecule and preventing the breakdown of hemoglobin into dimers. Furthermore, this also resulted in the modification of the 2,3-DPG

FIG. 3. Different types of modified hemoglobin (Hb). Tetrameric Hb being smaller can move across the intercellular junction of the endothelial cells. This Hb binds nitric oxide (NO) in the interstitial space and lowers the NO concentration. This results in vasoconstriction. Other types of modified hemoglobin contain a varying amount of tetrameric hemoglobin that can also act similarly. Removal of these smaller tetrameric hemoglobin from polyhemoglobin, conjugated hemoglobin and microencapsulated hemoglobin would prevent this. Reprinted with permission from Chang, T. M. S. (1997). *Artificial Cells, Blood Substitutes and Immobilization Biotechnology* 25: 1–24. Courtesy of Marcel Dekker, Inc.

pocket in such a way that there is no requirement for 2,3-DPG or pyridoxal phosphate. This has been developed by Somatogen and used in a phase II clinical trial (Freytag and Templeton, 1997). Being a single tetrameric hemoglobin, it can also cause the same effect on smooth muscle as described above for cross-linked tetrameric hemoglobin. They have now prepared a new generation of recombinant human hemoglobin in which they have blocked the binding site for nitric oxide (Doherty *et al.*, 1998). The resulting recombinant human hemoglobin no longer causes vasoconstriction. This is being developed by Baxter toward a clinical trial.

Chang (1964, 1965, 1972) has used interfacial polymerization to form a conjugated membrane consisting of polyamides and hemoglobin around hemoglobin. By decreasing the diameter of the conjugated membrane, all the hemoglobin can be cross-linked with polymer into conjugated hemoglobin. Wong (1988) cross-linked hemoglobin to dextran to form soluble conjugated hemoglobin. A PEG-conjugated bovine hemoglobin is now in phase II clinical trial (Shorr *et al.*, 1996). A conjugated human hemoglobin (Iwashita *et al.*, 1996) is also in phase II clinical trial.

Molecular Weight Distribution

Molecular weight (MW) distribution varies widely among the different types of cross-linked hemoglobin blood substitutes (Chang, 1997a). For intramolecularly cross-linked hemoglobin or recombinant hemoglobin, they are in the tetrameric form with a molecular weight of about 68,000. In polyhemoglobin the molecular weight distribution can vary widely. In polyhemoglobin, the molecular weights follow a distribution curve from tetrameric to much larger molecular weight. Some groups use a larger mean molecular weight. Other groups prefer

using a smaller mean molecular weight. Those with lower mean molecular weight also have more tetrameric hemoglobin. Those with higher mean molecular weight have less tetrameric hemoglobin because of the higher degree of polymerization. The pyridoxalated polyhemoglobin prepared from our laboratory procedure can be used as an example. The molecular weight distribution can be varied at will by changing the reaction time, ratio of glutaraldehyde to hemoglobin, and other reaction parameters. To measure the MW distribution, pyridoxalated polyhemoglobin (PP-PolyHb) was run on Sephadex G-200 (1.6 × 70 cm column) in 0.1 M Tris-HCl (pH 7.5) at 12 ml/hr. The fractions of polymerized hemoglobin were in the molecular weight ranges of 750,000 (10%); 470,000 (23%); 260,000 (39%); 130,000 (21%); and 66,000 (7%). Thus, 60% falls in the 130,000–350,000 range and 33% ranges in molecular weight from 350,000 to 750,000. Only 7% was in the tetrameric form. Gould's group (1998) has emphasized the need to remove as much tetrameric hemoglobin as possible. After their preparation of polyhemoglobin, they carried out another step to remove much of the tetrameric hemoglobin resulting in a preparation with less than 1% hemoglobin in the 68,000 MW range. Biopure has also removed much of the tetrameric hemoglobin resulting in preparation with less than 5% 68,000 MW hemoglobin (Pearce and Gawryl, 1998). These two preparations do not cause vasoconstriction or smooth muscle contraction because insignificant amounts of tetrameric hemoglobin crossing the endothelial cell junctions (Fig. 3).

In Vitro Biocompatibility Screening Test Using Human Plasma/Blood

Detailed *in vitro* and *in vivo* tests are required by the FDA before approval of using the blood substitutes for clinical trials (Fratantoni, 1991). However, even when the blood substitute is shown safe in animals, the response in animals is not always the same as for humans. This is especially true in tests for hypersensitivity, complement activation, and immunology. How do we bridge the gap between animal safety studies and use in humans? Complement activation is important in many adverse reactions of humans to modified hemoglobin (Chang and Lister, 1990, 1993a, b, 1994). Modified hemoglobin may be contaminated with trace amounts of blood-group antigen that can form antigen–antibody complexes. Other materials can potentially cause complement activation. These include endotoxin, microorganisms, insoluble immune complexes, chemicals, polymers, organic solvents, and others.

We have devised an *in vitro* test tube screening test using human plasma or blood (Chang and Lister, 1990, 1993a, b, 1994). The use of human plasma or blood gives the closest response to human testing next to actual injection. If we want to be more specific, we can use the plasma of the same patient who is to receive the blood substitute. Many components of human blood or plasma can be used for this *in vitro* screening test. If one were to select only one test, perhaps the most useful one would be the effect of modified hemoglobin on complement activation (C3a) when added to human plasma or blood. This simple test consists of adding 0.1 ml of modified

TABLE 1 Screening Test Based on Complement Activation (Chang and Lister, 1990, 1993a, b, 1994)

- 1 Immediately before use, the plasma sample is thawed.
- 2 400 μ l of the plasma is pipetted into 4-ml sterile polypropylene tubes.
- 3 100 μ l of pyrogen-free saline (or Ringer's lactate) for injection is added to the 400 μ l of human plasma as control; 100 μ l of hemoglobin or modified hemoglobin is added to each of the other tubes containing 400 μ l of human plasma.
- 4 The reaction mixtures are incubated at 37°C at 60 RPM for 1 hour in a Lab-Line Orbit Environ Shaker (Fisher Scientific, Montreal, Canada).
- 5 After 1 hour the reaction is quenched by adding 0.4 ml of this solution into a 2 ml EDTA sterile tube containing 1.6 ml of sterile saline.
- 6 The samples are immediately stored at -70°C until analysis.
- 7 The analytical kit for human complement C3a is purchased from Amersham Canada. The method of analysis is the same as the instructions in the kit with two minor modifications. Centrifugation is carried out at 10,000 *g* for 20 min. After the final step of inversion, the inside wall of the tubes is carefully blotted with Q-Tips.

hemoglobin to a test tube containing 0.4 ml of human plasma or blood. Then, the plasma is analyzed for complement activation after incubation for 1 hour. Blood preparation is described in Table 1.

Blood is obtained by clean venous puncture from human volunteers into 50-ml polypropylene (Sastedt) heparinized tubes (10 IU heparin/ml of blood). Immediately separate plasma by centrifugation at 5500 *G* at 2°C for 20 min and freeze the plasma in separate portions at -70°C. Do not use serum because coagulation initiates complement activation. EDTA should not be used as an anticoagulant, because it interferes with complement activation.

The exact procedure and precise timing described in Table 1 are important in obtaining reproducible results. The baseline control level of C3a complement activation will vary with the source and procedure for obtaining the plasma. Therefore, a control baseline level must be used for each analysis. Furthermore, all control and test studies should be carried out in triplicate. Much practice is needed to establish this procedure when used for the first time. Reproducibility must be established before this test can be used.

Instead of using plasma and the need to withdraw blood with a syringe, a simpler procedure involves obtaining blood from finger pricks (Chang and Lister, 1993a). Sterile methods are used to prick a finger. Blood is collected in heparinized microhematocrit tubes. The tubes are kept at 4°C, then used immediately. Each blood sample used in testing contains 80 μ l of whole blood and 20 μ l of saline. Each test solution is added to a blood sample. Test solutions include saline (negative control); Zymosan (positive control); or hemoglobin. This is incubated at 37°C at 60 rpm. After 1 hour of incubation, EDTA solution is added to the sample to stop the reaction. The analysis for C3a is then carried out as described. The test kit is based on the ELISA C3a enzyme immunoassay (Quidel Co., San Diego).

In research, development, or industrial production of blood substitute, different chemicals, reagents, and organic solvents are used. This includes cross-linkers, lipids, solvents, chemicals, polymers, and other materials. Some of these can potentially result in complement activation and other reactions in humans. Other potential sources of problems include trace contaminants from ultrafilters, dialyzers, and chromatography. The test described in Table 1 is a simple *in vitro* test based on using human plasma or blood. For example, this screening test can detect several problems related to potential hypersensitivity reactions, and anaphylactic reactions, effects due to antibody-antigen complexes, and others. These potential problems may be related to contamination with trace blood group antigens, polymeric extracts, organic solvents, emulsifiers, and others. This is useful for preclinical trial studies and for screening before clinical use. This is also useful for screening batches of modified hemoglobin blood substitutes for industrial production to rule out potential problems. It is also useful in research and development. What is very exciting is that this approach may be the basis of a large-scale *in vitro* "clinical trial" in a large number of patients without infusing the product. By doing this, we can analyze the percentage of patients who may have adverse reactions without having to introduce the product into patients. Of course, ultimately, human clinical trials are required.

Second-Generation Modified Hemoglobin Blood Substitutes

The present, first-generation blood substitutes described above are effective for short-term uses especially in elective surgery (Winslow, 1996; Chang, 1997a). On the other hand, these first-generation blood substitutes can stay in the body's circulation only for about 12-24 hours (a typical red blood cell lasts about 100 days). Thus, their present role is restricted to short-term applications. For example, substitutes are being tested in humans for replacing blood lost during some cardiac, cancer, orthopedic, and trauma surgeries. Furthermore, new generations of blood substitutes may be needed for other conditions such as sustained severe hemorrhagic shock, stroke, or other conditions with sustained ischemia (low oxygen). When oxygen from blood substitute is reperfused to ischemic organs or tissues, oxygen radicals will be produced (Fig. 4). The present generation of blood substitutes do not have the enzymes needed to protect the body against oxidants such as oxygen radicals. Unchecked, oxygen radicals may cause reperfusion injuries and other problems (Alayash *et al.*, 1998). Furthermore, peroxide formed can break down hemoglobin resulting in further increase in oxygen radicals (Fenton reaction). Researchers are studying ways to solve this problem, including cross-linking the required enzymes to the hemoglobin or further modifying the molecular structure of the hemoglobin. For example, we have reported the cross-linking of superoxide dismutase (SOD) and catalase to hemoglobin to result in polyhemoglobin-catalase-SOD (Fig. 4) (D'Agnillo and Chang, 1998a,b; Chang *et al.*, 1998). In a rat intestinal ischemia-reperfusion model, we showed that polyhemoglobin-catalase-SOD can markedly decrease the level

FIG. 4. Ischemic reperfusion injuries. Ischemia leads to accumulation of hypoxanthine and activation of xanthine oxidase. Reperfusion bringing oxygen results in superoxide formation. This and other resulting oxidants and oxygen radicals can cause tissue injury. First-generation modified hemoglobin is prepared from ultrapure hemoglobin and therefore does not contain the required deoxidant enzymes. We showed that cross-linking polyhemoglobin with superoxide dismutase and catalase can significantly decrease the formation of oxygen radicals (D'Agnillo and Chang, 1998). Reprinted with permission from Chang, T. M. S. (1997). *Artificial Cells, Blood Substitutes and Immobilization Biotechnology* 25: 1–24. Courtesy of Marcel Dekker, Inc.

of oxygen radicals when using polyhemoglobin with the cross-linked enzymes (Razack *et al.*, 1997). Unlike polyhemoglobin, cross-linked polyhemoglobin–superoxide dismutase–catalase supplies oxygen without causing blood–brain barrier disruption or brain edema in a rat model of transient global brain ischemia–reperfusion (Powanda and Chang, 2002).

Third-Generation Blood Substitutes

Second-generation substitutes, like the first-generation blood substitutes, only circulate with a half-time of 12–24 hours. They are therefore more suitable for shorter term applications. Furthermore, the hemoglobin molecules will not be protected by a red blood cell membrane and highly purified hemoglobin is needed. Thus, researchers are working on more complicated, third-generation blood substitutes that will encapsulate hemoglobin and the required enzymes inside artificial red blood cells. Encapsulated hemoglobin is the first modified hemoglobin studied (Fig. 1) (Chang, 1957, 1964, 1972), but being more complicated, it has only been seriously developed more recently. One method is to encapsulate hemoglobin inside lipid vesicles about 0.2 μm in diameter (Djordjevich and Miller, 1980; Rudolph *et al.*, 1997; Tsuchida, 1995). This technique also increases the circulation time. A more recent approach is to use nanotechnology methods to encapsulate hemoglobin and enzymes inside biodegradable polylactic acid membrane nanocapsules some 0.15 μm in diameter (Yu and Chang, 1996; Chang and Yu, 1997, 1998) (Fig. 5). Nano-dimension artificial red blood cells with ultrathin membranes of PEG-PLA [poly(ethylene glycol)–polylactide] copolymer stay in the circulation twice as long as polyhemoglobin (Chang and Yu, 2001).

PERFLUORO-CHEMICALS

Introduction

Silicone and fluorocarbon are known for their ability to carry oxygen. Thus, Clark and Gollan (1966) showed that mice immersed in oxygenated silicone oil or liquid fluorocarbon could breathe in the liquid. In the same year, Chang (1966) showed that artificial cells formed from a hybrid of silicone rubber and hemolysate were very efficient in carrying and releasing oxygen. However, these solid elastic silicone-rubber artificial cells were removed rapidly from the circulation. Sloviter and Kamimoto (1967) showed that perfusion using finely emulsified fluorocarbon could maintain rat brain function for several hours. Geyer *et al.* (1968) showed that finely emulsified fluorocarbon could replace essentially all the blood of rats with the rats surviving and recovering. This was extended and developed in Japan to produce Fluosol-DA 20 suitable for clinical testing (Naito and Yokoyama, 1976; Mitsuno and Naito, 1979).

Earlier Perfluorocarbons: Fluosol-DA

Fluosol-DA is a 20% (w/v) mixture of seven parts of perfluorodecalin and three parts perfluorotripropylamine, with 2.7% Pluronic F-68 as an emulsifier and 0.4% egg yolk phospholipids to form a membrane coating on the emulsion. The average particle size of the emulsion is 0.118 μm . Because of the viscosity of the fluorocarbon emulsion at high concentrations, the maximum amount used is only 20%. Patients have to breathe 70% to 90% oxygen for this amount of fluosol-DA to carry enough oxygen. The amount of oxygen dissolved in fluorocarbon determines the amount of available oxygen. When oxygen is increased to 70–90% from the atmospheric oxygen of 20%, more oxygen is dissolved in the fluorocarbon. CO_2 also dissolves in the fluorocarbon, which carries it to the lung for elimination.

Mitsuno and Ohyanagi (1985) reviewed the Japanese experience with 401 patients who received Fluosol-DA (20%).

Complement activation was the major clinical problem. Adverse effects were observed in some patients due to complement activation caused by the Pluronic surfactant used in Fluosol. The FDA approved the clinical use of Fluosol-DA only for coronary artery balloon angioplasties in 1989.

Modern Perfluorochemicals

Modern perfluorochemicals been discussed in detail (Riess, 1998; Keipert, 1998). Two new types of preparations have been developed. One type is based on perfluorooctyl bromide ($C_8F_{17}Br$) and perfluorodichlorooctane ($C_8F_{16}Cl_2$). Both types allow the use of higher concentrations of PFC. Oxygent from Alliance Pharmaceutical Corp., San Diego, is prepared from perfluorooctyl bromide ($C_8F_{17}Br$) with egg yolk lecithin as the surfactant. The use of egg yolk lecithin instead of Pluronic surfactant has solved the problem of complement activation. Another approach, Oxyfluor from HemoGen, St. Louis, is based on the use of perfluorodichlorooctane ($C_8F_{16}Cl_2$) with triglyceride and egg yolk lecithin.

Safety clinical trials using Oxygent shows that doses up to 1.8 g PFC/kg could be given without side effects (Keipert, 1998). Further increase in dosages may result in transient mild febrile response (38–39°C), a transient decrease in platelets. Oxygent is being used in phase II clinical trials in surgical patients. The use of 0.9 g/kg of Oxygent can avoid the need for 2 units of blood. This is also being combined with autologous blood transfusion in which about 1000 ml of each patient's blood is removed and stored before surgery. During surgery, Oxygent is given as needed. After surgery, the patient's blood is reinfused. There are several other potential applications for perfluorochemicals. One of the most important potential use is in patients who because of religious beliefs cannot use red blood cells or hemoglobin from animal sources.

GENERAL DISCUSSION

The basic ideas of cross-linked hemoglobin and encapsulated hemoglobin date back to before the 1960s. Concentrated efforts to develop blood substitutes for human use only seriously started after 1986 because of public concerns regarding HIV in donor blood. Unfortunately, a product must undergo years of research and development followed by clinical trials before it is ready for use in patients. It will take at least another one to two years for the first generation blood substitutes to be available for routine use. Had there been a serious development effort in the 1960s, blood substitutes would have already been available in 1986. As it is, the public has continued to be exposed to the potential, though extremely rare, hazard of HIV in donor blood. It is hoped that investigators will have the chance to develop new generations of blood substitutes discussed here long before another urgent need arrives. The principle of artificial cells has also been developed for other areas of medical applications including enzyme therapy, cell therapy, and other applications (Chang, 1997b; Chang and Prakash, 1998, 2001) (www.artcell.mcgill.ca).

7.6 EXTRACORPOREAL ARTIFICIAL ORGANS

Paul S. Malchesky

Historically, the term “extracorporeal artificial organs” has been reserved for life-support techniques requiring the on-line processing of blood outside the patient’s body. The substitution, support, or replacement of organ functions is performed when the need is only temporary or intermittent support may be sufficient. The category of extracorporeal artificial organs does not include various other techniques that may justifiably be considered as such, such as infusion pumps or dermal patches for drug delivery, artificial hearts used extracorporeally, eyeglasses and contact lenses for vision, and orthotic devices and manipulators operated by neural signals to control motion.

This chapter focuses on artificial organ technologies that perform mass-transfer operations to support failing or impaired organ systems. The discussion begins with the oldest and most widely employed kidney substitute, hemodialysis, and outlines other renal assist systems such as hemofiltration for the treatment of chronic renal failure and fluid overload and peritoneal dialysis. The blood treatment process of hemoperfusion, and apheresis technologies, which include plasma exchange, plasma treatment, and cytoapheresis—used to treat metabolic and immunologic diseases—are also discussed. In addition, blood-gas exchangers, as required for heart–lung bypass procedures, and bioartificial devices that employ living tissue in an extracorporeal circuit are addressed. Significant concerns and associated technological considerations regarding these technologies, including blood access, anticoagulation, the effects of the extracorporeal circulation, including blood cell and humoral changes, and the biomodulation effects of the procedure and materials of blood contact are also briefly discussed.

KIDNEY ASSIST

The kidney’s function is to maintain the chemical and water balance of the body by removing waste materials from the

FIG. 1. Schematic representation of the nephron.

blood. The kidneys do this by sophisticated mechanisms of filtration and active and passive transport that take place within the nephron, the single major functioning unit in the kidney, of which there are about 1 million per kidney (Fig. 1). In the glomerulus, the blood entry portion of the nephron, a blood filtration process occurs in which solutes up to 60,000 Da are filtered. As this filtrate passes through the nephron’s tubule system, its composition is adjusted to the exact chemical requirements of the individual’s body to produce urine. In addition to these functions, the kidneys support various other physiological processes by performing secretory functions that aid red blood cell production, bone metabolism, and blood-pressure control. Renal failure occurs when the kidneys are damaged to the extent that they can no longer function to detoxify the body. The failure may be acute or chronic. In chronic renal failure or in the absence of a successful transplant, the patient must be maintained on dialysis.

Dialysis

Dialysis is the process of separating substances in solution by means of their unequal diffusion through a semipermeable membrane. The essentials for dialysis are (1) a solution containing the substance to be removed (blood); (2) a semipermeable membrane permeable to the substances to be removed and impermeable to substances to be retained (synthetic membrane

in hemodialysis or the peritoneal membrane in peritoneal dialysis); and (3) the solution to which the permeable substances are to be transferred (dialysate).

The device containing the semipermeable membrane is called a dialyzer. Hemodialysis is performed on the majority (over 85%) of the patients while peritoneal dialysis is used for the rest.

Hemodialysis

Hemodialysis is the dialysis of blood. More than 300,000 patients in the United States and more than one million worldwide undergo hemodialysis typically three times a week, totaling more than 150 million treatments per year. The patient's blood is typically anticoagulated with heparin throughout the extracorporeal treatment, although other drugs may be used. Blood access is usually from a permanent fistula (a surgical connection between artery and vein) made in the patient's forearm. The blood is drawn from the body at a flow rate of 50 to about 500 ml/min, depending on patient conditions and procedural requirements, and then pumped with a roller pump through the extracorporeal circuit that includes the dialyzer. The transport process of water, electrolytes, and simple metabolites between the blood and the dialysate takes place in the dialyzer (Fig. 2A). The dialysate is a water solution of electrolytes of about the same concentration as normal plasma.

The membranes used, which initially were primarily cellulose, are now various synthetic membranes, including polyacrylonitrile, poly(methyl methacrylate), ethyl vinyl alcohol, and polysulfone. The membranes permit the low-molecular-weight solutes (typically less than about 5000 Da) such as

urea, creatinine, uric acid, electrolytes, and water to pass freely, but prevent the passage of high-molecular-weight proteins and blood cellular elements. However, some membranes utilized will pass appreciable amounts of solutes of a greater molecular weight (below about 20,000 Da) and with high rates of water transport. Such membranes are called high-flux membranes.

The stimulus for the introduction of synthetic membranes has primarily come from the need to improve biocompatibility. The term "biocompatibility" is loosely defined and generally refers to the response and effects of blood contact with the material. However, the influence of the flow, the properties of the blood, the choice of anticoagulant, and the dialyzer design and its method of sterilization may also be important. Major indices of biocompatibility studied include variations in blood coagulation, blood cell changes, variations in platelet and leukocyte activation, and complement system activation. Different membranes elicit different responses. The degree of the response is related also to the surface area of blood contact.

Most dialyzers in use are of the hollow-fiber design, employing hollow-fiber membranes. Also available are parallel-plate designs employing sheet membrane films. Many variations of these basic designs are commercially available. Generally, blood and dialysate flow in opposite directions (countercurrent).

Water is removed in hemodialysis primarily by ultrafiltration. Convective flux of water and associated solutes takes place under a hydraulic pressure gradient between the blood and the dialysate compartments. The functions of the dialysate delivery system are to prepare and deliver dialysate of the required chemical makeup for use in the hemodialyzer. Monitoring and control equipment is included as part of the system to ensure that the dialysate composition is correct and ready for use by the hemodialyzer and that the procedure is carried out in a safe manner.

Methods of preparing and delivering dialysate are either batch or continuous. In a continuous dialysate-supply system, concentrate and processed tap water (filtered to remove particulates, ions, and organic matter) are continuously mixed during the course of the dialysis and delivered to the dialyzer. This type of system eliminates the space required for mixing an entire batch of dialysate. However, to be effective, the system must be closely controlled, since any malfunction can result in an improperly mixed dialysate. Dialysate can be recirculated in the dialyzer, although fresh dialysate is most effective because it produces a high concentration gradient with the blood and therefore a high removal rate for solutes. In a single-pass system, the flow of dialysate is usually kept low (about 500 ml/min) to limit the amount required.

Dialysate delivery systems also include monitoring, control, and safety equipment. These systems range from the use of simple components to automated systems capable of operating without an attendant. Equipment includes flow meters, temperature and pressure monitors, dialysate-conductivity probes, and display meters. Control equipment includes thermostat-controlled heaters and mixing valves for regulating dialysate temperatures and composition, valves for regulating flow rates and patient fluid loss, and adjustable high and low limits on various safety and monitoring devices. Water conditioning and treatment equipment is usually available separately

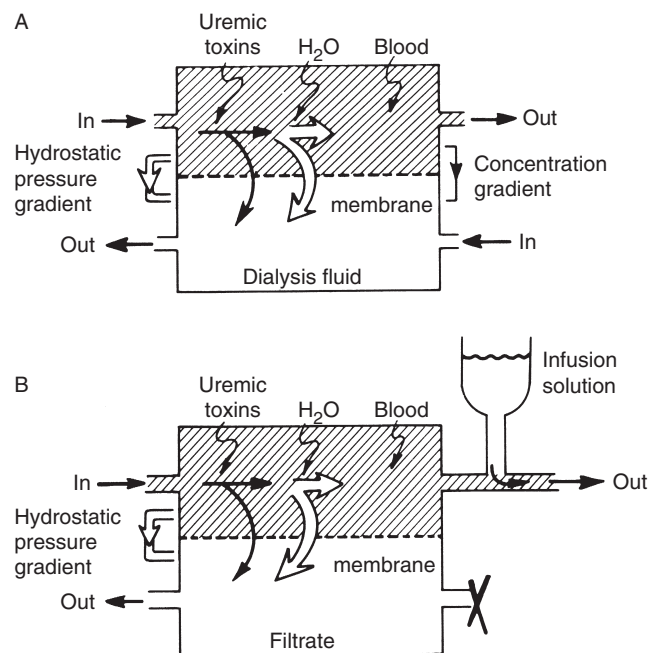

FIG. 2. Comparative operation principles in (A) hemodialysis and (B) hemofiltration with postfiltration addition of fluid.

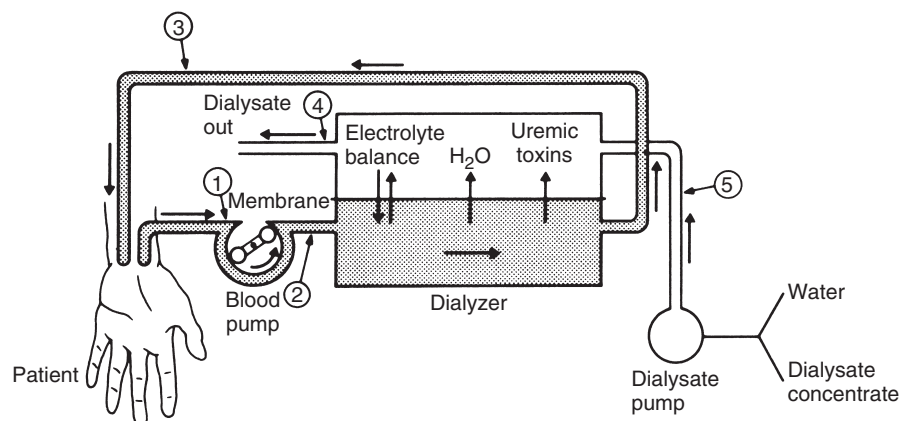

FIG. 3. Schematic of hemodialysis circuitry with on-line dialysate preparation. Numbered locations refer to instrumentation listed in Table 1.

from the dialysate delivery system. Safety equipment includes devices designed to indicate or correct any factor in dialysis that exceeds the established limits for safe operation. This equipment includes audio and/or visual alarms and failsafe shutdown sequences that would be employed during the course of dialysis. Present-day equipment allows one nurse to oversee several dialysis stations at one time.

Hemodialysis is generally performed for periods of 3–5 hours, three times a week. Hemodialysis may be performed in the hospital, in a dialysis center, or at home. Equipment requirements vary, depending upon where and by whom the dialysis is performed. Figure 3 schematically shows the circuitry with on-line dialysate preparation, and Table 1 outlines the most common factors monitored during hemodialysis with reference to the site of monitoring shown in Fig. 3. Portable or wearable systems have also been developed.

Peritoneal Dialysis

Peritoneal dialysis is carried out in the peritoneal cavity of the patient. The peritoneum is a thin membrane lining the abdominal cavity and covering the abdominal organs. It forms a closed sac. Through a cannula placed through the skin or a catheter permanently implanted, dialysate solution (about 2 liters in an adult) is infused, allowed to dwell for a designated time period, and drained. This process is repeated according to the needs of the patient. This semipermeable membrane permits transfer of solutes from the blood to the dialysate.

The efficiency of the process is strongly dependent upon the blood flow through the peritoneal membrane; the permeability of the peritoneal membrane; and the dialysate conditions of flow, volume, temperature, and net concentration gradient. Peritoneal dialysis may be performed intermittently or continuously.

The low volume of dialysate, the low degree of agitation of the dialysate in the peritoneal cavity, and blood flow dynamics in the peritoneum contribute to a lower efficiency for small solute transfer than hemodialysis. Thus, peritoneal dialysis requires longer treatment times than does hemodialysis.

In intermittent peritoneal dialysis, a single cycle for dialysate solution infusion, dwell, and drainage is generally

accomplished in less than 30 min and the procedure continued for 8 to 12 hours per treatment (Fig. 4). Dialysate is available in commercially prepared bags or bottles or can be made on site, as in hemodialysis, from dialysate concentrate and water. Additional precautions must be taken with its preparation in comparison with the dialysate used in hemodialysis because of the sterility requirement for infusion of the dialyzing solution into the body. Monitoring and control equipment for the preparation and delivery of the dialyzing fluid is generally automated and capable of operating without an attendant: it includes automatic timers, pumps, electrically operated valves, thermostat-controlled heaters, conductivity meter, and alarms.

In the more popular form of peritoneal dialysis referred to as continuous ambulatory peritoneal dialysis (CAPD), the infused dialysate is allowed to reside for only a few hours. Generally, five to six exchanges are made per day. The difference between this technique and that of intermittent peritoneal dialysis and hemodialysis is that body chemistries are more stable and not fluctuating between the extremes of the pre- and postdialysis periods.

In peritoneal dialysis, the hydraulic pressure difference between the blood and dialysate is insufficient to cause any appreciable water removal so osmotic forces are utilized. The necessary osmotic gradient between the blood and dialysate is achieved by utilizing high concentrations of dextrose in the dialysate. Typically, solutions containing 1.5 to 4.5% dextrose are used.

An advantage of peritoneal dialysis over hemodialysis is that direct blood contact with foreign surfaces is not required, eliminating the need for anticoagulation. A disadvantage includes the increased risk of peritonitis. Less than 15% of the U.S. patients with chronic renal failure are supported by peritoneal dialysis.

Hemofiltration

Hemofiltration refers to the removal of fluid from whole blood. Solute and water are removed strictly by convective flux. The standard hemodialysis membrane, however, is a poor reproduction of the filtration properties of the nephron's

TABLE 1 Factors Most Commonly Monitored during Hemodialysis

Factor	Equipment position (see Fig. 3)	Operation	Remarks
Extracorporeal blood pressure	1, 2, and/or 3	Measure pressure in drip chambers by mechanical or electronic manometer; abnormal pressure indicates any one of several malfunctions (increased line resistance, clotting, blood leak) and has high and low alarm limits	Installation in location 3 is considered mandatory and provides most meaningful information with respect to changes in flow (such as due to clots) or bloodline leak
Blood-leak detector	4	Photoelectric pickups in effluent dialysate line detect optical transmission changes due to presence of blood	Detection threshold is adjustable with alarm circuit to shut off blood pump or bypass the dialysate flow
Dialysate pressure	5 and/or 4	Measures pressure of dialysate inlet and/or outlet by mechanical or electronic manometer; usually has high and low alarm limit; abnormal operation can result in membrane rupture or improper ultrafiltration	Transmembrane pressure may be displayed with possible control of blood-side pressure
Dialysate temperature	5	Thermostatic measurement generally used to control electric heaters; dial thermometer or thermocouple gauge readout; out-of-range operation can result in patient discomfort or fatal blood damage	In central dialysate delivery system, the dialysate is centrally heated with trimming at individual stations
Dialysate flow rate	5	Measures and displays flow in a rotameter; unless extremely low, cannot result in undue harm to patient	Dialysate is normally used at a rate of 500 ml/min
Dialysate concentration	4 and 5	Flow differential is used to determine patient fluid loss and ultrafiltration rate	Ultrafiltration control is particularly important with the use of high-flux dialyzers
	5	Measures and displays electric conductivity of dialysate; improper concentration can result in blood cell and central nervous system damage	Continuous concentration measurement is a necessity in delivery systems using continuous proportioning of dialysate
Air trap and air bubble detector	3	Collects air prior to blood return to patient; if air is detected, clamp is activated to stop flow to patient	Mandatory

**FIG. 4.** Schematic of intermittent peritoneal dialysis with on-site dialysate preparation.

glomerulus. The standard hemodialysis membrane can separate from the blood solutes that are typically less than about 5000 Da. In an effort to make the process more like that of the natural glomerulus and to duplicate the process in the natural kidney, membranes of higher permeability (complete passage of solutes less than about 50,000 Da and more typically less than 20,000 Da) have been developed. In addition to their applicability for dialysis under controlled ultrafiltration conditions (referred to as high flux dialysis), such membranes have also found use as ultrafilters of fluid from blood. Membranes used for hemofiltration therapy are made of polysulfone, polyacrylonitrile, poly(methyl methacrylate), poly(ether sulfone), polyamide, and the cellulose.

Hemofiltration was originally designed for treating chronic renal failure by removing a substantial fraction of fluid and reconstituting blood by adding fluid either before or after filtration (Fig. 2B). Owing to the high physiological sensitivity to changes in circulatory volume, very sensitive monitoring and control equipment for fluid withdrawal and infusion must be

FIG. 5. Circuitry for sorbents or reactor (enzymatic, cellular, or tissue) hemoperfusion.

used to maintain the fluid flow balance accurately, as required for net removal of fluid from the patients. Only a few centers in the world are investigating this technique for treating chronic renal failure.

Modes of hemofiltration applications include continuous arteriovenous hemofiltration (CAVH), continuous venovenous hemofiltration (CVVH), or slow continuous ultrafiltration (SCUF). In these extracorporeal procedures, the patient's blood, under the driving force of arterial pressure (CAVH), or by an extracorporeal pump (CVVH), passes through a low-resistance device (typically of hollow-fiber design) and then is returned to the patient. Under force of the hydraulic resistance and aided by applied vacuum pressure if necessary on the filtrate side, fluid (ultrafiltrate) is removed from the blood. CAVH, CVVH, or SCUF is used to treat acute renal failure and fluid overload, particularly in critically ill patients who are in renal failure and require fluids, as in the form of parenteral nutrition. To enhance the solute transfer, the circuit may be modified to include the pumping of dialysate. This technique is referred to as hemodiafiltration. A further application of hemofiltration is the on-line removal of excess fluid during extracorporeal heart-lung bypass.

Hemoperfusion

Hemoperfusion refers to the direct perfusion of blood. In general, it refers to the perfusion of whole blood over a sorbent or reactor and therefore is different in this respect from hemodialysis (Fig. 5). In principle, the sorbent or reactor may consist of a wide variety of agents such as activated charcoal, nonionic or ionic resins, immunosorbents, enzymes, cells, or tissue. The purpose of biologically active agents may be to remove specific toxins from the blood or to carry out specific biochemical reactions. For practical reasons, such as biocompatibility concerns, hemoperfusion has been limited to the use of a small number of sorbents such as activated charcoal or resins in the treatment of drug intoxication or hepatic support.

The sorption of solute from the blood is based primarily upon its chemical affinity for the sorbents and less on its molecular size. The surface area for sorption may be as high as hundreds of square meters per gram of sorbent.

The use of hemoperfusion is limited primarily by biocompatibility concerns, including particulate release from the sorbent or reactor system. Sorbent and reactor systems are also applied to plasma perfusion (see the next section).

APHERESIS

Apheresis¹ refers to a procedure of separating and removing one or more of the various components of blood. This procedure can be used either therapeutically to remove cells or solutes that are considered harmful, or to obtain plasma or blood cells from normal donors. The procedure is referred to as plasmapheresis when plasma is separated and removed from the whole blood. If the plasma is discarded and replaced with donor plasma or a protein solution, the process is referred to as plasma exchange. If the separated plasma is processed and returned to the patient, the process is referred to as plasma treatment. Cytapheresis refers to the removal of cells and includes various types: leukocytapheresis, which involves the separation and removal of white blood cells; lymphocytapheresis, in which the lymphocytes are removed; erythrocytapheresis, in which the red blood cells are removed; and thrombocytapheresis, in which the platelets are removed.

Plasma Exchange

Plasma is routinely separated from whole blood in the medical laboratory and clinics. Millions of liters of plasma are collected annually in the United States for transfusion

¹Definitions taken from Report of the Nomenclature Committee in Plasma Separation and Plasma Fractionation, M. J. Lysaght and H. J. Gurland, eds., Karger, Basel, pp. 331–334.

and the production of plasma products. Therapeutic plasma replacement or on-line plasma treatment has been applied in a number of disease states, including renal, hematological, neurological, autoimmune, rheumatological, and hepatic. Plasma exchange is now a recognized therapy in selected disease states and is being investigated in many others. Traditionally, plasma separation has been carried out by centrifugal techniques. However, within the past decades, membrane devices have been used increasingly in therapeutic and bulk plasma collection. In centrifugal separation, the difference in density between blood cells and plasma is exploited. In membrane separation, the plasma is separated from the blood cells by the application of a low (typically less than 50 mm Hg) transmembrane pressure gradient across a microporous membrane permeable to all plasma components and impermeable to blood cells.

A number of membrane materials in the flat-film and hollow-fiber configuration have been utilized, including polyethylene, polypropylene, cellulose diacetate, poly(methyl methacrylate), polysulfone, poly(vinyl chloride), poly(vinyl alcohol), and polycarbonate. The membranes are of the tortuous path type and differ significantly in their physical properties such as porosity, mean pore size and its distribution, and pore number. Differences in the chemical nature of the membranes affect the amount and types of proteins that are deposited on the membrane surface. Such differences in protein adsorption can affect the filtration and biocompatibility properties of the membranes. Extensive filtration studies with bloods of various species and varying compositions show that membranes of different polymer types and varying microstructures have different plasma separation rates. Plasma separation efficiency for all membrane or module designs correlates with blood shear rate. Biocompatibility considerations similar to those used in assessing hemodialysis apply.

In therapeutic plasmapheresis, the separated plasma is discarded and replaced with an oncotic plasma substitute such as albumin solution or fresh-frozen plasma. Plasma exchange has several limitations, including the reliance on plasma products, reactions or contaminations (particularly viral) caused by plasma product infusion, and loss of essential plasma components.

Centrifugal Plasma Separation

The centrifugal separation of plasma from blood is schematically depicted in Figs. 6 and 7. As the blood volume is rotated, the contents of the fluid exert a centrifugal force outward to the walls. Since the density of the blood particulate components, the cells, is higher than that of the plasma medium, sedimentation of the cells occurs outwardly through the plasma. The centrifugal acceleration exceeds that of gravity by a factor of a thousand.

For particle settling in the Stokes' law range (Reynolds number is less than 1 for most blood centrifugal processes) the terminal velocity, V_t , at a radial distance, r , from the center of rotation is:

$$V_t = \frac{\omega^2 r D_p^2 (\rho_p - \rho)}{18\mu},$$

FIG. 6. Plasma separation in a test tube placed in a centrifugal field. The centrifugal separation of plasma from whole blood results in generally three distinct layers: the plasma, the buffy coat consisting of platelets and white blood cells, and the packed red cell layer.

FIG. 7. Continuous plasma separation in a rotating bowl. The blood components are continuously or discontinuously ported off. Several commercial systems are available for clinical use.

where ω , is the angular velocity, D_p is the particle diameter, ρ_p the particle density, ρ the liquid density, and μ the liquid viscosity. This basic formula serves as the theoretical foundation for investigations of the phenomena of the centrifugal separation of particulate matter from the suspending fluid. Corrections to this equation for the nonspherical nature of blood cells and the effects of cell concentration have been proposed by various authors and serve as a basis of continued investigations of this process.

Blood is a complex mixture consisting of plasma, plasma solutes in a broad range of sizes, and cells of varying densities

TABLE 2 Comparison of Cell Properties

	Normal concentration in blood	Cell diameter (μm)	Mean density (g/ml)	Sedimentation coefficient ($S \times 10^7$)
Red blood cell	$4.2\text{--}6.2 \times 10^{12}/\text{liter}$	8	1.098 (1.095–1.101)	12.0
White blood cell	$4.0\text{--}11.0 \times 10^9/\text{liter}$			
Lymphocyte	$1.5\text{--}3.5 \times 10^9/\text{liter}$	7–18	1.072 (1.055–1.095)	1.2
Granulocyte	$2.5\text{--}8.0 \times 10^9/\text{liter}$	10–15	1.082	
Monocyte	$0.2\text{--}0.8 \times 10^9/\text{liter}$	12–20	1.062	
Platelet	$150\text{--}400 \times 10^9/\text{liter}$	2–4	1.058	0.032
Plasma	—	—	1.027 (1.024–1.030)

and sizes (Table 2). When blood is allowed to sit in a tube or is centrifuged, the higher density red blood cells will settle to the bottom of the tube first, followed by the white blood cells and platelets (which are of intermediate density between the red cells and the plasma). Based on the sedimentation coefficients, the order of separation is red cell > white cell > platelet. For centrifugal speeds that are nondestructive to the cells, no appreciable separation of the individual plasma constituents occurs (proteins, amino acids, electrolytes). The high sedimentation rate of red cells is related to their ability to aggregate, forming rouleaux. With rouleaux formation, the effective cell diameter increases, augmenting the settling rate (see equation).

Table 3 lists the operational parameters and blood properties that affect the sedimentation rate of blood cells and that therefore dictate the plasma separation rate. From an operational point of view, the force produced during centrifugation is proportional to the radial distance of blood in the centrifugal field and the square of the angular velocity, or revolutionary rate, of the centrifugal apparatus. Whole-blood flow rates in and component flow rates out, which will determine cell residence times (and therefore particle radial travel), establish the degree of separation between the various cell groups in a given centrifugal design.

In clinical operation, visual inspection or optical sensors are employed to select component pumping rates. For specific collection purposes, two or more separation steps may

**FIG. 8.** Plasma separation from blood by a membrane. Based upon the membrane pore structure and operating conditions, the plasma is separated free of cells. Membranes of differing polymer types have been developed for clinical applications.

be employed. For example, the buffy coat is drawn from the whole blood and subjected to a second centrifugal separation or another process that concentrates specific white blood-cell types. In the preparation of blood cells for transfusion, further processing by filtration means may be necessary to purify the cell preparations (see Cytapheresis).

Owing to the varying densities and sedimentation velocities of the blood cells in routine operation of clinical centrifuges, a distinct separation of the cell types from plasma is not achieved. Thus in routine plasma collection, the plasma contains cells, most typically platelets.

Membrane Plasma Separation

Membrane separation of plasma is schematically shown in Fig. 8. Under low hydraulic transmembrane pressures, the plasma is separated. With the fine pore-size membranes employed, the cells do not pass; thus the separated plasma is devoid of any cells. Plasma solute removal, as assessed by

its sieving coefficient (ratio of the concentration in the separated plasma to the concentration in the plasma entering the separator), has been shown to be near complete for all macromolecular weight solutes (albumin, immunoglobulins, lipids) of clinical interest. It has been shown that exceeding the safe limits of blood and plasma flow rates and transmembrane pressure leads to deterioration of plasma flux and solute sieving and may cause hemolysis. In comparison with other membrane filtration processes such as reverse osmosis, dialysis, and ultrafiltration, the separation fluid flux ($\text{ml}/\text{min}\cdot\text{m}^{-2}$) and solute sieving rates are high for membrane plasma separation. This is due to the membrane styles employed. Such microporous membranes have relatively high porosities and high mean membrane pore diameters. Studies have also shown that the cellular and macromolecule concentrations of the blood will to a significant extent dictate operational limits of the membrane plasma separation process. Thus in the control of the process, membrane and module properties, blood properties, and operating conditions should be considered (Table 4).

Conventional filtration theories have been applied to the use of membranes to separate plasma from blood with only limited success. With increasing amounts of data collected on modules and membranes of varying properties, the theories have had to be modified to improve experimental correlations.

Operation of a hollow-fiber membrane plasma separation system is shown in Fig. 9. This schematic may be used to depict the control necessary for operation of membrane systems. For a given membrane or module design, and operation with a blood of given specification (cell and solute concentrations), it has been determined from studies on multiple types of membrane units that a unique relationship exists among the plasma flow and the transmembrane pressure for a given membrane type. Exceeding specified plasma flows causes the transmembrane pressure to rise unsteadily and the plasma

flux to decline (Fig. 10). The plasma flux–transmembrane pressure relationship has been found to be highly dependent on module design and membrane properties, blood flow and membrane properties, blood flow conditions, and blood properties. It is recognized that membrane polymer type and module sterilization method influence the degree of complement activation, coagulation, and solute–material interactions (such as adsorption) that occur at the membrane–plasma interface and that can influence the net pore size of the membrane during use. However, there is no evidence to suggest that the membrane chemical composition directly influences filtration.

Plasma separation is controlled through the blood and plasma flow rates (Fig. 9). The maximum value of the transmembrane pressure ($P_i - P_F$) is an indicator of the stability of the plasma separation process, and the feedback control for the blood and plasma pumps. The value of ($P_i - P_F$) is generally

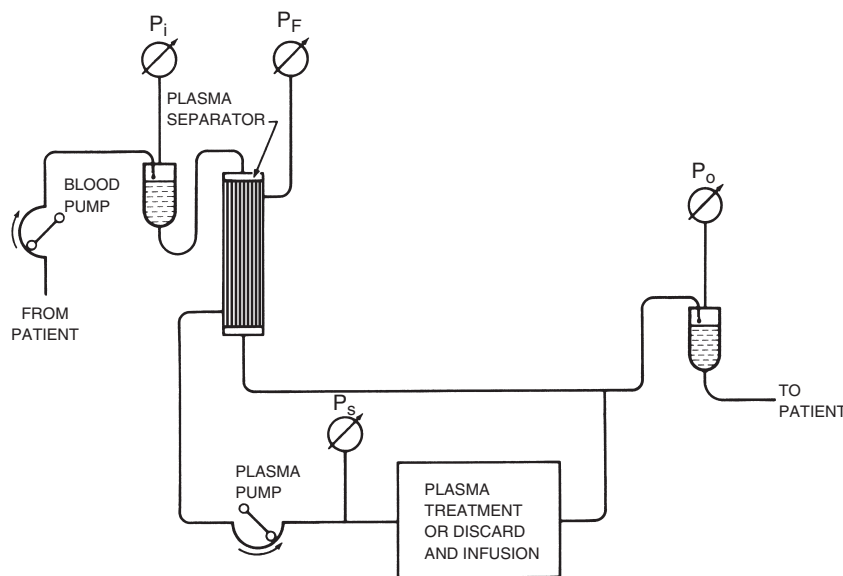

FIG. 9. Scheme of operation with a hollow-fiber membrane plasma separator.

FIG. 10. *In vitro* test with bovine blood of a poly(vinyl alcohol) hollow-fiber plasma separator. Note that sieving for macromolecules is close to unity and that plasma flow below a given value (in this case, 40 ml/min) shows stability with respect to the transmembrane pressure. Unstable plasma separation is readily noted by the rising transmembrane pressure when the plasma flow is increased above 40 ml/min.

a more sensitive indicator than the mean transmembrane pressure $(P_i + P_o)/2 - P_F$ because P_o may be monitored at a point downstream that will cause a significant difference between the mean and maximum values. As shown in Fig. 10, when the maximum allowable plasma flow rate is exceeded, the transmembrane pressure will rise and not stabilize. This has been shown to be the case for all membrane modules evaluated.

Increases in transmembrane pressure with increases in plasma flow in the stable transmembrane pressure region have been shown to depend on the membrane microstructures (pore size and pore number). An unstable operation is recognizable when the maximum transmembrane pressure does not stabilize with time for a given constant plasma flow. The plasma separation rate can be controlled manually or automatically through the transmembrane pressure change, or by preselecting a maximum operating transmembrane pressure.

The pore properties of the membranes employed for plasma separation are too small to pass even the smallest of the blood cells, the platelet, at operating conditions for which the plasma separation rate is stable. A plasma product devoid of particulate is deemed more desirable when on-line treatment of the plasma is carried out since the particulate may be interfering with the on-line treatment processes. Furthermore, the separation of cellular elements with plasma may result in biological systemic reactions. On-line treatment systems being

employed at present include membrane filtration, sorption, and processing by enzyme and biological reactors.

Plasma Treatment

The rationale for therapeutically applying plasmapheresis is that the removal from plasma of macromolecules accumulated in a disease will correct the abnormality. For plasmapheresis techniques to be effective, the macromolecules must be accessible through the circulation and exhibit favorable kinetics with respect to their rates of production and intercompartmental transfer (tissue, or interstitial, to plasma). In theory, plasma exchange can remove all solutes and achieve a postexchange solute concentration that is dependent on the initial solute concentration, the patient's plasma volume, and rate of plasma exchange as described by the equation:

$$C_f = C_i \exp(-Q_p t / V),$$

where C_f is the postexchange solute concentration, C_i is the initial plasma solute concentration, Q_p is the mean plasma exchange flow rate for the treatment time period t , or $Q_p t$ is the volume exchange per treatment period, and V is the patient's plasma volume (one-compartment model).

Plasma exchange is carried out when the specific factors in the plasma to be removed are not known or a specific technique for their selective removal is not available, or a group of solutes are to be removed and exchange is the simplest technique to be employed. However, plasma exchange has certain limitations. Since a large volume of plasma is discarded, many plasma constituents that are important to maintain homeostasis are discarded. This necessitates reliance on plasma products to replace the discarded plasma. Typically, albumin is used to replace the discarded plasma but in some cases whole plasma or other plasma fractions such as immunoglobulins are required. Annually, 12–14 million liters of plasma are collected in the United States, yet in recent years there has been a critical shortage of albumin, thus placing limits on its use. In addition to the limited supply of plasma product, the products are a potential source of contamination.

Schemes of plasma treatments that would remove specific plasma factors, minimize total volume and mass of plasma solutes removed, and eliminate or minimize the need for replacement protein solution could be particularly beneficial and more cost effective. A number of systems for on-line treatment have been developed. These are generally classified into their broad categories: membrane plasma fractionation, plasma sorption, and other physicochemical methods.

Membrane Plasma Filtration

Membrane filtration is the technique by which plasma is filtered through single or multiple membranes following its separation from the blood. The principle of macromolecule solute removal from plasma by membrane filtration is based on solute size differences. Molecules that are smaller than the pores of the membrane pass through, whereas molecules larger than the size of the pores are retained by the membrane.

The membranes used for plasma filtration are of the microporous types, with permeability and pore sizes typically much larger than those of the standard hemodialysis membranes, and smaller than those of the plasma separation membranes. Most membranes available have a broad range of pore sizes and therefore produce plasma solute separation efficiencies that are a function of the membrane media and the conditions of operation. Separation efficiency may be defined in terms of sieving coefficient (SC) or rejection coefficient (R) where $R = 1 - SC$. Sieving coefficient is calculated as the ratio of the concentration of the solute in filtrate to that in the incoming plasma. A sieving coefficient of 1 means the solute passes completely; a sieving coefficient of 0 means the solute is completely rejected and therefore retained by the membrane. Most macromolecular-weight plasma solutes have sieving coefficients between these extremes.

On-line membrane plasma fractionation techniques can be classified according to the temperature range of their separation, namely: (1) cascade (double) filtration (filtration at ambient temperature); (2) cryofiltration (filtration below physiological temperature); and (3) thermofiltration (filtration at or above physiological temperature). These techniques have been developed and used in clinical plasma therapy. The temperature and membrane chosen for various procedures are dependent on the targeted macromolecules to be removed. For instance, cryofiltration is used in treating disease states associated with cold-aggregating serum solutes. Thermofiltration has been used to selectively remove low-density lipoproteins (LDLs) in hyperlipidemic patients.

Sorption Plasma Fractionation

Sorption methods have been developed and used in plasma therapy to selectively remove pathological solutes to eliminate the need for substitution fluids. As in membrane plasma fractionation, the procedure involves the separation of plasma followed by perfusion through a sorbent column. Following treatment, the plasma is mixed with the concentrated cell fraction from the plasma separator and returned to the patient. Over the past two decades the development and use of sorbents in hemoperfusion or on-line plasma perfusion has been applied in treating drug overdose, uremia, liver insufficiency, autoimmune disorders, and familial hypercholesterolemia. Table 5 outlines the sorbents evaluated. Only a limited number of sorbents have reached clinical use.

Other Physicochemical Methods

Plasma fractionation may also be carried out by other methods. For example, on-line precipitation of LDL or the globulin fraction of plasma has been studied. Convective electrophoresis has also been investigated for protein separation.

Cytapheresis

Cytapheresis is most commonly performed by centrifugation (see the section on centrifugal plasma separation). The

most common application of cytappheresis has been in the treatment of leukemia by leukocytapheresis. Lymphocytapheresis has been investigated in a number of autoimmune disorders, including rheumatoid arthritis and renal allograft rejection. Erythrocytapheresis has been employed in sickle-cell anemia and severe parasitemia such as malaria. Thrombocytapheresis has been used to treat patients whose platelet concentrations are greater than 1×10^{12} /liter.

In addition to the centrifugal technique, filters have been developed specifically for the removal of leukocytes and lymphocytes. It has been shown that granulocytes adhere to various kinds of fibers such as nylon or cotton. Acrylic and polyester fibers have been found to bind granulocytes and lymphocytes. In such procedures, the blood is generally perfused on-line through a device containing the fibers. Several liters of blood may be processed over a couple of hours. The adhesion of cells to the fiber materials is related to the diameter of the fiber. Fiber devices are also used in blood collections to reduce certain cell populations. Specific adsorbent materials and magnetic separation techniques are also being developed to more specifically separate and collect cells.

A unique white blood cell treatment scheme referred to as photopheresis is now clinically available. In photopheresis, patients are orally administered the drug methoxypsoralen. The drug enters the nucleus of the white blood cells and

weakly binds to the DNA. Blood is drawn, centrifugation is carried out, and the separated plasma and the lymphocytes are combined and exposed to ultraviolet A light. The photoactivated drug is locked across the DNA helix and blocks its replication. After the irradiation, this fraction is combined with the remainder of the blood and reinfused. The technique is used to treat skin manifestations of cutaneous T-cell lymphoma.

LUNG SUBSTITUTES AND ASSIST

The lungs are the body's interface with the air. They provide the means of getting oxygen into the blood and carbon dioxide out. The lungs perform their transport processes via a membrane that separates the air from the blood. As the blood cells deform to pass through the intricate and very fine capillary network, oxygen and carbon dioxide transport occur through the membrane. Failure of the lungs or their inability to carry out these functions requires artificial respiratory support in the form of mechanical assistance or substitution.

A ventilator provides mechanical assistance in breathing. It can be of two types, volume or pressure controlled. The cycling of the ventilator may be controlled and in most cases ventilators are set to operate continuously and independently of the patient's inspiratory efforts.

Artificial lungs are of two general types: direct blood contacting and membrane. Direct blood contacting devices may be of two types: bubble or film. In bubble-type oxygenators, oxygen gas is bubbled through the blood. The large surface area of the bubbles and their intimate contact with blood promote high gas-transport rates. Since the blood cells can be damaged by the mixing action, this type is restricted to short-term use for routine cardiac surgery. In film-type oxygenators, the gas contacts the blood, which is spread or distributed in

films. These devices generally incorporate a mechanical mixing device so that the blood film is continually renewed. Since such complex devices are not made in disposable form, they are no longer employed clinically.

In membrane oxygenators, the blood and gas are separated by a membrane. The membrane may be of two types, diffusion (as silicone rubber) or microporous (as polypropylene), and may be in the form of film or hollow fibers. Combination-type membranes (thinly coated microporous membrane) are also available. Such membranes are designed to reduce water vapor transfer and improve biocompatibility. In hollow-fiber devices, the blood flow may be on the inside or outside of the fiber. In membrane oxygenators, the gas transport is similar to that in the natural lungs where a thin tissue layer separates the blood and gas. Damage to blood in membrane oxygenators is generally considered to be less than in direct-contacting devices. This allows them to be used for extended periods of time, even up to several weeks as in extracorporeal membrane oxygenation (ECMO) used in lung disorders, such as acute respiratory distress syndrome (ARDS), carbon dioxide retention, and in particular, ARDS caused by immature lung development in the newborn. Such extended uses are rare at present.

More than 500,000 open heart surgery procedures are performed each year worldwide and these procedures require a blood-gas exchanger or so-called artificial lung or oxygenator. Membrane oxygenators are used predominantly for routine cardiopulmonary bypass. In open-heart surgery, the oxygenator is used in conjunction with a pump ("heart-lung machine") as shown in Fig. 11. Membrane oxygenators are also used in organ preservation to provide oxygen and remove carbon dioxide from the perfusate circulated through the organ.

Most recent has been the investigation of membrane oxygenators as intravascular devices. When placed in the vascular system, such devices can provide partial support.

FIG. 11. Circuitry for heart-lung bypass.

BIOARTIFICIAL DEVICES

Because of the limitations of mechanical and passive mass transport devices, there is a growing interest in the development of hybrid artificial organ technologies. Hybrid artificial organs combine some form of biological material and nonbiological material to make a substitution or assist an organ system. The biological system may consist of enzymes or cells that carry out the biological and chemical functions absent or destroyed in the diseased organ system. The nonbiological material is used to encapsulate or enable the utilization of the biological material. Such applications typically involve the use of membranes. Two areas of investigation involve hepatic (liver) and pancreatic assist.

The liver is a complex organ, often referred to as the body's chemical factory. Its many functions can be classified as secretion of bile; metabolism of proteins, fats, and carbohydrates; detoxification of drugs and metabolites; and storage of vital substances such as iron and vitamins. Under certain clinical conditions the liver may regenerate itself in a short span of time, thereby making assist systems practical. However, substitution for the required metabolic support is not possible with present knowledge. The culturing of hepatic cells or the use of liver cells or tissue in membrane modules that permit extracorporeal perfusion but prevent direct blood-to-hepatic-cell contact is being experimentally investigated. The membrane may provide a means for containing the cells; ensure the transport of oxygen, carbon dioxide, nutrients, and cell products; and provide a barrier against immunologic interactions between the cells or tissue and the patient. Because of this last concern, membranes with a molecular weight below about 70,000 Da and typically below 50,000 Da are employed.

A major function of the pancreas is the secretion of insulin by its beta cells in the islet tissue in response to glucose increases in the blood. The lack of such control leads to diabetes.

In addition to mechanical and chemical modes of insulin delivery, efforts are directed at transplanting islet cells. Because of the immunologic-related problems discussed earlier, macroencapsulation (as in semipermeable hollow-fiber membranes) or microencapsulation of islets within thin semipermeable films is being investigated. Such systems may be implanted or used outside the body.

IMPORTANT AREAS OF CONCERN IN DEVELOPMENT OF EXTRACORPOREAL ARTIFICIAL ORGANS

Significant progress has been made and applications not considered possible have become reality; however, the field of extracorporeal artificial organs is still considered to be in its infancy. For example, chronic hemodialysis has only been possible since 1960. At present, all extracorporeal applications require the use of anticoagulants. Although efforts are being expanded to develop materials and coatings that will not require anticoagulation, few practical applications are possible at present. By design, extracorporeal artificial organs are invasive; blood access in many cases limits carrying out the procedures safely and effectively.

Extracorporeal artificial organs require the use of varied types of materials in contact with whole blood or plasma cells. Blood-materials interactions, through generally of only intermittent and short duration, can greatly affect various physiological systems, including the complement and coagulation cascades and the humoral and cellular immunological systems. While investigations point to changes and disturbances in such systems, the short- and long-term impacts are not known. The effects of a procedure may extend beyond the treatment times.

Since the systems are applied in a variety of disease states, the effects are also clouded by the variables related to the clinical situation (concomitant drug therapy, stage of the disease, type of disease, and frequency and duration of the treatment). An extracorporeal artificial organ should not be viewed in engineering analysis as a black box but must be viewed as actively interacting with the physiological system. Therapeutic applications tend not to be tailored to the needs of the patients. Hemodialysis is commonly prescribed without quantitation of the procedure. The question of adequacy is still debated. The prescription requirements for other extracorporeal therapies are even more vague and there are no markers or guidelines to assess adequacy and efficacy. Even so, dialysis for renal assist and some of the other technologies discussed are viewed as mature developments and generally taken for granted.

Transplantation benefits only a small percentage of those patients with chronic renal failure. Dialysis continues to support the large majority of patients, yet research on this technique or on improved technologies is poorly funded. Optimization of the devices used for extracorporeal therapies and processes is rarely achieved. These problems point to the need for a better understanding of the machine-human interface.

Regulatory requirements for new devices have considerably increased the time from concept to clinical application through marketing. Reimbursement issues on new technologies also greatly affect the research and development cycles. Concerns about animal research and the relationship of animal testing to the clinical situation also affect the development cycle.

The move to the development of hybrid organs emphasizes the lack of knowledge on organ system design as well as the lack of technology to substitute for the organ functions, and the need to make technologies more user friendly. Studies on organ substitution have been made possible by progress in such technologies as biomaterials and separation science. Developments in such fields will advance the science of and applications of extracorporeal artificial organs. This field is challenging. With a better understanding of the functions of the body, it holds promise for providing organ substitutes not only in end organ failure or as a bridge to transplantation, but also prophylactically.

7.7 ORTHOPEDIC APPLICATIONS

Nadim James Hallab, Joshua J. Jacobs,
and J. Lawrence Katz

Orthopedic biomaterials are enormously successful in restoring mobility and quality of life to millions of individuals each year. Orthopedic implants include reconstructive implants, fracture management products, spinal products, rehabilitation products, arthroscopy products, electrical stimulation products, and casting products. These products are generally used for either fracture fixation or joint replacement. More specific orthopedic applications within these two categories are listed below.

1. Fracture fixation devices

- Spinal fixation devices
- Fracture plates
- Wires, pins and screws
- Intramedullary devices
- Artificial ligaments

2. Joint replacement (Fig. 1)

- Hip arthroplasty
- Knee arthroplasty
- Ankle arthroplasty
- Shoulder arthroplasty
- Elbow arthroplasty
- Wrist arthroplasty
- Finger arthroplasty

Orthopedic Biomaterials Market

The overwhelming success of orthopedic biomaterials is perhaps best exemplified by their worldwide market, which dominated biomaterial sales at approximately \$14 billion in 2002 with an expected growth rate of 7% to 9% annually. Global sales of fracture management products only totaled approximately \$1.5 billion in 2000, whereas the other approximately \$12 billion was spent on joint replacements (Fig. 1). Global sales of knee implant products equaled approximately \$2.5 billion in 2002, representing approximately 700,000 knee replacement surgeries, which include first-time joint replacement procedures and revision procedures for replacement, repair, or enhancement of an implant product or component from a previous procedure. Revision procedures are growing at

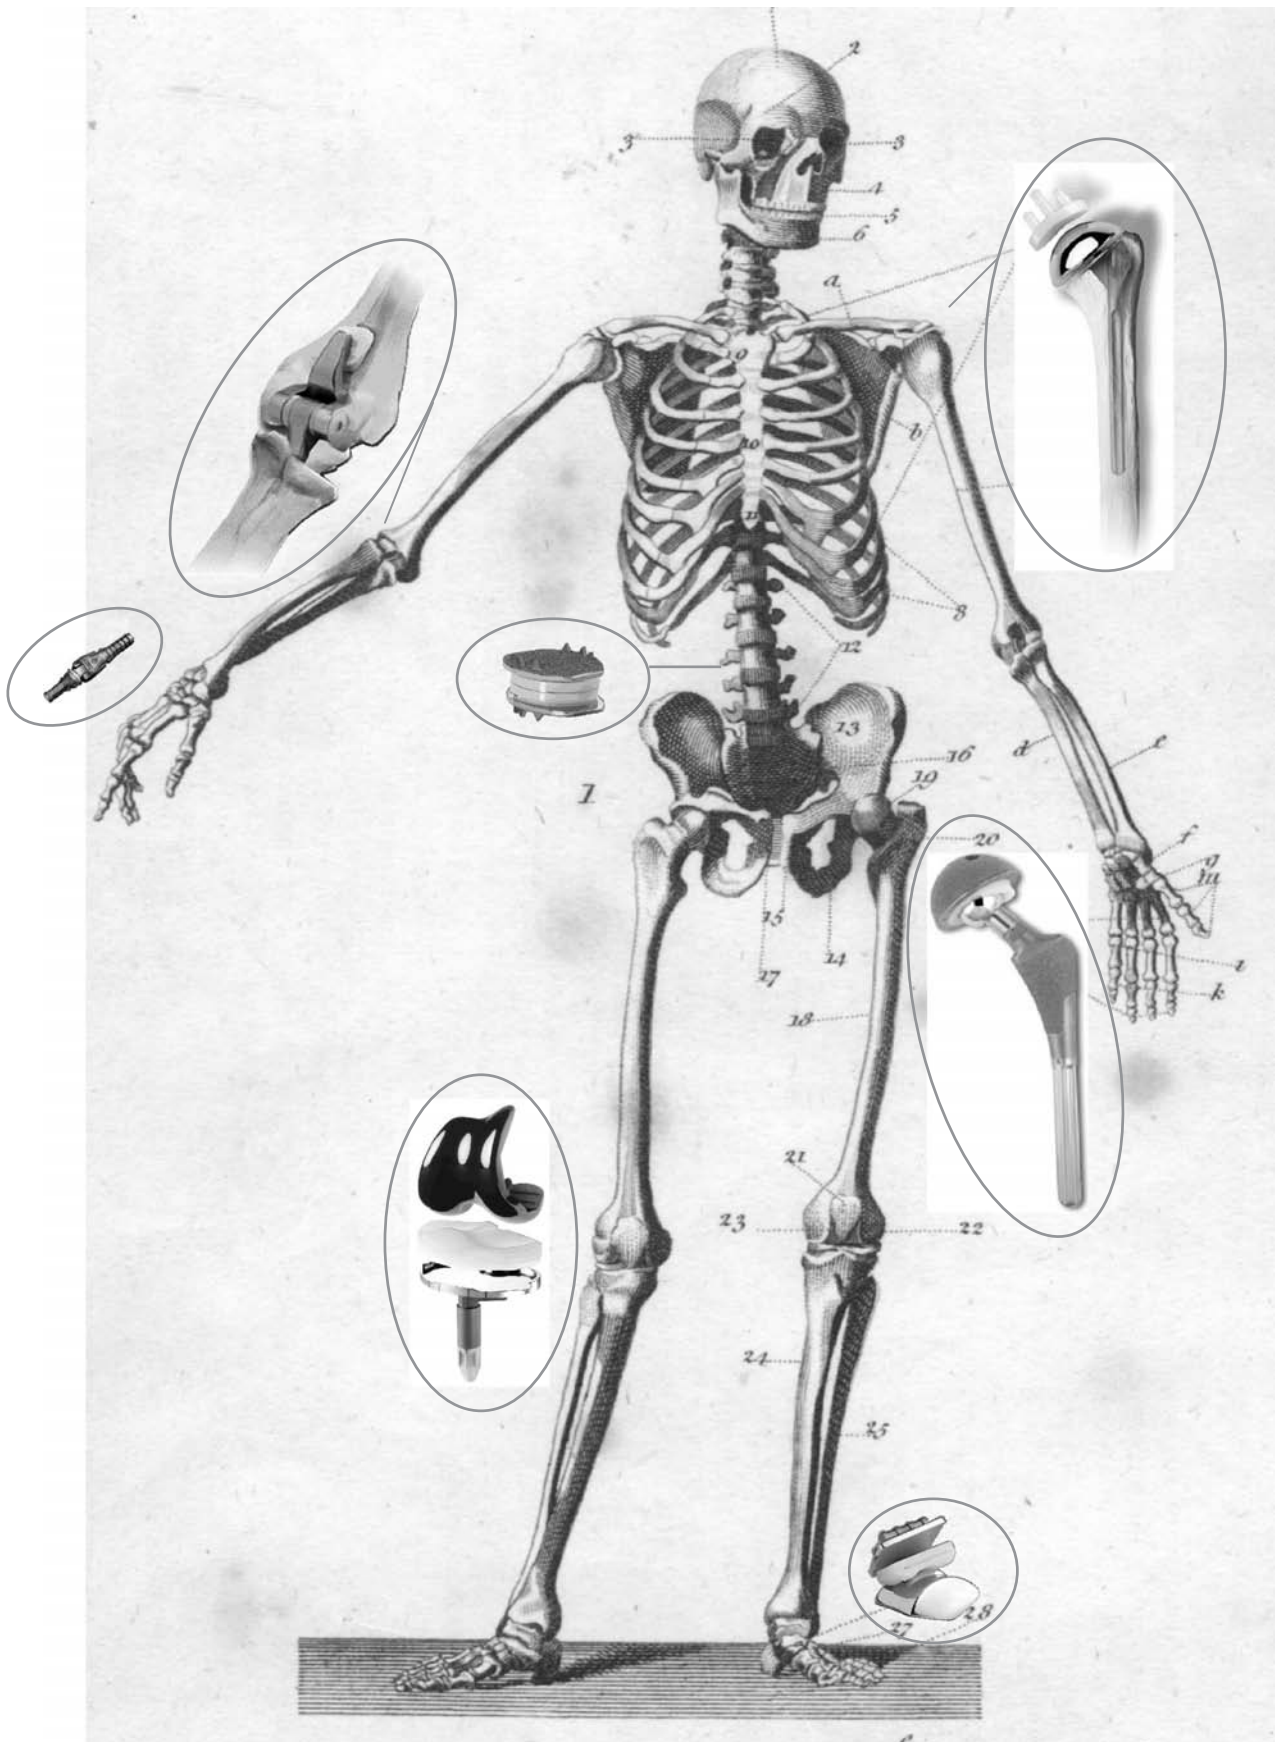

FIG. 1. The diagram shows seven locations where total joint arthroplasties (TJAs) are currently used to replace poorly functioning joints.

an accelerated rate of approximately 60% in the United States. Global sales of hip implant products equaled approximately \$2.5 billion in 2002, representing approximately 700,000 hip replacement surgeries. Because of the clinical success of total joint replacement procedures for knees and hips, demand for total joint replacement of other joints, such as the shoulder and elbow, continues to grow. Approximately 55,000 shoulder and elbow implant procedures were conducted in 2000.

Orthopedic Biomaterials

Orthopedic biomaterials are generally limited to those materials that withstand cyclic load-bearing applications. Although metals, polymers, and ceramics are used in orthopedics, it is metals that have, over the years, uniquely provided the appropriate material properties such as high strength, ductility, fracture toughness, hardness, corrosion resistance, formability, and biocompatibility that are necessary for most load-bearing roles required in fracture fixation and total joint arthroplasty (TJA). The use of orthopedic biomaterials generally falls into one of three surgical specialty categories: upper extremity, spine, or lower extremity. Each specialty is typically divided into three general categories: pediatric, trauma, and reconstruction. Despite these numerous specialties and the hundreds of orthopedic applications, there are only a few orthopedic metals, ceramics, and polymers that dominate. Knowing the general properties, uses, and limitations of the “primary” orthopedic biomaterials is requisite to understanding what is required to improve the performance of current implant materials and why only a few dominate the industry. A summary of seven more prevalent orthopedic biomaterials and their primary use(s) are listed in Table 1.

Orthopedic Biomaterials Design

The developer of new biomaterials for orthopedic purposes faces the same duality of concerns present in all other implant use: (1) the material must not adversely affect its biological environment, and (2) in return the material must not be adversely affected by the surrounding host tissues and fluids. And it must do this in a way that exceeds that of present materials used for the same application, if any exist. In order for

new “improved” orthopedic biomaterials to address this issue, there should be some understanding of the interrelationship between the structure and properties of the natural tissues that are being replaced. An appreciation of the “form–function” relationship in calcified tissues will help provide insight into factors determining implant design as well as deciding which are the materials of choice to meet a specific orthopedic need.

STRUCTURE AND PROPERTIES OF CALCIFIED TISSUES

There are several different calcified tissues in the human body and several different ways of categorizing them. All calcified tissues have one thing in common: in addition to the principal protein component, collagen, and small amounts of other organic phases, they all have an inorganic component hydroxyapatite [abbreviated OHAp, HA or $\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$]. In the case of long bones such as the tibia or femur, an understanding of the organization of these two principal components is the beginning phase of the characterization of bone structure according to scale (i.e., the level of the observation technique). It has been convenient to treat the structure of compact cortical bone (e.g., the dense bone tissue found in the shafts of long bones) on four levels of organization.

The first level or molecular level of organization is the collagen triple helical structure (tropocollagen) and OHAp crystallography. It forms a hexagonal unit cell with space group symmetry $P6_3/m$ and lattice constants $a = 9.880 \text{ \AA}$ and $c = 6.418 \text{ \AA}$, containing two molecular units, $\text{Ca}_5(\text{PO}_4)_3\text{OH}$, per unit cell. How cells produce this mineral phase and whether it is the first calcium phosphate laid down are subjects of considerable research at present. Because of its small crystallite size in bone (approximately $2 \times 20 \times 40 \text{ nm}$), the X-ray diffraction pattern of bone exhibits considerable line broadening, compounding the difficulty of identifying additional phases. A Ca-bearing inorganic compound in one of the components of calcified tissues has led to the development of a whole class of ceramic and glass-ceramic materials that are osteophilic within the body (i.e., they present surfaces that bone chemically attaches to).

As yet, we do not know fully how the two components, collagen and OHAp, are arranged or what forms hold them

TABLE 1 Most Common Orthopedic Biomaterials

Material	Primary use(s)
Metals	
Ti alloy (Ti-6%Al-4%V)	Plates, screws, TJA components (nonbearing surface)
Co-Cr-Mo alloy	TJA components
Stainless steel	TJA components, screws, plates, cabling
Polymers	
Poly(methyl methacrylate) (PMMA)	Bone cement
Ultra-high-molecular-weight polyethylene (UHMWPE)	Low-friction inserts for bearing surfaces in TJA
Ceramics	
Alumina (Al_2O_3)	Bearing-surface TJA components
Zirconia (ZrO_2)	Bearing-surface TJA components

together at this molecular level. Whatever the arrangement, when it is interfered with (as is apparently the case in certain bone pathologies in which the collagen structure is altered during formation), the result is a bone that is formed with seriously compromised physical properties.

The second or ultrastructural level may be loosely defined as the structural level observed with transmission electron microscopy (TEM) or high-magnification scanning electron microscopy (SEM). Here too, we have not yet achieved a full understanding of the collagen-OHAp organization. It appears that the OHAp can be found both inter- and intrafibrillarly within the collagen. As we shall see later, at this level, it appears that we can model the elastic properties of this essentially two-component system by resorting to some sort of linear superposition of the elastic moduli of each component, weighted by the percent volume concentration of each.

The third or microstructural level of organization is where these fibrillar composites form larger structures, fibers, and fiber bundles, which then pack into lamellar-type units that can be observed with both SEM and optical microscopy. The straight lamellar units forming the plexiform (lamellar) bone are found generally in young quadruped animals the size of cats and larger. This is the structural level that is described when the term “bone tissue” is used or when histology is generally being discussed. At this level, composite analysis can also be used to model the elastic properties of the tissue, thus providing an understanding of the macroscopic properties of bone (i.e., those associated with the behavior of the whole bone, or fourth level of structure). Unfortunately, this modeling is much very complex and a complete description lies beyond the scope of this chapter. Interested readers are referred to some of the original sources. (Katz, 1980a, b).

Since a significant portion of bone is composed of collagen, it is not surprising to find that in addition to being anisotropic and inhomogeneous, bone is also viscoelastic like all other biological tissues. Duplicating such properties with a long-lasting synthetic biomaterial remains an unrealized goal of orthopedic biomaterials where the history of implant development has been characterized by the elimination of available candidate materials based on their poor performance rather than production of biocompatible synthetic bone-mimetic materials.

Perhaps the best example of how advances in biomaterials over the past century have directed implant design improvements and resulted in widespread popularity is embodied in that of the total joint replacement (TJR), the earliest and most popular of which is the total hip replacement (THR). Many if not all of the biomaterial related issues (both mechanical and biological) that affect the performance of the THRs embody those applicable to other orthopedic implants. Therefore this chapter will detail the history of the total hip arthroplasty, current orthopedic materials technology, and future developments to highlight clinical concerns of orthopedic biomaterial development and current technology. The history of total hip arthroplasty is particularly pertinent to biomaterials science because it is one of the best illustrations of how an implant first used over a century ago has evolved to the highly successful status it has, primarily because of advances in biomaterials. Current clinical issues associated with orthopedic biomaterials biocompatibility focus on the degradation product and can be

broken down into four basic questions: (1) how much material is released from the implant; (2) where the material is transported and in what quantity; (3) what the chemical form of the released degradation products is (e.g., inorganic precipitate versus soluble organometallic complex); and (4) what the pathophysiological interactions and consequences of such degradation are.

HISTORY OF TOTAL HIP ARTHROPLASTY

The earliest attempts to restore mobility to painful and deformed hip joints took place in the 1820s (White, 1822; Barton, 1827) and centered on simply removing the affected femoral and acetabular bone involved. This evolved in the 1830–1880s into ghastly attempts to restore mobility using interpositional membranes between the femoral head and acetabulum, where such materials as wooden blocks and animal (e.g., pig) soft tissue were tried. The first prosthetic hip replacement is dated to 1890 where Gluck published a description of a carved ivory femoral head replacement using bone-cement-like materials such as pumice and plaster of Paris to secure the implants in place (Walker, 1978; Stillwell, 1987).

The interpositional membrane strategy continued from the 19th into the 20th century where the use of new implant materials in the early 1900s (1900–1920) included organic materials (e.g., pig bladders and periimplant soft tissues) and inorganic materials such as gold foil. The use of the individual's own soft tissues was the most popular method of interpositional membrane hip surgery. The limited success of this procedure prevented widespread use and thus the treatment of painful, disfigured, and “frozen” (ankylosed) hip joints remained commonplace into the 1920s.

Mold Arthroplasty

It was not until 1923 when Marius Smith-Peterson was credited with ushering in the modern era of total joint replacement with his development of the “mold” arthroplasty (Fig. 2). Made of glass, it was inspired by a shard of glass found in a patient's back with a benign synovial-like membrane around it. This mold or cup arthroplasty was designed as a cup that fit in between the femoral head and the acetabular cup and articulated on both surfaces prompting a “tissue engineered” synovial/cartilage-like layer. This was the first widespread attempt to develop a better interpositional membrane, a technique that had been in practice for the previous 100 years. The efforts of Smith-Peterson and his colleagues over the years from 1923 to 1938 was spent improving the fracture resistance of the glass mold arthroplasty cup design using materials such as early polymers (e.g., celluloid or phenol-formaldehyde Bakelite or Formica) and improved glass, e.g., Pyrex. But it was not until 1939 when the first metal, a cobalt alloy termed Vitallium, was available and used by Venable, Stuck, and Beach that the corrosion resistance of the hip arthroplasty provided sufficient biocompatibility and performance (Fig. 2).

FIG. 2. The history of total hip arthroplasty is particularly pertinent to biomaterials science because it is one of the best illustrations of how an implant first used over a century ago has evolved to the highly successful status it has, primarily because of advances in biomaterials.

In 1937 Venable, Stuck, and Beach published a landmark article that was the first to analyze in a systematic fashion the electrolytic effects of various metals on bone and tissues (e.g., aluminum, copper, iron, nickel, lead, gold, magnesium, silver, stainless steel, and other alloys) and arrived at the conclusion that Vitallium (a cobalt–chromium alloy) was superior to the other metals in corrosion resistance and mechanical properties required for an implant (Venable *et al.*, 1937; Charnley, 1979). By observing the effects of corrosion and proposing guidelines for performance Venable, Stuck, and Beach set the standard by which future metallic alloys were selected for use in hip and other types of implants.

The superior material properties of the Vitallium alloy facilitated further design modifications of the mold arthroplasty by Otto E. Aufranc (Fig. 2) where the rim of the Smith–Peterson mold was removed (which often was the cause of adhesions and cup “freezing,” and subsequent pain and immobility) and matching curves on the inner and outer surface were machined to meet at the rounded outer edge. Despite the high short-term success rates (<4 years) reported by Aufranc (>82%), the overall failure rate remained high (>50%). Another design modification of the mold arthroplasty in the 1940–1950s was the fixation of the mold to the acetabulum rim with screws, by such physicians as Albee-Pearson and Gaenslen. Although

used in only four cases, Gaeslen reported using a cobalt alloy mold fixed to the acetabulum and another fixed to the femoral head creating a metal-on-metal total hip replacement. The popularity of mold arthroplasties endured into the 1970s when they remained touted as the treatment of choice for traumatic arthritis of the hip by leading orthopedic surgeons (Harris, 1969). However, back in the 1930s the natural progress in THA development was the progression from mold arthroplasty to short-stem prosthesis.

Femoral Head Prostheses/Short-Stem Prostheses

Femoral-head prosthetics were first made of such materials as ivory (Gluck, 1890) and rubber (Delbet, 1919) and were cemented (using a plaster-like cement) for stability (Walker, 1978; Stillwell, 1987). At about the same time these replacement heads were first fitted with a short stem by Earnest Hey Groves, who used an ivory nail to replace the articular surface of the femur. These types of implants were rare and remained unpopular compared to mold arthroplasties until 1937 when Harold Bohlman, using the work of Venable and Stuck, designed a corrosion resistant cobalt–chromium alloy femoral-head replacement with a short stem. This design was popularized by the Judet brothers in Paris in 1946, who used poly(methyl methacrylate) (PMMA), which was presumed biologically inert *in vivo*, to manufacture short-stemmed prostheses (Fig. 2). Initial good results were soon replaced with problems of implant fracture and excessive wear debris and by the early 1950s these implants were losing favor and being removed by surgeons. Vitallium (cobalt–chromium alloy) eventually replaced acrylic in several other short-stem designs. However, there were sound short stem designs as early as 1938 where Wiles introduced the cobalt alloy femoral shell attached to the femur with a central nail. This design was later popularized by Peterson in 1950, where he used a similar Vitallium shell design with a central nail and a plate attached to the nail for added stability. Others adopted and adapted the Judet brothers design using Vitallium, such as J. Thompson (1951) and Rossignal (1950). Rossignal designed large threads onto the stem to aid in fixation. These short stem designs were subject to what was deemed high shear stress and resulted in early loosening and failure in some patients. Short-stem designs were gradually replaced by longer stem designs that provided less stress concentration.

Long-Stem Prostheses

Long-stem prostheses continued the trend established by short-stemmed prostheses, that is, more and more weight-bearing forces were transferred to the femur though an intramedullary stem. The pattern for a long-stem prosthesis was established in 1940 by Bohlman in collaboration with Austin T. Moore in which they implanted a 12-inch Vitallium prosthesis that replaced the femoral head and had long supports that were screwed into the outside of the femoral shaft (Moore, 1943). And although there were innovations in long-stem design in the 1940s, such as the doorknob design of Earl McBride, where a threaded stem was screwed into the

intramedullary canal of the femur for fixation and load transfer, these designs were not popular. It was not until 1950 with the designs of Frederick R. Thompson and Austin T. Moore that long-stemmed prostheses became popular (Fig. 2). These designs were cast in Vitallium (cobalt–chrome alloy) and required the removal of the femoral head but only part of the neck. The design of Moore differed from that of Thompson in that it had fenestrations through the implant to allow bone growth and it had a rear vane to enhance rotational stability. Initially these implants were used without bone cement. Evidence for the successful designs of the Thompson and Moore prostheses is proved by their continued use with only slight variations from the original. Despite the excellent design of these early long-stemmed prostheses they were primarily successful when used in place of diseased femoral heads and did not work well when acetabular reaming was required. Therefore, this inadequacy prompted the development of the total hip replacement arthroplasty.

Total Hip Replacement Arthroplasty

Philip Wiles is credited with first total hip arthroplasty in 1938 when he used a stainless steel ball secured to the femur with a bolt and a stainless acetabular liner secured with screws (Wiles, 1953). The results of this design were disappointing because of the poor corrosion resistance of early stainless steel *in vivo* and the high stress concentrations of short-stemmed prostheses. An adaptation of this design that proved successful was developed by G. K. McKee and J. Watson-Farrar in 1951. They used a stainless steel cup and long-stemmed prosthesis (Thompson stem), which failed rapidly because of the poor corrosion resistance of the stainless steel, and was then changed to cobalt–chromium alloy with greater success. The McKee–Farrar prosthesis evolved quickly to incorporate a true spherical femoral head that was undercut at the neck to reduce the impingement of the head on the rim of the acetabular prosthesis and provide for a greater range of mobility (Fig. 2) (McKee and Watson-Farrar, 1943).

The next milestone in the evolution of modern total hip arthroplasty was the advent/popularization of acrylic dental bone cement, first used by Sven Kiar in 1950 to attach a plastic prosthesis to bone (Charnley, 1964). Later that year the Hospital for Joint Diseases in New York used poly(methyl methacrylate) (acrylic) bone cement as a means of fixation in total hip arthroplasties (Charnley, 1960; Wilson and Scales, 1970). The development of acrylic bone cement dramatically reduced the rates of loosening associated with metal–metal total hip arthroplasty. The Stanmore metal–metal design, which used a horseshoe-shaped cup, was popular but led to excessive wear and was replaced by a complete cup. McKee and Watson-Farrar adapted their design to facilitate bone cement with a land-mine-like studded acetabular cup intended to maximize mechanical fixation.

The 1950s marked the introduction and popularization of the total hip arthroplasty where it became simple and reliable enough to be practiced on a wide scale by the average orthopedic surgeon. However, the squeaking reported to occur in Judet and some later metal prostheses was identified by

Charnley to be a result of the relatively high frictional forces in the joint. These high torque and frictional forces resulted in the generation of significant metallic debris which purportedly resulted in early loosening. In 1960 Charnley developed a “low friction arthroplasty” device using shells of polytetrafluoroethylene, PTFE (commonly called Teflon in related publications) on the femoral and acetabular sides, which resulted in early/immediate failures because of the massive debonding and wear debris. This was quickly followed by a thick-walled Teflon acetabular component articulating on a small head designed to reduce the shearing forces and torque. However, this design also generated excessive wear debris that produced immediate and severe inflammation and failure of the prosthesis. Charnley then replaced the Teflon with high-density polyethylene, which was not as friction-free as Teflon but was 1000 times more wear resistant. This prototype of total hip arthroplasty developed in 1962 was the basis for future designs, which remain the most popular form of total hip arthroplasty performed today (Fig. 2).

The basic design of Charnley was modified by Muller with variable neck sizes and larger heads. At the same period metal-on-metal designs by Smith, Ring and others (Ring, 1968) were unsuccessful challengers to the basic Charnley metal-on-polymer design. Other currently adopted design modifications were developed by Ling, Aufranc, Turner, Amstutz, Harris, and Galante, which include such innovations as femoral prosthesis geometrical modification for increases in stability and mobility, modular components for increased customization, porous coatings, and surface texturing/coating to increase fixation and bone ingrowth. Charnley is often deified in orthopedic literature as the metaphorical spark that lit the flames of innovation in prosthetic design. This is a typical surgeon-centered overglorification. For one thing other implant designs that predate Charnley such as the all-metal McKee–Farrar THA implant have enjoyed similar success rates to those reported by Charnley. More importantly, total hip arthroplasty is, perhaps, the best example of how orthopedic biomaterials and implant success have evolved over the past century through the innovation and hard work of many scientists and physicians and advances in areas of materials technology, biomechanics, biochemistry, immunology, infectious diseases, thrombosis, and pharmacology, to name a few.

TOTAL HIP ARTHROPLASTY: CURRENT TECHNOLOGY

Today the archetype of the total hip implant remains much as it was in the 1970s, albeit with a greater variety of implant materials and geometries (Fig. 3). Current THA is typically constructed of a titanium or cobalt–chromium alloy femoral stem [cemented with poly(methyl methacrylate), PMMA, or press fit into place, Fig. 4], connected to a “modular” cobalt–chromium alloy or ceramic head that articulates on an ultrahigh-molecular-weight polyethylene (UHMWPE) or ceramic acetabular cup fitted into a titanium or cobalt–chromium cup liner that is cemented, screwed, or press-fit into place (Fig. 4). Despite this simple archetype of the total hip replacement there exist hundreds of variations on this theme offered to today’s orthopedic surgeons, with little in terms of absolute guidelines as

FIG. 3. Examples of a typical current total hip arthroplasty (THA) components available from a single manufacturer, titanium alloy stem, with a cobalt-base alloy (ASTM F-75) modular head bearing on an ultrahigh-molecular-weight polyethylene (UHMWPE) liner within a titanium alloy cup. Also shown is a ceramic head and three acetabular sockets with various surfaces for both cemented and cementless fixation. From left to right the stems are all components of the Versys Hip System (Zimmer Inc., Warsaw, IN) and from left to right are designated Beaded Fullcoat, Beaded Fullcoat with distal flutes, Cemented, Fiber Metal Taper, and Fiber Metal Midcoat. (Photographs courtesy of Zimmer Inc.)

to which type of implant is (or which of the more than 10 major manufacturers has) the best for well-defined orthopedic disease states. However, there are some general guidelines. Typically implants in older individuals (>80 years of age) are cemented into place with PMMA bone cement, because the chance for revision is minimal when compared to younger individuals (<60 years) and removing bone cement is both technically challenging and may compromise the availability of bone stock. Generally there are choices of surface roughness, coatings, geometry, material composition, etc., and each manufacturer claims that its product is superior to the rest. This, in combination with little to no publicly available information tracking the performance of each type of implant in patients, precludes accurate scientific analysis of which implant materials and design perform best. Additionally, stiff competition between manufacturers and the requisite attention to marketing required to compete in the marketplace has resulted in a dizzying array of new implants released each year claiming to be improved over last year’s model. These claims are suspect, because the typical total hip replacement enjoys a success rate of over 90% at 7 years; therefore in most cases a minimum of 7 to 10 years must pass before such claims can be substantiated, and even then proof of superior performance is compromised by a myriad external factors such as surgeon, region of the country, and average activity of patient populations. This conflict between science and marketing and market share may (in

FIG. 4. Examples of cemented and noncemented stems showing the plug and centralizer used with a cemented stem (picture courtesy of Zimmer Inc.).

the opinion of this author) represent the single biggest obstacle to the scientific determination of superior implant design and progress. The unenviable responsibility rests with the FDA to prevent the zeal of economic pressure from undermining implant design in a regressive fashion. Today we see the result of implant technology that has excelled to the point where very real and hard decisions of implant selection are based on material alone (e.g., material couple selection in THA; Fig. 5).

Polymers

Polymers are most commonly used in orthopedics as articulating bearing surfaces of joint replacements (Fig. 3) and as an interpositional cementing material between the implant surface and bone (Fig. 4). Polymers used as articulating surfaces must have low coefficients of friction and low wear rates when in articulating contact with the opposing surface, which is usually made of metal. Initially, John Charnley used Teflon (PTFE) for the acetabular component of his total hip arthroplasty (Fig. 2). However, its accelerated creep and poor stress corrosion (for the material he used) caused it to fail *in vivo*, requiring replacement with his ultimate choice, ultrahigh-molecular-weight polyethylene (UHMWPE). Thus, the twofold demands of “not doing damage” and “not being damaged” were preeminent once again. Polymers used for fixation as a structural interface between the implant component and bone tissue require appropriate mechanical properties of a polymer,

FIG. 5. Examples of the three types of bearing couples using in modern TJA. From top to bottom: metal-on-polymer, ceramic-on-ceramic, and metal-on-metal (Lineage line from Wright Medical Technology, Inc., Arlington TN).

which can be molded into shape and cured *in vivo*. The first type to be used, PMMA, was again popularized by Charnley, who borrowed from the field of dentistry. He adapted PMMA as a grouting material to fix both the stem of the femoral component and the acetabular component in place, and thus distribute the loads more uniformly from the implants to the bone. Since high interfacial stresses result from the accommodation of a high-modulus prosthesis within the much lower modulus bone, the use of a lower modulus interpositional material has been a goal of alternatives seeking to improve upon PMMA fixation. Thus, polymers such as polysulfone have been tried as porous coatings on the implant's metallic core to permit mechanical interlocking through bone and/or soft tissue ingrowth into the pores. However to date PMMA remains the method of choice for orthopedic surgeons. This requires that polymers have surfaces that resist creep under the stresses found in clinical situations and have high enough yield

strengths to minimize plastic deformation. As indicated earlier, the important mechanical properties of orthopedic polymers are yield stress, creep resistance, and wear rate. These factors are controlled by such parameters as molecular chain structure, molecular weight, and degree of branching or (conversely) of chain linearity.

One of the more prevalent polymers used in orthopedics today is a highly cross-linked ultrahigh-molecular-weight polyethylene, which is typically used in total joint arthroplasty as a load-bearing articulating surface, designed to provide low-friction load-bearing articulation. Polyethylene is available commercially in three different grades: low-density, high-density, and UHMWPE. The better packing of linear chains within UHMWPE results in increased crystallinity and provides improved mechanical properties required for orthopedic use even though there is a decrease in both ductility and fracture toughness. In total hip arthroplasty applications an acetabular cup of UHMWPE typically articulates against a femoral ball of cobalt-chromium alloy. The predominant problem presented by these metal-polymer articulating surfaces is the production of wear particles, i.e., polymer debris. The resultant wear of the polyethylene bearing purportedly produces billions of submicron-sized wear particles annually, in the $<1\text{--}10\ \mu\text{m}$ range. Producing greater cross-linking of polyethylene, using chemical and radiation techniques, has only recently improved its wear resistance in orthopedic applications. Wear tests have shown that the wear resistance of UHMWPE is improved by cross-linking with gamma irradiation at 2.5–5.0 Mrad and below as evidenced by simulator studies; however, this can negatively affect such physical properties as tensile strength (McKellop *et al.*, 2000). Therefore, care must be taken to minimize any negative oxidative effects while preserving high wear characteristics. Although newer, more highly cross-linked polyethylene has generally been accepted as superior to previous implant UHMWPE, there remains incomplete data regarding its ultimate long-term performance. In order to maximize the performance characteristics of polyethylene it is cross-linked prior to fabrication into its final form, e.g., an acetabular cup. Typically, an extruded bar of polyethylene is cross-linked using conventional gamma irradiation and then heat treated to reduce residual free radicals.

Ceramics

In recent years, ceramics and glass-ceramics have played an increasingly important role in implants. Although used in Europe for over a quarter century, only recently (Feb. 3, 2003) has the FDA approved the first ceramic-on-ceramic bearing hip implant to be used in total hip replacement procedures (Fig. 5). The primary reason for the introduction of this alternative bearing surface is the superior wear resistance of ceramics when compared to metal-metal or metal-polymer bearing surfaces. This and other improved properties such as resistance to further oxidation (implying inertness within the body), high stiffness, and low friction requires the use of full-density, controlled, small, uniform grain size (usually less than $5\ \mu\text{m}$) ceramic materials. The small grain size and full density are important since these are the two principal bulk parameters

controlling the ceramic's mechanical properties. Any voids within the ceramic's body will increase stress, degrading the mechanical properties. Grain size controls the magnitude of the internal stresses produced by thermal contraction during cooling. In ceramics, such thermal contraction stresses are critical because they cannot be dissipated as they can in ductile materials via plastic deformation.

Alumina (Al_2O_3) and zirconia (ZrO_2) ceramics have been used in orthopedic THA for the past 30 years. The first ceramic couple (alumina/alumina) was implanted in 1970 by Pierre Boutin. From the outset the theoretical advantage of hard-on-hard articulating surfaces was low wear. Ceramics, because of their ionic bonds and chemical stability, are also relatively biocompatible. Initial concerns about fracture toughness and wear have been addressed by lowering grain size, increasing purity, lowering porosity, and improving manufacturing techniques (e.g., hot isostatic pressing, HIP). Early failures of these couples were plagued with both material-related and surgical errors. The very low wear rates combined with steadily decreasing rates of fracture (now estimated to occur 1/2000 over 10 years) have resulted in the growing popularity of all-ceramic bearings.

Zirconia was introduced in 1985, as a material alternative to Al_2O_3 for ceramic femoral heads, and has been gaining market share because of its demonstrable enhanced mechanical properties in the laboratory when compared to alumina. Femoral heads of zirconia can typically withstand 250 kN (or 25 tons), a value generally exceeding that possible with alumina or metal femoral heads. However, mechanical integrity of all ceramic components is extremely dependent on manufacturing quality controls, as evidenced by the recall of thousands of zirconia ceramic femoral heads by their manufacturer, St. Gobain Desmarquest, on August 14, 2001. This was because of *in vivo* fracture of some components due to a slight unintended variation in the manufacturing sintering process caused when the company bought a newer high-throughput assembly-line-type oven. In general ceramic particulate debris are chemically stable and biocompatible and cause untoward biologic responses at high concentrations.

There have been attempts to take advantage of the osteophilic surface of certain ceramics and glass ceramics. These materials provide an interface of such biological compatibility with osteoblasts (bone-forming cells) that these cells lay down bone in direct apposition to the material in some form of direct chemico-physical bond. Special compositions of glass-ceramics, termed bioglasses, are used for implant applications in orthopedics. The model proposed for the "chemical" bond formed between glass and bone is that the former undergoes a controlled surface degradation, producing an SiO-rich layer and a Ca,P-rich layer at the interface. Originally amorphous, the Ca,P-rich layer eventually crystallizes as a mixed hydroxycarbonate apatite structurally integrated with collagen, which permits subsequent bonding by newly formed mineralized tissues. There is still an entirely different series of inorganic compounds that also have been shown to be osteophilic. These include OHAp, which is the form of the naturally occurring inorganic component of calcified tissues, and calcite, CaCO_3 , and its Mg analog, dolomite, among others being studied. The most extensive applications in both orthopedics and dentistry

TABLE 2 Mechanical Properties of Dominant Orthopedic Biomaterials

have involved OHAp. This has been used as a cladding for metal prostheses for the former, and in dense, particulate form for the latter. The elastic properties of OHAp and related compounds are compared with those of bone, dentin, and enamel in Table 2. The use of both OHAp and the glass ceramics as claddings on the metallic stems of hip prostheses is still another method of providing fixation instead of using PMMA. In these cases, the fixation is via the direct bonding of bone to the cladding surface.

Metals

Since the principal function of the long bones of the lower body is to act as load-bearing members, it was reasonable that the initial materials introduced to replace joints, such as artificial hips, were metals. Both stainless steel, such as 316L, and Co–Cr alloys became the early materials of choice, because of their relatively good corrosion resistance and reasonable fatigue life within the human body. Of course, their stiffness,

rigidity, and strength considerably exceeded those of bone. However, in certain applications, owing to size restrictions and design limitations (e.g., in rods used to straighten the spine in scoliosis), fatigue failures did occur. Metals remain the central material component of state of the art total hip arthroplasties. Metals provide appropriate material properties such as high strength, ductility, fracture toughness, hardness, corrosion resistance, formability, and biocompatibility necessary for use in load-bearing roles required in fracture fixation and total joint arthroplasty (TJA). Implant alloys were originally developed for maritime and aviation uses where mechanical properties such as high strength and corrosion resistance are paramount. There are three principal metal alloys used in orthopedics and particularly in total joint replacement: (1) titanium-based alloys, (2) cobalt-based alloys, and (3) stainless steel alloys. Alloy specific differences in strength, ductility, and hardness generally determine which of these three alloys is used for a particular application or implant component. However, it is the high corrosion resistance of all three alloys, more than anything, which has led to their widespread use as load-bearing implant materials. These material properties of metals (Table 2) are due to the miraculous nature of the metallic bond, molecular microstructure, and elemental composition of metals.

Stainless Steel Alloys

Stainless steels were the first metals to be used in orthopedics in 1926. However, it was not until 1943, when ASTM 304 was recommended as a standard implant alloy material, that steels were reliable as an implant alloy. All steels are composed of iron and carbon and may typically contain chromium, nickel, and molybdenum. Trace elements such as manganese, phosphorus, sulfur, and silicon are also present. Carbon and the other alloy elements affect the mechanical properties of steel through alteration of its microstructure.

The form of stainless steel most commonly used in orthopedic practice is designated 316LV (American Society for Testing and Materials F138, ASTM F138; others include

F139, F899, F1586, F621, etc.). “316” classifies the material as austenitic, and the “L” denotes the low carbon content and “V” the vacuum under which it is formed. The carbon content must be kept at a low level to prevent carbide (chromium-carbon) accumulation at the grain boundaries.

Although the mechanical properties of stainless steels are generally less desirable than those of the other implant alloys (lower strength and corrosion resistance), stainless steels do possess greater ductility indicated quantitatively by a threefold greater “percentage of elongation at fracture” when compared to other implant metals (Table 2). This aspect of stainless steel has allowed it to remain popular as a material for cable fixation components in total knee arthroplasty, and a low-cost alternative to Ti and Co alloys.

Cobalt-Chromium Alloys

Of the many Co-Cr alloys available, there are currently only two predominantly used as implant alloys (Table 3). These two are (1) cobalt-chromium-molybdenum (CoCrMo), which is designated ASTM F-75 and F-76, and (2) cobalt-nickel-chromium-molybdenum (CoNiCrMo), designated as ASTM F-562. Other Co alloys approved for implant use include one that incorporates tungsten (W) (CoCrNiW, ASTM F-90) and another with iron (CoNiCrMoWFe, ASTM F-563). Co-Ni-Cr-Mo alloys that contain large percentages of Ni (25–37%) promise increased corrosion resistance, yet raise concerns of possible toxicity and/or immunogenic reactivity (discussed later) from released Ni. The biologic reactivity of released Ni from Co-Ni-Cr alloys is cause for concern under static conditions, and because of their poor frictional (wear) properties Co-Ni-Cr alloys are also inappropriate for use in articulating components. Therefore the dominant implant alloy used for total joint components is CoCrMo (ASTM F-75).

Cobalt alloys are generally cast into their final shape because they are susceptible to work-hardening at room temperatures. That is, the improvements in strength and hardness gained by cold working are not worth the loss in fracture toughness. Thus Co-Cr-Mo alloy hip implant components

TABLE 3 Approximate Weight Percent of Different Metals within Popular Orthopedic Alloys

Alloy	Ni	N	Co	Cr	Ti	Mo	Al	Fe	Mn	Cu	W	C	Si	V

are predominantly manufactured using lost wax (investment) casting methods.

Although Co–Cr–Mo alloys are the strongest, hardest, and most fatigue resistant of the metals used for joint replacement components, care must be taken to maintain these properties because the use of finishing treatments can also function to reduce these same properties (Table 2). For example, sintering of porous coatings onto femoral or tibial TJA Co–Cr–Mo stems can decrease the fatigue strength of the alloy from 200–250 MPa to 150 MPa after heating (annealing) the implant at 1225°C.

Titanium Alloys

Titanium alloys were developed in the mid-1940s for the aviation industry and were first used in orthopedics around the same time. Two post–World War II alloys, commercially pure titanium (CPTi) and Ti-6Al-4V, remain the two dominant titanium alloys used in implants. Commercially pure titanium (CPTi, ASTM F67) is 98–99.6% pure titanium. Although CPTi is most commonly used in dental applications, the stability of the oxide layer formed on CPTi (and consequently its high corrosion resistance, Table 4) and its relatively higher ductility (i.e., the ability to be cold worked), compared to Ti-6Al-4V, has led to the use of CPTi in porous coatings (e.g., fiber metal) of TJA components. Generally, joint replacement components (i.e., TJA stems) are made of Ti-6Al-4V (ASTM F-136) rather than CPTi, because of its superior mechanical properties (Table 2).

Titanium alloys are particularly good for THA components because of their high corrosion resistance compared with stainless steel and Co–Cr–Mo alloys. A passive oxide film (primarily of TiO₂) protects both Ti-6Al-4V and CPTi alloys. Generally Ti-6Al-4V has mechanical properties that exceed those of stainless steel, with a flexural rigidity less than stainless steel and Co–Cr–Mo alloys. The torsional and the axial stiffness (moduli) of Ti alloys are closer to those of bone and theoretically provide less stress shielding than do Co alloys and stainless steel. However, titanium alloys are particularly sensitive to geometrical factors, in particular notch sensitivity. This reduces the effective strength of a component by increasing

the material's susceptibility to crack propagation through the component. Therefore care is taken both in the design geometry and in the fabrication of Ti alloy components. Perhaps the greatest drawback to Ti alloys is their relative softness compared to Co–Cr–Mo alloys (Table 2) and their relatively poor wear and frictional properties. Ti-6Al-4V is >15% softer than Co–Cr–Mo alloys and also results in significantly more wear than Co–Cr–Mo when used in applications requiring articulation, e.g., TKA or THA femoral heads. Thus Ti alloys are seldom used as materials where hardness or resistance to wear is the primary concern.

New Alloys and Surface Coatings

The quest for new THA metal alloys with improved biocompatibility and mechanical properties remains an ongoing one. The use of Ti alloys, Co–Cr–Mo alloys, or stainless steels in a specific application generally involves trade-offs of one desirable property for another. Some examples of this are the sacrifice of chemical inertness for hardness (wear resistance), as is the case with Ti alloy for Co–Cr–Mo in TJA bearing surfaces, and the compromise of strength for ductility when using stainless steel instead of Ti and Co–Cr–Mo alloys for bone fixation cables. Although new alloys claim to be just that, “new,” they are often merely variations of the three categories of implant metals previously described (which are already approved for use as implant materials). These improved alloys usually contain only the minor addition of new elements to protect assertions of substantial equivalence to existing ASTM- and FDA-approved alloys, therefore easing the burden of regulatory approval. These new alloys generally fall under one of four categories: (1) titanium alloys, (2) cobalt alloys, (3) stainless steels, and, less approved, (4) refractory metals.

New Zirconium and Tantalum Alloys

Zirconium (Zr) and tantalum (Ta) are characterized as refractory metals (others include molybdenum and tungsten) because of their relative chemical stability (passive oxide layer)

TABLE 4 Electrochemical Properties of Implant Metals (Corrosion Resistance) in 0.1 M NaCl at pH 7

Alloy	ASTM designation	Density (g/cm ³)	Corrosion potential ^a (vs calomel) (mV)	Passive current density (mA/cm ²)	Breakdown potential (mV)
Stainless steel	ASTM F138	8.0	–400	0.56	200–770
Co–Cr–Mo Alloys	ASTM F75	8.3	–390	1.36	420
Ti alloys					
CPTi	ASTM F67	4.5	–90 to –630	0.72–9.0	>2000

Ni45Ti	**	6.4–6.5	–430	0.44	890

** No current ASTM standard.

^aThe corrosion potential represents the open circuit potential (OCP) between the metal and a calomel electrode. The more negative the OCP, the more chemically reactive and thus the less corrosion resistance. Generally low current density indicates greater corrosion resistance. The higher the breakdown potential the better, (i.e. the more elevated the breakdown potential, the more stable the protective layer).

FIG. 6. Examples of new THA and TKA oxidized zirconium components currently gaining popularity because of enhanced mechanical and biocompatibility properties (Oxinium, Smith and Nephew Inc., Memphis, TN) (photographs courtesy of Smith and Nephew Inc.).

and high melting points. Because of their high strength, chemical stability, and resistance to wear, alloys such as Zr (e.g., Oxinium) are likely to gain popularity as orthopedic biomaterials. Because of their surface oxide layer's stability, Zr and Ta are highly corrosion resistant. Corrosion resistance generally correlates with biocompatibility (although not always) because more stable metal oxides tend to be less chemically active and/or biologically available and are thus less participatory in biologic processes. This enhanced biocompatibility is produced by the relatively thick surface oxide layer (approximately $5\ \mu\text{m}$) and the ability to extend ceramic-like material properties (i.e., hardness) into the material through techniques such as oxygen enrichment has resulted in the production of new implant components using these alloys (Fig. 6) (e.g., Oxidized Zirconium TKA femoral components, Smith and Nephew Inc.). Although new Zr alloys such as Oxinium generally possess high levels of hardness (12 GPa) and wear resistance (approximately 10-fold that of Co and Ti alloys, using abrasion testing), which makes them well suited for bearing-surface applications, they are costly to manufacture and currently are sought after in special circumstances where issues such as a metal allergy (or more accurately metal hypersensitivity) require particular attention to biocompatibility. As difficulties associated with the cost of forming and machining

these metals are overcome the use of these materials is expected to grow (Black, 1992).

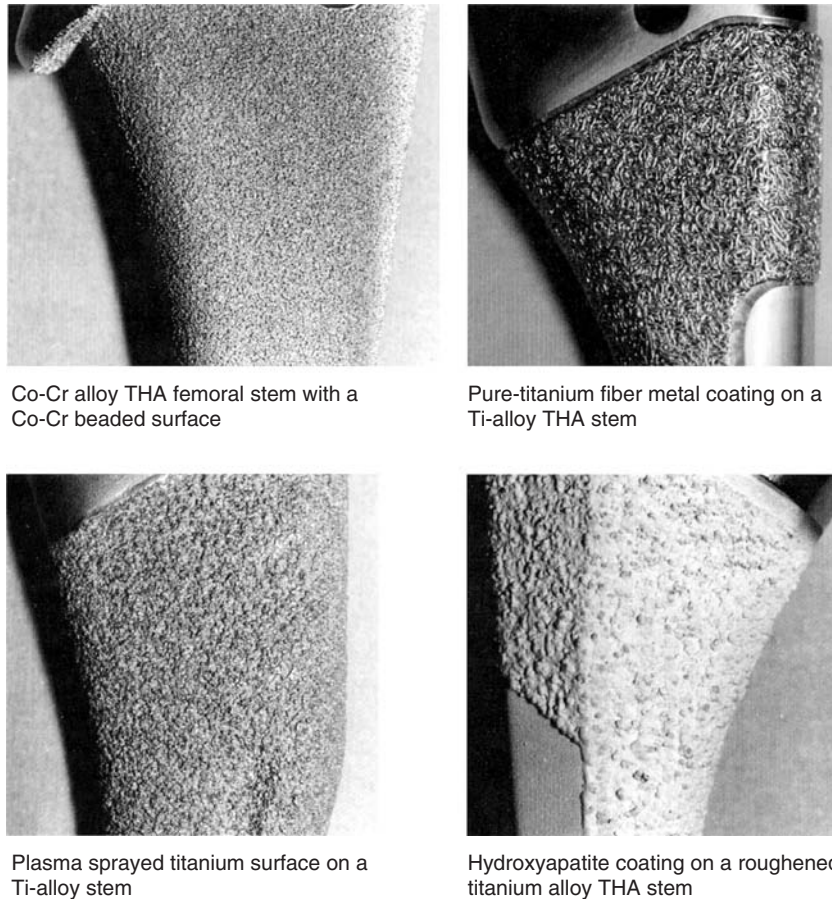

New Titanium Alloys

One new group of Ti alloys put forward for orthopedic component uses molybdenum at concentrations greater than 10%. The addition of Mo acts to stabilize the BCC (beta) phase at room temperature; thus these alloys are referred to as beta Ti alloys. These beta Ti alloys promise 20% lower moduli, which are closer to bone and thus provide better formability with maintenance of other mechanical properties typical of Ti-6Al-4V.

Other attempts at improving traditional Ti-6Al-4V alloys seek to improve biocompatibility and mechanical properties by the substitution of V (a relatively toxic metal) with other less toxic metals. Two such Ti alloys include Ti5Al2.5Fe and Ti6Al17Nb which substitute Fe and Nb for V, respectively. These alloys have similar properties to traditional Ti-6Al-4V, yet they claim higher fatigue strength and a lower modulus, thus enhancing bone-to-implant load transfer.

New Cobalt Alloys

Some "new" cobalt alloys are identical in composition to traditional alloys, but use novel processing techniques to

manipulate the microstructure of the implant materials to improve their mechanical properties. One such example recently patented, TJA-1537, although compositionally identical to ASTM F-75, claims enhanced wear resistance and fatigue strength through elimination of carbide, nitride, and second-phase particles (Allegheny Technologies). These particles normally form at the grain boundaries within a standard F75 CoCrMo alloy and act to decrease wear and fatigue resistance. Other new Co alloys under development for use in orthopedics seek to improve biocompatibility by eliminating Ni and improve mechanical properties by reducing the carbon content, thus avoiding carbide precipitation at grain boundaries.

New Stainless Steels

The relatively poor corrosion resistance and biocompatibility of stainless steels when compared to Ti and Co–Cr–Mo alloys provide incentive for development of improved stainless steels. New alloys such as BioDur 108 (Carpenter Technology Corp.) attempt to solve the problem of corrosion with an essentially nickel-free austenitic stainless alloy. This steel contains a high nitrogen content to maintain its austenitic structure and boasts improved levels of tensile yield strength, fatigue strength, and improved resistance to pitting corrosion

and crevice corrosion as compared to nickel-containing alloys such as Type 316L (ASTM F138).

Surfaces and Coatings

A variety of surface coatings are currently used to enhance the short- and long-term performance of implants by encouraging bone ingrowth and providing enhanced fixation. These different surfaces include roughened titanium, porous coatings made of cobalt chromium or titanium beads, titanium wire mesh (fiber mesh), plasma-sprayed titanium, and bioactive nonmetallic materials such as hydroxyapatite or other calcium phosphate compositions (Fig. 7). Currently osteoconductive and osteoinductive growth factors such as transforming growth factor beta (TGF beta) are being developed for use as osteogenic surface coating treatments to enhance orthopedic implant fixation.

ORTHOPEDIC BIOMATERIALS: CLINICAL CONCERNS

The millions of total joint replacements implanted over the years have restored quality of life and longevity to millions of people worldwide and an aging population demographic

in the United States. Current implant designs represent the cumulative efforts of scientists, engineers, and physicians and generally last 10–20 years with an approximate revision rate of 7% after 10 years of service. The benefits provided to patients by orthopedic implants in terms of pain, mobility, and quality of life are immeasurable. Therefore the following sections, which focus on the problems associated with implants, seek to provide the student of biomaterials a foundation for understanding the relevant issues for orthopedic research and is not intended to serve as an indictment of orthopedic materials.

Despite their overwhelming success over the long term (>7 years), orthopedic biomaterials have been associated with adverse local and remote tissue responses. It is generally the degradation products of orthopedic biomaterials (generated by wear and electrochemical corrosion) that mediate these adverse effects. This debris may be present as particulate wear, colloidal nanometer-size complexes (specifically or nonspecifically bound by protein), free metallic ions, or inorganic metal salts/oxides, or in an organic storage form such as hemosiderin. Clinical aspects of biocompatibility regarding polymer and metal release from orthopedic prosthetic devices have taken on an increasing sense of urgency because of the escalating rates of people receiving implants and the recognition of extensive implant debris within local and remote tissues. Particulate debris have enormous specific surface areas available for interaction with the surroundings and chronic elevations in serum metal content. Clinical issues associated with biomaterial degradation can be broken down into four basic questions: (1) How much material is released from the implant? (2) Where is the material transported and in what quantity? (3) What is the chemical form of the released degradation products (e.g., inorganic precipitate versus soluble organometallic complex)? (4) What are the pathophysiological interactions and consequences of such degradation? The answers to these questions, over the long term, remain largely unknown. There is a growing body of literature addressing the issues associated with the first two questions. However, little is currently known with regard to the latter two questions. The remainder of this chapter will focus on that which is known (and of orthopedic clinical concern) regarding biomaterial degradation (through wear and electrochemical corrosion), dissemination of debris, and consequent local/systemic effects.

Orthopedic Biomaterial Wear

The generation of wear debris, and the subsequent tissue reaction to such debris, is central to the longevity of total joint replacements. In fact, particulate debris are currently extolled as the primary factor affecting the long-term performance of joint replacement prostheses, and the primary source of orthopedic biomaterial degradation (based on overall implant mass or volume lost). Particulate debris generated by wear, fretting, or fragmentation induces the formation of an inflammatory reaction, which at a certain point promotes a foreign-body granulation tissue response that has the ability to invade the bone–implant interface. This commonly results in progressive, local bone loss that threatens the fixation of both cemented and cementless devices alike (Jacobs *et al.*, 1994b; Jacobs, 1995; Jacobs *et al.*, 2001).

Mechanisms of Wear Debris Generation

Wear involves the loss of material in particulate form as a consequence of relative motion between two surfaces. Two materials placed together under load will only contact over a small area of the higher peaks or asperities. Electrorepulsive and atomic binding interactions occur at the individual contacts and, when the two surfaces slide relative to one another, these interactions are disrupted. This results in the release of material in the form of particles (wear debris). The particles may be lost from the system, transferred to the counterface, or remain between the sliding surfaces. There are primarily three processes which can cause wear: (1) abrasion—by which a harder surface “plows” grooves in the softer material; (2) adhesion—by which a softer material is smeared onto a harder countersurface, forming a transfer film; and (3) fatigue—by which alternating episodes of loading and unloading result in the formation of subsurface cracks which propagate to form particles that are shed from the surface.

Wear Rates

During an initial “wearing in” period, the relative motion of surfaces causes a large number of asperities to break resulting in a high wear rate. After this initial period, the actual contact area increases and the two surfaces can be said to have adapted to one other. Over time, the wear rates decrease and eventually become linearly dependent on the contact force and sliding distance represented by the steady-state wear equation:

$$V = KFx \quad (1)$$

where V is volumetric wear (mm^3/year), K is a material constant of the material couple, F is the contact force (N), and x is the distance of relative travel (mm).

In general, the softer of two bearing materials will wear more rapidly. In the most popular joint replacement couple, a metal-on-polymer pair, the polymer wears almost exclusively, whereas in the case of a metal-on-ceramic pair (not commercially available), the metal wears to a greater extent. The *in vitro* wear rates for the socket (in hip-joint simulation studies) range from 0 to 3000 mm^3/year depending on the type of couple employed and the environment (e.g., lubricant). There is a great deal of variability associated with *in vivo* wear rates of orthopedic biomaterials, which are generally measured by radiographic follow-up studies. Radiographic wear measurements are expressed as linear wear rates whereas *in vitro* studies generally report volumetric wear. Volumetric wear can be directly related to the number of wear particles released into periprosthetic fluids (typically on the order of 1×10^9 of particles per year). The most common wear couple for hip and knee arthroplasty currently in use in the United States is a cobalt-base alloy head (most commonly a Co–Cr–Mo alloy ASTM F-75,) bearing on an ultrahigh-molecular-weight polyethylene (UHMWPE) cup or liner. The wear rates of this couple are generally on the order of 0.1 mm/year , with particulate generation as high as 1×10^6 particles per step or per cycle. Clinically, implant wear rates have been found to increase with the following: (1) physical activity, (2) weight of the patient, (3) size of the femoral head (32 versus 28 mm), (4) roughness of the

metallic counterface, and (5) oxidation of the polyethylene (Jacobs *et al.*, 1994b; Jacobs, 1995; Jacobs *et al.*, 2001).

Orthopedic Biomaterial Corrosion

Electrochemical corrosion occurs to some extent on all metallic surfaces including implants. This is undesirable for two primary reasons: (1) the degradative process may reduce structural integrity of the implant, and (2) the release of products of degradation is potentially toxic to the host. Metallic biomaterial degradation may result from electrochemical dissolution phenomena or wear, but most commonly occurs through a synergistic combination of the two. Electrochemical processes include generalized corrosion uniformly affecting an entire surface, and localized corrosion affecting either areas of a device relatively shielded from the environment (crevice corrosion), or seemingly random sites on the surface (pitting corrosion). Additionally, these electrochemical and other mechanical processes interact, potentially causing premature structural failure and/or accelerated metal release (e.g., stress corrosion cracking, corrosion fatigue, and fretting corrosion; Brown and Merritt, 1981; Cook *et al.*, 1983; Bundy *et al.*, 1991; Brown *et al.*, 1992; Collier *et al.*, 1992b; Gilbert and Jacobs, 1997).

Corrosion Mechanisms

Corrosion of orthopedic biomaterials is a multifactorial phenomenon and is dependent on five primary factors: (1) geometric variables (e.g., taper crevices in modular component hip prostheses), (2) metallurgical variables (e.g., surface microstructure, oxide structure and composition), (3) mechanical variables (e.g., stress and/or relative motion), (4) solution variables (e.g., pH, solution proteins, enzymes) and (5) the mechanical loading environment (e.g., degree of movement, contact forces). Current investigational efforts to minimize the corrosion of orthopedic biomaterials deal directly with the complex interactions of these factors.

There are two essential features associated with how and why a metal corrodes. The first has to do with thermodynamic driving forces, which cause corrosion (oxidation/reduction) reactions. In general, whether or not corrosion will take place under the conditions of interest depends on the chemical driving force (ΔG) and the charge separation. This separation contributes to what is known as the electrical double layer (Fig. 8), which creates an electrical potential across the metal–solution interface (much like a capacitor):

$$\Delta G = -nF\Delta E \quad (2)$$

where n is the valence of the ion, F is the Faraday constant (95,000 coulombs/mole electrons), and E is the voltage across the metal–solution interface. This potential is a measure of the reactivity of the metals or the driving force for metal oxidation. Therefore the more negative the potential of a metal in solution, the more reactive it will tend to be (i.e., the greater is ΔG for reduction).

The second factor governing the corrosion process of metallic biomaterials is the kinetic barrier to corrosion (e.g., surface

FIG. 8. Schematic of the interface of a passivating alloy surface in contact with a biological environment.

oxide layer). Kinetic barriers prevent corrosion not by energetic considerations but by physically limiting the rate at which oxidation or reduction processes can take place. The well-known process of passivation or the formation of a metal-oxide passive film on a metal surface is one example of a kinetic limitation to corrosion. In general, kinetic barriers to corrosion prevent the migration of metallic ions from the metal to the solution, the migration of anions from solution to metal, or the migration of electrons across the metal–solution interface. Passive oxide films are the most well known forms of kinetic barriers in corrosion, but other kinetic barriers exist, including polymeric coatings (Gilbert and Jacobs, 1997; Jacobs *et al.*, 1998a).

Passivating Oxide Films

Most alloys used in orthopedic appliances rely on the formation of passive films to prevent significant oxidation from taking place. These films consist of metal oxides, which form spontaneously on the surface of the metal in such a way that they prevent further transport of metallic ions and/or electrons across the film. Passive films must have certain characteristics to be able to limit further oxidation. The films must be compact and fully cover the metal surface, they must have an atomic structure that limits the migration of ions and/or electrons across the metal oxide–solution interface, and they must be able to remain on the surface of these alloys even with the mechanical stressing and abrasion that can be expected with orthopedic devices.

Passivating oxide films, which spontaneously grow on the surface of metals, have five primary structural and physical characteristics, which are particularly relevant to implant degradation processes:

1. First, these oxide films are very thin, typically on the order of 5 to 70 Å, which depends on the potential across the interface as well as solution variables (e.g., pH). Furthermore, the oxide structure may be amorphous or crystalline. Since the potential across the metal solution interface for these reactive metals is typically 1 to 2 volts, the electric field across the oxide is very high, on the order of 10^6 – 10^7 V/cm. One of the more widely accepted models is based on the theory of Mott and Cabrera, which states that oxide film growth depends on the electric field across the oxide. If the potential across the metal oxide–solution interface is decreased (i.e., made closer to the electrochemical series potential), then the film thickness will decrease by reductive dissolution processes at the oxide. If the interfacial potential is made sufficiently negative or the pH of the solution is made low enough, then these oxide films will no longer be thermodynamically stable and will undergo reductive dissolution, without which corrosion will increase (Gilbert and Jacobs, 1997; Jacobs *et al.*, 1998a).

2. Second, oxide films have the characteristics of semiconductors with an atomic defect structure, which determines the ability for ionic and electronic transport across films. Metal cations and oxygen anions require the presence of cationic or anionic vacancies (respectively) in the oxide for transport of these species across the film. If there is a deficit of metal ions in the oxide film (i.e., there are cationic vacancies), for example, then metal ion transport is possible and these oxides are known as p-type semiconductors. Chromium oxide (Cr_2O_3) is such a metal-deficit oxide. On the other hand, if there is an excess of metal ions in the oxide (or a deficit of anions) then cation transport is limited but anion transport can occur. These oxides will also have excess electrons and are known as n-type semiconductors. TiO_2 spontaneously formed on titanium alloy implant (Ti-6Al-4V) surfaces is one such n-type semiconductor. The greater the number of defects (vacancies or other valence species) the less able is the oxide film to prevent migration of ionic species and the lower is the kinetic barrier to corrosion. TiO_2 is very close to being stoichiometric (chemically homogeneous) and hence does not have many ionic defects, resulting in an increased resistance to ionic transport. Other defects may be present in these passive oxide films that may alter their ability to limit corrosion. For instance, the addition of other metal ions with valence states, which are different from the native metal ions, can alter both the electronic and ionic transport of charge across the interface. These additions may enhance or degrade the ability of the oxide to prevent corrosion depending on the nature of the oxide. One example of improved corrosion resistance from mixed oxides comes from what is known as a spinel. Spinel is typically mixed oxides of the form $(\text{A}_2\text{O}_3)\text{BO}$, where A and B are +3 and +2 valence metal ions. In Co–Cr alloys, for instance, a spinel of $(\text{Cr}_2\text{O}_3)\text{CoO}$ can form on the surface. Spinel is typically known to have higher strengths and better resistance to diffusion of ions compared to single metal ion oxides. Therefore a high concentration of spinels in the oxide layer will act to resist dissolution

of a metal implant (Gilbert and Jacobs, 1997; Jacobs *et al.*, 1998a).

3. Third, the ratio of the “oxide specific volume” to metal alloy specific volume (i.e., Pilling Bedworth ratio) will determine if the oxide will adhere to the metal or not. If there is too great a mismatch between the metal and oxide lattice parameters then consequential stresses will be generated between the two. The magnitude of the internal stress will vary with the thickness of the oxide. Too great an oxide thickness will thus result in spontaneous fracture or spalling of the oxide, lowering the kinetic barrier effect of the oxide to corrosion (Gilbert and Jacobs, 1997; Jacobs *et al.*, 1998a).

4. Fourth, the morphology of these oxide films is not one of a smooth, flat, continuous sheet of adherent oxide covering the metal. Transmission electron microscopy (TEM) and atomic force microscopy (AFM) techniques have shown that oxides of titanium, for instance, consist of needle or dome shapes. The size and shape of these oxide domes change with applied potential when immersed in oxalic and other acids (Gilbert and Jacobs, 1997; Jacobs *et al.*, 1998a).

5. Finally, mechanical factors such as fretting, micromotion, or applied stresses may abrade or fracture oxide films. When an oxide film is ruptured from the metal substrate, fresh unoxidized metal is exposed to solution. When these films reform or repassivate, the magnitude of the repassivation currents that are subsequently generated may be great. This is because large driving forces exist for oxidation and when the kinetic barrier is removed these large driving forces can operate to cause oxidation. However, the extent and duration of the oxidation currents will depend on the repassivation kinetics for oxide film formation. Hence, the mechanical stability of the oxide films, as well as the nature of their repassivation process, is central to the performance of oxide films in orthopedic applications (Gilbert and Jacobs, 1997; Jacobs *et al.*, 1998a).

Corrosion at Modular Interfaces of Joint Replacements

One issue associated with orthopedic alloys is the corrosion observed in the taper connections of retrieved modular joint replacement components (Fig. 9). With the growing number of total joint designs that use metal on metal conical tapers as modular connectors between components, the effects of crevices, stress, and motion take on increasing importance. Severe corrosion attack can take place in the crevices formed by these tapers *in vivo*. Gilbert *et al.* have shown that of 148 retrieved implants, approximately 35% showed signs of moderate to severe corrosion attack in the head–neck taper connections of total hip prostheses. This attack was observed in components that consisted of Ti-6Al-4V alloy stems and Co–Cr heads as well as Co–Cr stems on Co–Cr heads. This corrosion process is likely the result of a combination of stress and motion at the taper connection and the crevice geometry of the taper. The stresses resulting from use cause fracturing and abrasion of the oxide film covering these passive metal surfaces. This, in turn, causes significant changes in the metal surface potential (makes it more negative) and in the crevice solution chemistry as the oxides continuously fracture and repassivate. These changes may result in deaeration (loss of O_2) of the crevice solution and a lowering of the pH in the crevice as

FIG. 9. Modular junction taper connection of a total hip arthroplasty showing corrosion of the taper connections. Macrograph of deposits of CrPO_4 corrosion particle products on the rim of a modular cobalt–chrome femoral head.

is expected in crevice corrosion attack. The ultimate result of this process is a loss of the oxide film and its kinetic barrier effect and an increase in the rate of corrosive attack in the taper region. The corrosion processes in the Co–Cr alloys have been observed to consist of intergranular corrosion, etching, selective dissolution of cobalt, and the formation of Cr-rich particles. In isolated cases, this occurs to such an extent that intergranular corrosion caused fatigue failure in the neck of a Co–Cr stem. Corrosion attack of titanium alloy stems has also been observed in some cases.

Very little is known about the mechanical stability of passive oxide films and the electrochemical reactions (e.g., ion and particle release) that occur when the oxide film is fractured. What is known is that when the oxide films of these orthopedic alloys are abraded or removed from the surface by rubbing, the open circuit potential can decrease to as low as -500 mV (versus standard calomel electrode). These voltage potentials may be significant and prolonged enough to cause changes in the oxide structure and stability by bringing the interface potential into the active corrosion range of the alloy, thereby dramatically accelerating the corrosion rate and decreasing implant performance (Brown *et al.*, 1992; Collier *et al.*, 1992a; Gilbert *et al.*, 1993; Bobyn *et al.*, 1994; Jacobs *et al.*, 1995; Brown *et al.*, 1995; Urban *et al.*, 1997b).

Local Tissue Effects of Wear and Corrosion

Normal bone maintenance relies on the balance of bone formation and bone resorption, which mainly involves the coordinated function of osteoblasts and osteoclasts. Thus, either a decrease in osteoblastic bone formation or an increase in osteoclastic bone resorption can result in net bone loss and osteolysis. Bone loss (i.e., osteolysis) around an implant is the primary concern associated with the local effects of orthopedic implant degradation. This osteolysis causing implant debris occurs through both wear and corrosion mechanisms. Osteolysis is observed either as diffuse cortical thinning or as a focal cyst-like lesion. It was initially thought that reaction to particulate poly(methyl methacrylate) bone cement produced osteolytic lesions based on histological studies demonstrating cement debris associated with macrophages, giant

cells, and a vascular granulation tissue. More recently, however, osteolysis has been recognized in association with loose and well-fixed uncemented implants, demonstrating that the absence of acrylic cement does not preclude the occurrence of osteolysis (Jacobs *et al.*, 2001; Vermes *et al.*, 2001a).

There are numerous secretory products created by the cells around implants that can negatively affect bone turnover (Fig. 10). These include the pro-inflammatory cytokines IL-1, IL-6, and TNF- α , to name a few. In addition, anti-inflammatory cytokines such as IL-10 may modulate this process. Other factors involved with bone resorption include the enzymes responsible for catabolism of the organic component of bone. These include matrix metalloproteinases collagenase and stromelysin. Prostaglandins, in particular PGE₂, also are known to be important intercellular messengers in the osteolytic cascade produced by implant debris. More recently, several mediators known to be involved in stimulation or inhibition of osteoclast differentiation and maturation, such as RANKL (also referred to as osteoclast differentiation factor) and osteoprotegerin, respectively, have been suggested as key factors in the development and progression of bone loss (osteolytic lesions) produced from implant debris.

Goldring *et al.* (1983) were among the first to describe the synovial-like character of the bone implant interface in patients with loose total hip replacements and determine that the cells within the membrane have the capacity to produce large amounts of bone-resorbing factors PGE₂ and collagenase. However, since studies typically can only document the end stage of the loosening process, rather than those initiating processes, pharmacologic interventions have been limited.

Osteolysis associated with total knee arthroplasty has been reported less frequently than that associated with total hip arthroplasty. It is unclear why. However, in addition to obvious factors such as implant/bone mechanical loading environments, other more subtle differential mechanisms of hip and knee wear, and differences in interfacial barriers to migration of debris have been postulated to account for this apparent disparity.

Although polyethylene particles are generally recognized as the most prevalent particles in the periprosthetic milieu, metallic and ceramic particulate species are also present in

FIG. 10. A schematic showing examples of the most common cytokines produced by cells reacting to implant debris acting through a variety of pathways to negatively affect bone turnover.

FIG. 11. Photomicrograph (5 \times) of a section through an acetabular section of a femoral stem retrieved at autopsy, 89 months after implantation. Note that the periprosthetic cavity surrounded development of a granuloma emanating from an unfilled screw hole.

variable amounts and may have important repercussions. The bulk of this debris originates from the articular surface and has easy access to local bone. When present in sufficient amounts, particulates generated by wear, corrosion, or a combination of these processes can induce the formation of an inflammatory, foreign-body granulation tissue with the ability to invade the bone-implant interface (Fig. 11). Localized osteolytic lesions in these areas are common, but their clinical significance is limited unless large granulomatous lesions develop.

The common observance of particle-induced osteolysis remote from the articulation surfaces has shown there is substantial particle migration between the joint space and the distal regions of the THA implant space. Autopsy specimens of retrieved implants have demonstrated the presence of connective tissue macrophages (histiocytes) in cavities surrounding regions of the femoral component. While the overall incidence of femoral osteolysis associated with THA tends to be proximal in the initial stages, over time it tends to progress distally. The volume of debris generated from THA polyethylene is related to a number of variables, including the smoothness of the concave metallic surface of the acetabular component, the tolerance between polyethylene and metal shell, and the relative stability of the insert (LaBerge, 1998; Shanbhag *et al.*, 1998; Wimmer *et al.*, 1998).

The relative contribution of each of the particulate species to the overall process of periprosthetic bone loss remains unknown. *In vitro* cell culture studies have demonstrated that the macrophage and fibroblast response to particulate debris is a function of particle size, composition, and dose. However, particles of different compositions may exhibit differential cytotoxicity. Polyethylene particles are believed to be the most biologically active by virtue of their greater number and small size, giving rise to an enormous surface area for interaction with the surrounding tissues (Jacobs *et al.*, 2001).

Histological Features

The tissues surrounding modern implants may include areas of osseointegration, fibrous encapsulation, and a variable

presence of the foreign-body response to polyethylene and cement debris in joint replacement devices. Absent is any specific histologic evidence of the slow release of metallic species that is known to occur with all metallic implants. However, accelerated corrosion and a tissue response that can be directly related to identifiable corrosion products can be demonstrated in the tissues surrounding multi-part devices (Urban *et al.*, 1997b, 1998, 2000).

Stainless Steels Histological sections of the tissues surrounding stainless steel internal fixation devices generally show encapsulation by a fibrous membrane with little or no inflammation over most of the device. At screw-plate junctions, however, the membranes often contain macrophages, foreign-body giant cells, and a variable number of lymphocytes in association with two types of corrosion products. The first consists of iron-containing granules. The second, termed microplates, consists of relatively larger particles of a chromium compound. Microplates are found within the tissues as closely packed, platelike particle aggregates ranging in size from 0.5 mm to 5.0 mm.

Hemosiderin-like granules often surround the collections of microplates, but the granules are found alone as well. The granules are yellow-brown, mainly spherical, and 0.1 to 3 or more micrometers in diameter. They are predominantly intracellular, most often in macrophages, but may also be found in other periprosthetic cells (e.g., fibroblasts). X-ray diffraction has indicated that the granules consist of a mixture of two or more of the iron oxides, $\alpha\text{Fe}_2\text{O}_3$ and $\sigma\text{Fe}_2\text{O}_3$, and the hydrated iron oxides, $\alpha\text{Fe}_2\text{O}_3\cdot\text{H}_2\text{O}$ and $\sigma\text{Fe}_2\text{O}_3\cdot\text{H}_2\text{O}$.

Cobalt-Base Alloys The nature of corrosion at modular connection products is similar whether modular heads are mated with cobalt-chromium alloy or Ti-6Al-4V alloy femoral stems. The principal corrosion product identified by electron microprobe energy-dispersive X-ray analysis and Fourier-transform infrared microprobe spectroscopy is a chromium phosphate ($\text{Cr}(\text{PO}_4)_4\text{H}_2\text{O}$) hydrate rich material termed "orthophosphate." This corrosion product can be found at the

FIG. 12. Transmission electron photomicrographs. (A) Macrophage containing phagocytized titanium particles. (B) Endothelial cell lining with embedded titanium debris. These specimens were obtained from a tissue sample overlying the posterolateral fusion mass (16-week autograft + titanium) (original TEM magnification 20,000 \times).

modular head–neck junction and as particles within the joint capsules, at the bone–implant interfacial membranes, and at sites of femoral osteolytic lesions. Particles of the orthophosphate material have been found at the bearing surface of the UHMWPE acetabular liners, suggesting their participation in three-body wear and an increased production of polyethylene debris. Particles of the chromium orthophosphate hydrate-rich corrosion product found in the tissues ranged in size from submicron to aggregates of particles up to 500 micrometers.

Titanium-Base Alloys The degradation products observed in histologic sections of tissues adjacent to titanium base alloys are of a different nature than the precipitates associated with stainless steel and cobalt base alloys. Despite the remarkable corrosion resistance of titanium base alloys, there have been persistent reports of tissue discoloration due to metallic debris in the periprosthetic tissues. These particulates observed in local tissues surrounding titanium alloy implants have the same elemental composition as the parent alloy, as opposed to the precipitated corrosion products that occur with stainless steel and cobalt–chromium alloys (Fig. 12). However, wear debris present an enormous surface area for electrochemical dissolution, which in all likelihood is a major factor contributing to observed systemic elevations in titanium of patients with titanium implants (Urban *et al.*, 1996, 1997a, 1997b).

Remote and Systemic Effects of Wear and Corrosion

Implant surfaces and wear debris generated from the implant may release chemically active metal ions into the surrounding tissues. While these ions may stay bound to local tissues, there is an increasing recognition that released metal products bind to specific protein moieties and are transported in the bloodstream and/or lymphatics to remote organs. The concern about the release and distribution of

metallic degradation products is justified by the known potential toxicities of the elements used in modern orthopedic implant alloys: titanium, aluminum, vanadium, cobalt, chromium, and nickel. In general terms, metal toxicity may occur through (1) metabolic alterations, (2) alterations in host/parasite interactions, (3) immunologic interactions of metal moieties by virtue of their ability to act as haptens (specific immunological activation) or antichemotactic agents (nonspecific immunological suppression), and (4) by chemical carcinogenesis (Luckey and Venugopal, 1979; Beyersmann, 1994; Goering and Klaasen, 1995; Britton, 1996; Hartwig, 1998).

Cobalt, chromium, and possibly nickel and vanadium are essential trace metals in that they are required for certain enzymatic reactions. In excessive amounts, however, these elements may be toxic. Excessive cobalt may lead to polycythemia, hypothyroidism, cardiomyopathy, and carcinogenesis. Excessive chromium can lead to nephropathy, hypersensitivity, and carcinogenesis. Nickel can lead to eczematous dermatitis, hypersensitivity, and carcinogenesis. Vanadium can lead to cardiac and renal dysfunction and has been associated with hypertension and depressive psychosis.

Biologically nonessential metallic elements also possess specific toxicities. Titanium, although generally regarded as inert, has been associated with pulmonary disease in patients with occupational exposure and with platelet suppression in animal models. Aluminum toxicity is well documented in renal failure and has been associated with anemia, osteomalacia, and neurological dysfunction, possibly including Alzheimer's disease. However, when considering the variety of documented toxicities of these elements, it is important to keep in mind that the toxicities generally apply to soluble forms of these elements and may not apply to the chemical species that result from prosthetic implant degradation.

At this time, the association of metal release from orthopedic implants with any metabolic, bacteriologic, immunologic, or carcinogenic toxicity is conjectural since cause and

effect have not been well established in human subjects. However, this is due in large part to the difficulty of observation in that most symptoms attributable to systemic and remote toxicity can be expected to occur in any population of orthopedic patients (Jacobs *et al.*, 1999a).

Metal Ion Release

In the long clinical experience of permanent and temporary metallic implants, there has always been concern with local tissue reactions. Implants, or wear debris generated from implants, may release chemically active metal ions into the surrounding tissues. While these ions may stay bound to local tissues, metal ions may also bind to protein moieties that are then transported in the bloodstream and/or lymphatics to remote organs (Jacobs *et al.*, 2001).

There is a considerable publication concerning serum and urine chromium (Cr), cobalt (Co), and nickel (Ni) levels following total joint replacement, but relatively fewer studies examining titanium (Ti), aluminum (Al), and vanadium (V) levels. Many investigations have been hampered by technical limitations of the analytical instrumentation. Normal human serum levels of prominent implant metals are approximately 1–10 ng/ml Al, 0.15 ng/ml Cr, <0.01 ng/ml V, 0.1–0.2 ng/ml Co, and <4.1 ng/ml Ti. Following total joint arthroplasty, levels of circulating metal (Al, Cr, Co, Ni, Ti, and V) have been shown to increase (Table 5).

Multiple studies have demonstrated chronic elevations in serum and urine Co and Cr following successful primary total joint replacement. In addition, transient elevations of urine and serum Ni have been noted immediately following surgery. This hypernickemia/hypernickeluria may be unrelated to the

implant itself since there is such a small percentage of Ni within these implant alloys. Rather, this may be related to the use of stainless steel surgical instruments or the metabolic changes associated with the surgery itself.

Chronic elevations in serum Ti and Cr concentrations are found in subjects with well-functioning Ti- and/or Cr-containing THR components without measurable differences in urine and serum Al concentrations. Vanadium concentrations have not been found greatly elevated in patients with TJA (Table 5) (Dorr *et al.*, 1990; Michel *et al.*, 1991; Stulberg *et al.*, 1994; Jacobs *et al.*, 1994c, 1998a).

Metal ion levels within serum and urine of TJA patients can be affected by a variety of factors. For example, patients with total knee replacement components containing Ti-base alloy and carbon fiber reinforced polyethylene wear couples demonstrated tenfold elevations in serum Ti concentrations at an average of 4 years after implantation. Up to a hundred times higher than normal control values of serum Ti elevations have also been reported in patients with failed metal-backed patellar components where unintended metal/metal articulation was possible. However, even among these TJA patients, there was no elevation in serum or urine Al, serum or urine V levels, or urine Ti levels. Mechanically assisted crevice corrosion in patients with modular femoral stems from total hip arthroplasty has been associated with elevations in serum Co and urine Cr. It has been previously assumed that extensively porous coated cementless stems would give rise to higher serum and urine chromium concentrations due to the larger surface area available for passive dissolution. More recent studies suggest that disseminated Cr can predominantly come from fretting corrosion of the modular head/neck junction.

TABLE 5 Approximate Average Concentrations (ng/ml or ppb) of Metal in Human Body Fluids with and without Total Joint Replacements (Dorr *et al.*, 1990; Michel *et al.*, 1991; Stulberg *et al.*, 1994; Jacobs *et al.*, 1994c, 1998a)

However, wear of the articulating surface remains the purported predominant source of metallic implant debris (Jacobs *et al.*, 1998a, b, 1999b).

Homogenates of remote organs and tissue obtained post-mortem from subjects with Co base alloy total joint replacement components have indicated that significant increases in Co and Cr concentrations occur in the heart, liver, kidney, spleen, and lymphatic tissue (Table 6). Similarly, patients with Ti base alloy implants demonstrated elevated Ti, Al, and V levels in joint pseudocapsules (with up to 200 ppm of Ti six orders of magnitude greater than that of controls, 880 ppb of Al, and 250 ppb of V). Spleen Al levels and liver Ti concentrations can also be markedly elevated in patients with failed titanium-alloy implants (Jacobs *et al.*, 1994a).

Particle Distribution

Variables influencing accumulation of wear debris in remote organs are not clearly identified. When the magnitude of particulate debris generated by a prosthetic device is increased, it seems likely that a corresponding elevation in both the local and systemic burden of particles may be expected. Thus, component loosening, duration of implantation, and the modular designs of contemporary hip and knee replacement prostheses provide the potential for increased generation of metallic and polymeric debris (Fig. 12). Wear particles found disseminated beyond the periprosthetic tissue are primarily in the sub-micron size range. Numerous case reports document the presence of metallic, ceramic, or polymeric wear debris from hip and knee prostheses in regional and pelvic lymph nodes (Fig. 13) along with the findings of lymphadenopathy, gross pigmentation due to metallic debris, fibrosis (buildup of fibrous tissue), lymph-node necrosis, and histiocytosis (abnormal function of tissue macrophages), including complete effacement of nodal architecture. The inflammatory response to metallic and polymeric debris in lymph nodes has been demonstrated to include

FIG. 13. Polarized light micrograph (orig. 190 \times) of paraaortic lymph node demonstrates the abundance and morphology of birefringent particles within macrophages. The larger filamentous particles were identified by infrared spectroscopy to be polyethylene.

immune activation of macrophages and associated production of cytokines. Metallic wear particles have been detected in the paraaortic lymph nodes in up to 70% of patients with total joint replacement components.

Lymphatic transport is thought to be a major route for dissemination of wear debris. Wear particles may migrate via perivascular lymph channels as free or phagocytosed particles within macrophages. Within the abdominal paraaortic lymph

FIG. 14. Epithelioid granulomas (A) within the portal tract of the liver (orig. 40 \times) and (B) within the splenic parenchyma (orig. 15 \times) in a patient with a failed titanium-alloy total hip replacement and symptomatic hepatitis. (C) Backscattered SEM of a granuloma in the spleen (orig. 3000 \times) demonstrating titanium alloy particles.

nodes the majority of disseminated particles are submicron in size; however, metallic particles as large as 50 μm and polyethylene particles as large as 30 μm have also been identified. These particles may further disseminate to the liver or spleen where they are found within macrophages or, in some cases, as epithelioid granulomas throughout the organs. Within liver and spleen, the maximum size of metallic wear particles is nearly an order of magnitude less than that in lymph nodes, indicating there may be additional stages of filtration preceding the lymphatic system or alternate routes of particle migration. In the liver and spleen, as in the lymph nodes, cells of the mononuclear-phagocyte system may accumulate small amounts of a variety of foreign materials without apparent clinical significance. However, accumulation of exogenous particles can induce granulomas or granulomatoid lesions in the liver and spleen (Fig. 14). It is likely that the inflammatory reaction to particles in the liver, spleen and lymph nodes is modulated, as it is in other tissues, by (1) material composition, (2) the number of particles, (3) their rate of accumulation, (4) the duration for which they are present, and (5) the biologic reactivity of cells to these particles. Metallic particles in the liver or spleen have been more prevalent in subjects with previously failed arthroplasties when compared with cases of well-functioning primary joint replacements. Metal particles, unlike polyethylene debris, can be characterized using an electron microprobe, which allows identification of individual, submicron metallic wear particles against a background of particulates from environmental or sources other than the prosthetic components. Overall, the smallest disseminated particles identifiable, using the microprobe are approximately 0.1 μm in diameter. However, metallic wear debris may extend into the nanometer range, suggesting that additional methods of

specimen preparation and analytic instrumentation may be required to more fully define the high burden of metallic wear particles in remote tissues (Urban *et al.*, 1995, 2000).

Polyethylene particles comprise a substantial fraction of the disseminated wear particles in subjects with revision and those with primary TJAs. While the presence of these polyethylene particles in lymph nodes can be confirmed by Fourier transform infrared spectroscopy microanalyses, polyethylene particulates in liver and spleen have so far precluded unequivocal identification. In these sites, the size of wear particles may be much smaller than 0.1 μm , making differentiation impossible by polarized light microscopy or infrared spectroscopy.

Diseases that cause obstruction of lymph flow through lymph nodes, such as metastatic tumor, or that cause generalized disturbances of circulation, such as chronic heart disease or diabetes, may be expected to decrease particle migration to remote organs. Other diseases, such as acute or chronic-active inflammation in the periprosthetic tissues, may increase particle migration (Jacobs *et al.*, 1999a, 2001; Vermes *et al.*, 2001b).

Hypersensitivity

Some adverse responses to orthopedic biomaterials are subtle and continue to foster debate and investigation. One of these responses is “metal allergy” or hypersensitivity to metallic biomaterials. Released ions, although not sensitizers in on their own, can activate the immune system by forming complexes with native proteins. These metal-protein complexes are considered to be candidate antigens (or allergens) in human clinical applications. Polymeric wear debris are not easily chemically degraded *in vivo* and have not been implicated as sources

of allergic-type immune responses. This is presumably due to the relatively large degradation products associated with the mechanical wear of polymers *in vivo*, which may be large enough to prevent the formation of polymer-protein haptenic complexes with human antibodies (Hallab *et al.*, 2000a, b, c, 2001a, b).

Metal hypersensitivity is a well-established phenomenon. Moreover, dermal hypersensitivity to metal is common, affecting about 10–15% of the population. Dermal contact and ingestion of metals have been reported to cause immune reactions that most typically manifest as skin hives, eczema, redness, and itching. Although little is known about the short- and long-term pharmacodynamics and bioavailability of circulating metal degradation products *in vivo*, there have been many reports of immunologic type responses temporally associated with implantation of metal components. Individual case reports link hypersensitivity immune reactions with adverse performance of metallic clinical cardiovascular, orthopedic and plastic surgical and dental implants. These phenomenon were discussed in Chapter 4.5.

Metals accepted as sensitizers (haptenic moieties in antigens) include beryllium, nickel, cobalt, and chromium, while occasional responses have been reported to tantalum, titanium, and vanadium. Nickel is the most common metal sensitizer in humans followed by cobalt and chromium. Cross sensitivity reactions between metals are common. Nickel and cobalt are, reportedly, the most frequently cross reactive. The amounts of these metals found in medical-grade alloys are shown in Table 3.

Type IV delayed type hypersensitivity (DTH) is a cell-mediated type of response with which orthopedic implant-associated hypersensitivity reactions (metal sensitivity or metal allergy) are generally associated. Metal-antigen sensitized T-DTH lymphocytes release various cytokines that result in the accumulation and activation of macrophages. The majority of DTH participating cells are macrophages. Only 5% of the participating cells are antigen-specific T lymphocytes (T-DTH cells), within a fully developed DTH response. The effector phase of a DTH response is initiated by contact of sensitized T cells with antigen. In this phase T cells, which are antigen-activated, are termed T-DTH cells and secrete a variety of cytokines that recruit and activate macrophages, monocytes, neutrophils, and other inflammatory cells. These released cytokines include IL-3 and GM-CSF, which promote hematopoiesis of granulocytes; monocyte chemotactic activating factor (MCAF) which promotes chemotaxis of monocytes toward areas of DTH activation; INF- γ and TNF- α , which produce a number of effects on local endothelial cells facilitating infiltration; and migration inhibitory factor (MIF), which inhibits the migration of macrophages away from the site of a DTH reaction. Activation, infiltration, and eventual migration inhibition of macrophages is the final phase of the DTH response. Activated macrophages, because of their increased ability to present class II MHC and IL-2, can trigger the activation of more T-DTH cells, which in turn activates more macrophages, which activates more T-DTH cells, and so on. This DTH self-perpetuating response can create extensive tissue damage.

The first apparent correlation of eczematous dermatitis to metallic orthopedic implants was reported in 1966 by

Foussereau and Lauggier, where nickel was associated with hypersensitivity responses. Over the past 20 years growing numbers of case reports link immunogenic reactions with adverse performance of metallic cardiovascular, orthopedic and plastic surgical and dental implants. In some instances clinical immunological symptoms have led directly to device removal. In these cases reactions of severe dermatitis (inflammation of the skin), urticaria (intensely sensitive and itching red round wheals on the skin), and/or vasculitis (patch inflammation of the walls of small blood vessels) have been linked with the relatively more general phenomena of metallosis (metallic staining of the surrounding tissue), excessive periprosthetic fibrosis, and muscular necrosis. The temporal and physical evidence leaves little doubt that the phenomenon of hypersensitivity to metal released from orthopedic implants does occur in some patients. These cases of severe metal sensitivity raise the greatest concern.

Incidence of Hypersensitivity Responses among Patients with Metal Implants

Some studies have shown that the incidence of metal sensitivity among patients with both well and poorly functioning implants is roughly twice as high as that of the general population, approximately 25% (Fig. 15). Furthermore, the average incidence of metal sensitivity among patients with a “failed” implant (in need of revision surgery) is approximately 50–60% (Fig. 15). This is greater than five times the incidence of metal sensitivity found in the general population and two to three times that of patients with metal implants. This increased prevalence of metal sensitivity among patients with a loose prosthesis has prompted the speculation that immunological processes may be a factor in implant loosening.

Specific types of implants with greater propensity to release metal *in vivo* may be more prone to induce metal sensitivity. Failures of total hip prostheses with metal-on-metal bearing surfaces were associated with greater incidence of metal allergy than similar designs with metal-on-ultrahigh molecular weight polyethylene bearing surfaces. Alternatively, several published reports have indicated that after total joint replacement with metallic components some patients show an induction of metal tolerance; that is, previously diagnosed metal sensitivity abated after implantation of a metallic prosthetic.

Additionally confounding to any clear connection between metal sensitivity and implant failure is the lack of any reported correlation between incidence of metal sensitivity and implant residence time, infection, reason for removal, or pain. This lack of causal evidence implicating cell-mediated immune responses has prompted some to conclude that implantation of cemented metal-to-plastic joint prosthesis is safe, even in the case of a preexisting metal allergy. However, this is not a consensus opinion. At this time, however, it is unclear whether metal sensitivity causes implant loosening or whether implant loosening results in the development of metal sensitivity.

The majority of investigations conclude that metal sensitivity can be a contributing factor to implant failure. Such cases include instances in which clinical immunological symptoms lead directly to the need for device removal. In these

FIG. 15. A compilation of investigations showing the averaged percentages of metal sensitivity among the general population for nickel, cobalt, and chromium, among patients after receiving a metal containing implant, and among patient populations with failed implants. All subjects were tested by means of a patch or LIF test.

or similar cases there have been reported reactions of severe dermatitis, urticaria, and/or vasculitis all presumably linked to what has been reported as metallosis, excessive periprosthetic fibrosis, and muscular necrosis. The clinical observation of apparent immune sensitivity to metallic implants is not limited to orthopedic surgery. Some case reports suggest metal sensitivity to pacemakers, heart valves, and reconstructive, dental, and general-surgical devices. The temporal and physical evidence associated with such cases leaves little doubt that the phenomenon of metal-induced hypersensitivity does occur in some cases, currently accepted within the orthopedic community to be <1% of patients. However, it is currently unclear whether metal sensitivity exists only as an unusual complication in a few susceptible patients, or is more subtle and common phenomenon, which over time plays a significant role in implant failure. It is likely that cases involving implant-related metal sensitivity have been underreported because alternate causes were attributed to failure of the implant. Mechanisms by which *in vivo* metal sensitivity occurs have not been well characterized. Thus, the degree to which a pre-condition of metal hypersensitivity may elicit an overaggressive immune response in a patient receiving an implant remains unpredictable. Continuing improvements in immunologic testing methods will likely enhance future assessment of patients

susceptible to hypersensitivity responses (Hallab *et al.*, 2000a, b, c, 2001a, b).

Carcinogenesis

The carcinogenic potential of the metallic elements used in TJA remains an area of on-going research. Animal studies have documented the carcinogenic potential of orthopedic implant materials. Small increases in rat sarcomas were noted to correlate with high serum cobalt, chromium, or nickel content from metal implants. Furthermore, lymphomas with bone involvement were also more common in rats with metallic implants. Implant site tumors in dogs and cats—primarily osteosarcoma and fibrosarcoma—have been associated with stainless steel internal fixation devices.

Initially, epidemiological studies implicated cancer incidence in the first and second decades following total hip replacement. However, larger, more recent studies have found no significant increase in leukemia or lymphoma; although these studies did not include as large a proportion of subjects with a metal-on-metal prosthesis. There are constitutive differences in the populations with and without implants that are independent of the implant itself, which confound the interpretation of epidemiological investigations.

The association of metal release from orthopedic implants with carcinogenesis remains conjectural since causality has not been definitely established in human subjects. The identification of such an association depends both on the availability of comparative epidemiology and on the ability to perform tests on the patient before and after device removal. The actual number of cases of tumors associated with orthopedic implants is likely underreported. However, with respect to the number of devices implanted on a yearly basis the incidence of cancer at the site of implantation is relatively rare. Continued surveillance and longer-term epidemiological studies are required to fully address these issues (Gillespie *et al.*, 1988; Visuri and Koskenvuo, 1991; Matheisen *et al.*, 1995; Nyren *et al.*, 1995).

Preventive Strategies and Future Directions

Current strategies designed to address the problem of biomaterial-related implant failure are primarily aimed at decreasing the amount of periprosthetic particulate burden and any subsequent effects. Recently there has been a great deal of innovation regarding stronger, more wear-resistant polyethylene. These more highly cross-linked UHMWPE polymers are currently in various phases of clinical trial. However, initial results show demonstrable decrease in polyethylene wear with potential for less particulate induced bioreactivity/osteolysis and therefore greater implant performance. In the same vein, femoral heads with diameters of 32-mm have been associated with increased volumetric polyethylene wear; to combat this smaller 28-mm heads are currently extolled as more biocompatible. Manufacturing flaws such as fusion defects and foreign-body inclusions have also been suggested to contribute to adverse polyethylene wear properties. The elimination of polyethylene is another approach being investigated clinically in various centers. With the realization that early problems may have been related to the design and not the articulation, there has been a renewed interest in the application of metal-metal and ceramic-ceramic bearings. Future designs that attempt to reduce wear include: improved tolerances between polyethylene inserts and their metal backing, improved surface finish on the metallic concave surfaces, secure locking mechanisms, and the avoidance of holes on the convex portion of the acetabular prosthesis.

Metallic wear is also being addressed through techniques such as nitriding and nitrogen ion implantation to decrease the potential for abrasive wear and fretting in titanium alloy and cobalt alloy stems. Fabrication of metallic bearing surfaces with extremely low roughness can be expected to decrease articular wear rates. A polished metal head can be made as smooth as a ceramic head. Polishing of the stem will remove surface asperities and decrease particle generation from stem/bone fretting. In addition, enhanced polishing could minimize any secondary surface contamination.

New metallic biomaterials are being proposed that attempt to improve load transfer to the bone and reduce the incidence of loosening and thigh pain. Currently used alloys (Co-Cr-Mo alloy, $E = 227$ GPa and Ti-6Al-4V alloy, $E = 115$ GPa) have relatively high elastic moduli that limit smooth

transfer of load to the surrounding bone in THA. Designs to improve load transfer can use a reduced cross-sectional area to increase flexibility, but at the expense of adequate stability of the implant within the bone. Additionally, the stresses may exceed the relatively low fatigue strength of Co-Cr-Mo implant alloy. Lower-modulus, more corrosion-resistant implant alloys are being developed. A Ti-13Nb-13Zr ($E = 79$ GPa) alloy is one such alloy that contains fewer elements of questionable cell response (i.e., Co, Cr, Mo, Ni, Fe, Al, V), and that possesses comparable strength and toughness to existing Ti-6Al-4V implant alloy. The Nb and Zr constituents seek to improve bone biocompatibility and corrosion resistance. Additionally, novel surface treatments on implant alloys such as the diffusion hardening (DH) treatment proposed for the Ti-13Nb-13Zr alloy can produce a hardened surface with wear resistance superior to that of Co-Cr-Mo alloy, currently the industry leader. These enhanced surface properties may lead to an improvement in the resistance to microfretting occurring within femoral head-neck taper regions and modular interfaces of current implant designs.

Electrochemical corrosion of orthopedic implants remains a significant clinical concern. Although the freely corroding implants used in the past have been replaced with modern corrosion-resistant "super alloys," deleterious corrosion processes have been observed in certain clinical settings. Attention to metallurgical processing variables, tolerances of modular connections, surface processing modalities, and appropriate material selection can diminish corrosion rates and minimize the potential for adverse clinical outcomes. For example, nitriding can reportedly significantly reduce the magnitude of fretting corrosion of Ti-6Al-4V devices. A need to further investigate the mechanical-electrochemical interactions of metal oxide surfaces in implants persists. Characterization of the stresses and motion needed to fracture passivating oxide films as well as the effects of repeated oxide abrasion on the electrochemical behavior of the interface and ultimately the implant remain avenues of active investigation.

The clinical significance of elevated metal content in body fluids and remote organs of patients with metallic implants needs to be further elucidated. Considerably more work will be required to discern the specific chemical forms and distribution of metal degradation products associated with the various forms of implant degradation. Additionally uncharacterized is how these degradation products interact with proteins *in vivo* in terms of (1) metal-ion/protein complexes, (2) nanometer-particle/protein complexes (ion-like particles) and (3) particle/protein-biofilm complexes. Although much has been revealed regarding the deleterious end effects of particulate debris (e.g., osteolysis) little is known of how in terms of cellular mechanics this phenomenon occurs. Therefore, an understanding of both the constituents of orthopedic implant degradation and their biological ligands is necessary to investigate and ultimately characterize their associated toxicity and bioreactivity. The importance of this line of investigation in the evaluation of orthopedic biomaterial performance is growing as the use of present implant is increasing, as new orthopedic implants are being developed (Fig. 16) and as expectations of implant durability and performance increase (Jacobs *et al.*, 1996); (Black, 1996).

FIG. 16. The LINK SB Charité III artificial disk showing the range of standard sizes available. This design consists of an UHMWPE sliding core, which articulates unconstrained between two highly polished metal endplates, simulating the natural movement of spine (i.e., the nucleus within its annular containment).

QUESTIONS

1. What are the general qualifications for orthopedic biomaterials and what are the two major types of orthopedic implants?

ANS: Generally orthopedic implants must be capable of load bearing and are used in either in bone fixation or total joint arthroplasty.

2. (a) What is the primary problem associated with the longevity of current total joint replacement implants and why? (b) How could this be solved by improved biomaterials?

ANS: (a) Particle and wear debris generation at the articulating surfaces of total joint replacements causes aseptic loosening of the implants through the induction of inflammation around the implant (macrophage-particle overload) which causes a decreased production of new bone and increased bone resorption. (b) More wear-resistant materials at the articulating surface while maintaining current available levels of other mechanical properties.

3. What are the primary cytokines associated with particle-induced osteolysis, and what is the primary cell type involved in this process?

ANS: The primary cytokines associated with osteolysis are TNF-alpha, IL-6 IL-1, prostaglandin E₂, etc., produced by macrophage interaction with particulate debris from implants.

4. What are the seven primary orthopedic implant biomaterials?

ANS: (a) Co-base alloys, Ti-base alloys, stainless steel, PMMA, UHMWPE, alumina, and zirconia.

5. Name one new orthopedic biomaterial and why it was introduced (i.e., what specific problem/deficit it is attempting to solve).

ANS: Zirconium alloy was introduced to decrease the amount of metallic wear debris being generated at the bearing surface and as an alternative metal less likely to induce hypersensitivity reactions.

6. What is one way in which current designs of orthopedic implants are creating more challenging conditions for biomaterials to overcome and why?

ANS: Increasing popularity and degree of orthopedic implant component modularity is creating more interfacial surfaces from which implant debris can be generated through fretting corrosion and interact both locally and systemically.

7.8 DENTAL IMPLANTATION

A. Norman Cranin and Jack E. Lemons

The most frequent surgical procedure performed upon humans is dental extraction. Without question, the most frequently employed prosthesis is the complete or partial denture (Fig. 1). These are available as both fixed and removable devices. Most often, they are supplied in the latter form owing to their relative ease of production as well as economy. There are numerous instances where, because of a paucity of natural teeth, a lack of posterior teeth (required as abutments), or in the presence of anatomic aberration resulting from traumatic, congenital, or metabolic causes, the most desirable type of prosthesis, the fixed or nonremovable type, cannot be used. In such circumstances, surgical implants may be placed to anchor prosthetic denture superstructures. Depending on the areas requiring such devices and the purposes which they must serve, dental implants are available in a variety of materials and an abundant number of designs (Cranin *et al.*, 1987; Worthington, 1988).

HISTORY

The Egyptians were known to have secured teeth to the jawbone with gold wire, and through the centuries, surgeons have sought techniques for implanting tooth substitutes, with little reported success. In the days of the American Revolution, seamen were attacked in darkened waterfront areas and their teeth extracted, to be implanted into the mouths of the wealthy and more fortunate gentry. Those biologic specimens were

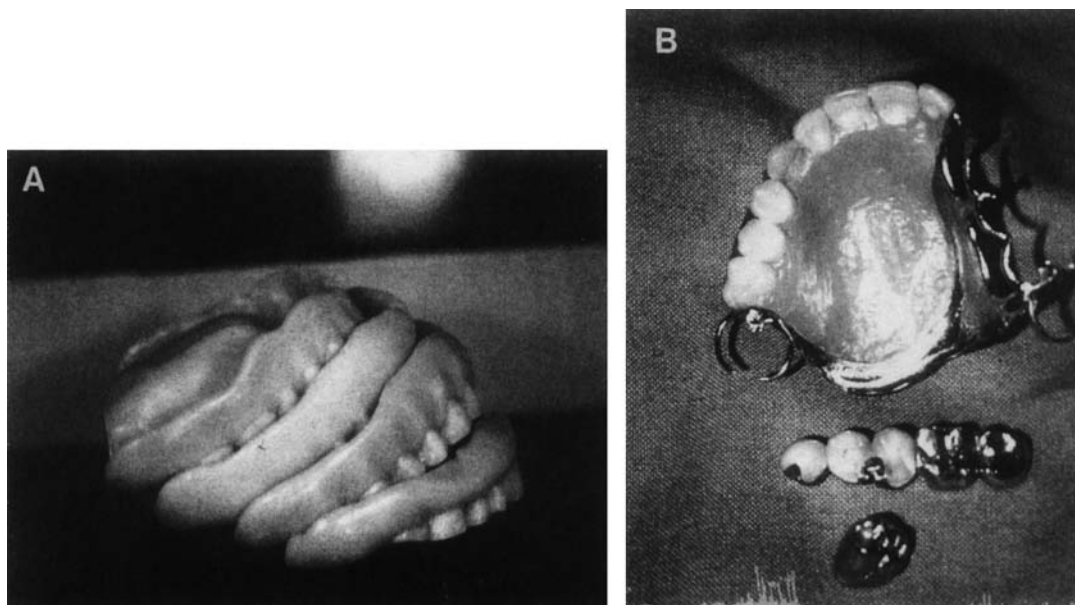

FIG. 1. (A) Complete, removable dentures are the prosthetic replacement used by most edentulous people. As can be seen in this picture, some denture wearers find it difficult to accommodate to conventional prostheses. They represent one segment of the population who can be helped with the use of dental implants. (B) Removable partial dentures, fixed partial dentures (bridges), and crowns are widely accepted replacements for missing teeth.

lost quickly owing to the immune responses of the recipients (Guerini, 1969; Cranin, 1970; Driskell, 1987).

In the early 20th century, Greenfield reported on the implantation of circular gold and platinum cribs as artificial dental roots, to which porcelain teeth were attached by a slotted coupling device. Later, the Strock brothers, using a Vitallium cast in the shape of self-tapping wood screws (after the work of Venable and Stuck), implanted more than dozen cast alloy screws as free-standing dental implants. One was reported to have survived for over 20 years (Strock, 1939; Strock and Strock, 1949). The most consistent dental implant reported in the first half of this century, and which initiated the current era of enthusiasm, was the subperiosteal device. It was introduced by Gershkoff and Goldberg (1949). Enthusiasts flourished, and reports of long-term success came from all parts of the world. These castings, made from nonferrous, cobalt-chromium-based alloys, were employed at first only for completely edentulous mandibles, and in so doing satisfied a significant and popular need. The individual who required single or unilateral implants, however, was not served well by adaptations of these early subperiosteal implants (which, for the first few years were not fabricated from direct bone impressions, but rather, by using a “guesswork” X-ray or intraoral replica template measuring system) (Weinberg, 1950). In 1951, Berman introduced the direct bone impression, which created opportunities for more accurate, longer lasting, and more predictable subperiosteal implants (Berman, 1951) (Fig. 2).

In 1947, Formaggini discovered a technique for placing the first of the modern-day, endosteal root-form implants (Formaggini, 1947). His method was improved by Rafael Chercheve, whose system was heralded universally (Chercheve,

FIG. 2. This direct bone impression of a surgically exposed maxilla using a polysulfide material shows the accurate anatomic reproduction produced. The model produced from this impression will be used to fabricate a cast cobalt-based alloy subperiosteal implant (see Fig. 6).

1956) (Fig. 3). Those root forms, however, failed to serve all patients who were in need because their large dimensions could not be accommodated by the commonly found posterior alveolar ridge, which was thin because of atrophy after tooth loss.

Roberts in 1967 made a laminar-shaped stainless steel device that he called a blade implant. It was placed in a narrow osteotomy that all but the thinnest ridges could accept and showed considerable promise (Roberts and Roberts, 1970).

FIG. 3. These Chercheve implants are being used to help support a fixed (nonremovable) bridge in conjunction with the natural teeth (1974).

FIG. 4. The one-piece blade implant made of commercially pure titanium is a laminar appliance designed to fit into jawbone ridges too thin to accommodate the three-dimensional root-form types. The insertion operation requires the cutting of a longitudinal bone groove into the alveolar crest.

Linkow developed this device into a globally acceptable system by creating a wide variety of sizes and shapes designed to fit almost any clinical requirement and by changing the biomaterial to unalloyed titanium (Linkow, 1968). The 1970s were the era of popularity for the blade endosteal implant (Fig. 4).

The concept of osseointegration was developed and the term coined by Professor Per-Invar Branemark at the University of Goteburg, Sweden. Osseointegration has been defined as a direct structural and functional connection between ordered, living bone and the surface of a load-carrying implant (Branemark, 1983). The initial concept stemmed from vital

FIG. 5. The NobelBiocare implant (designed by Branemark) is completely buried under the gum with its superior border level with or slightly below the crest of bone. These submergible implants are left buried for a healing period of 3–6 months, at which time they are uncovered and coupled to permucosal abutments that will be used a foundations for dental prostheses.

microscopic studies of bone and other tissues, which involved the use of an implanted titanium chamber containing an optical system for transillumination. The investigators observed that the screw-shaped titanium chambers became incorporated within the bone tissue, which actually grew onto the irregularities of the titanium surface (Branemark *et al.*, 1969). These findings led to research exploring the possibilities of artificial root replacement. The experimental studies that followed involved extraction of teeth in dogs and their replacement by osseointegrated screw-shaped implants. Fixed prostheses were connected after an initial healing period of 3 to 4 months during which they bore minimum load (Fig. 5). Radiologic and histologic studies showed that integration could be maintained for 10 years in dogs, without inflammatory reactions. Further, the load-bearing capacity of the individual implants was shown to be extremely high. Based on these findings, the Foundation for osseointegration and the Branemark Implant System were established in 1962. Basic research continued in the years that followed and the first edentulous patient was treated in 1965 (Branemark, 1983).

Clinical data on osseointegrated implants were presented to North America at a scientific meeting held at Toronto in 1982 (Zarb, 1983). Success rates of 90–100%, initially presented by the Swedish group, were confirmed by longitudinal follow-up studies from over 50 osseointegrated implant centers around the world (Adell, 1983; Laney *et al.*, 1986; Albrektsson *et al.*, 1988).

Today, osseointegrated implants are used to treat both partially edentulous and completely edentulous ridges. Severely atrophied ridges, however, required several surgical procedures involving bone augmentation to prepare the host site for acceptance of endosteal devices. A staunch group of implantologists continues to utilize the subperiosteal implant for those patients who are considered untreatable by endosteal root-form or blade-type devices.

The main disadvantage of the subperiosteal implant continued to be the necessity of performing a two-stage operation; the first, a direct bone impression in order to make the implant

casting, and the second, 24 hours to 6 weeks later, in order to insert the casting surgically. Using computer-based design and machining technology (CAD/CAM), Truitt and James, in 1982, introduced a method by which computerized axial tomography (CT) scans of facial skeletons could be employed to generate relatively accurate models of the jawbones. These models then were used to develop subperiosteal implant castings (Truitt *et al.*, 1986). Such castings have served successfully and have eliminated the need for first-stage, bone-impression surgery (Fig. 6). More recently, because of studies performed by Cranin (1998), which demonstrated inaccuracies of CAD-CAM technology,

newer techniques for replication, such as stereolithography, were introduced. The 1980s also witnessed a wide range of root-form, two-stage endosteal implants following the work of Branemark, using numerous adaptations of his original threaded device. These have incorporated materials and designs that include press-fit (nonthreaded) configurations and coatings of alumina, hydroxylapatite, and titanium oxide plasma spray, as well as roughened surfaces created by blasting or etching techniques (Lemons, J. E. 1977. Surface conditions for surgical implants and biocompatibility. *J. Oral Impl.* 7(3): 362–374. Niznick, 1982; Kay *et al.*, 1986; Kirsch, 1986)

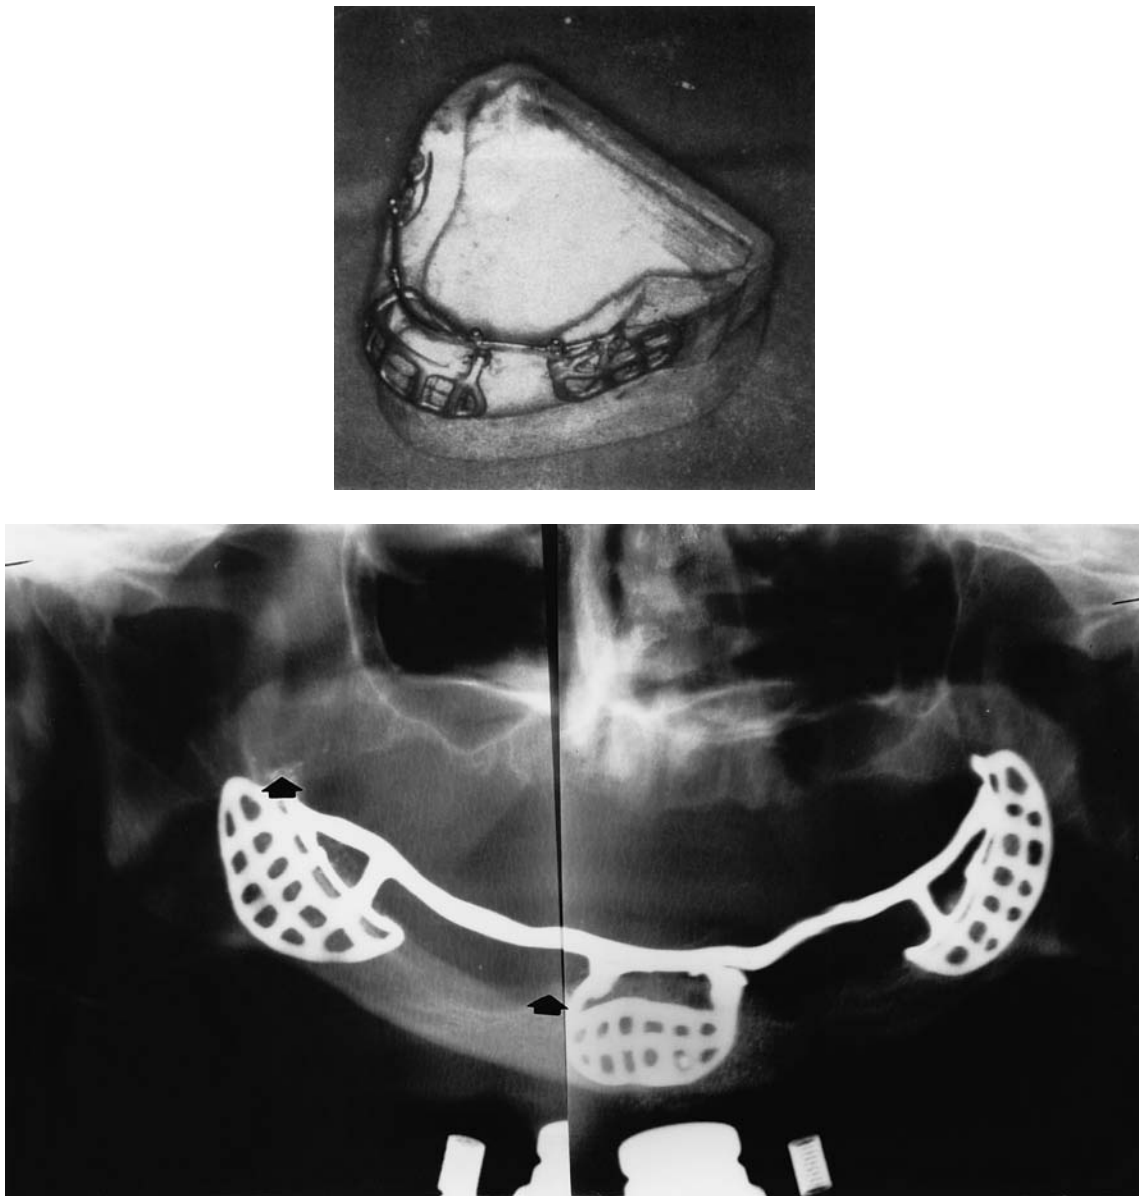

FIG. 6. CAD/CAM-generated models of the mandible or maxilla eliminate first-stage bone impression surgical procedures (see Fig. 2) for subperiosteal implants. Seen here is the mandibular tripodal subperiosteal implant that fits on the bone beneath the gum. Only the post and bars protrude to serve as retainers for dental prostheses. (B) A panoramic radiograph shows the aggressive extensions of newer designs.

FIG. 7. Exact size and shape holes (osteotomies) are made to accommodate (endosteal) implants placed within the bone. This hydroxylapatite (Integral) coated press-fit implant is stabilized initially by a precise frictional grip.

FIG. 8. These threaded, root-form implants are supplied in a wide variety of sizes and lengths. Each is supplied with a number of abutments designed to accommodate many prosthetic situations.

(Figs. 7 and 8). Self-tapping implants have also broadened the field to a level that now offers the clinician a large and often confusing spectrum of implant varieties, the benefits of some remain unclear, and the selection of which is dependent upon a number of poorly defined criteria and prejudices (English, 1988). Of more recent interest are the one-stage root form implant, first introduced by ITI, and the immediate-load philosophy (Schnitman, 1988), which can be practiced with all forms of threaded root-form implants, both one- and two-stage. The latter is accomplished by simply attaching the abutment to the implant body at the time of its insertion. The obvious advantages of this technique are the saving of from 3 to 6 months of time awaiting osseointegration, the elimination of a second surgical procedure, and the availability of abutments for immediate use.

CURRENTLY USED IMPLANT MODALITIES

Designs and Methods

Dental implant designs can be separated into two categories called endosteal (endosseous), which extend into the bone tissue, or subperiosteal systems, which contact the exterior bone surfaces (Lemons, 1988). These are shown schematically in Figs. 5 and 6. The endosteal forms, such as root forms (cylinders, screws), blades (plates), transosseous or staples, ramus frame, and endodontic stabilizers, are placed into the bone as shown. In contrast, the subperiosteal devices are fitted to the bone surface as customized shapes while bone plates are placed into the bone under the periosteum and fixed with endosteal screws.

Synthetic materials for root form devices were originally fabricated from precious metals such as gold, platinum, iridium, and palladium. Cost and strength considerations soon resulted in the development and use of alloys and reactive group metals such as tantalum, titanium, and zirconium, and the inert cast and wrought cobalt- (stellites) and iron (stainless steel)-based alloy systems. Since the 1950s, materials formerly used for general industrial applications (automotive, aircraft, aerospace, etc.) have been reconstituted to include a wide range of metals and alloys, ceramics and carbons, polymers, combinations and composites (ASTM, 2002). Some commonly used biomaterials for early dental implants are listed in Table 1.

The more commonly used biomaterials for endosteal implants are titanium and titanium alloy, aluminum oxide, and surface coatings of hydroxyapatite. The cobalt based casting alloys are most often used for the subperiosteal implant devices (McKinney, 1991). Since the properties of these biomaterials are quite different from one another, specific criteria must be applied to each device design and clinical application. These details are discussed in the following sections.

Subperiosteal

Subperiosteal dental devices may be used for partially and completely edentulous jaws and are the implants of choice for those regions that contain insufficient bone to accommodate endosteal implants of either the blade- or root-form varieties (Schnitman, 1987). They consist of a mesh-type infrastructure cast of a surgical-grade cobalt-chromium-molybdenum alloy to which are attached from four to six perimucosal abutments. Atop these protrusions into the oral cavity may be prosthetic abutments to serve as retainers for fixed bridge prostheses or retentive bars, which connect the abutments together into a single structure. These may be used to gain the retention of overdentures (Yurkstas, 1967; Dalise, 1979; Cranin *et al.*, 1978) (Figs. 9 and 10). Subperiosteal implants are cast to models of maxillae or mandibles made either by direct bone impressions using polysulfide or poly(vinyl siloxane) elastomeric impression materials or by CAD/CAM-generated models. They are designed to rest on the cortical bone and are entrapped and fixed by a reattachment of periosteal fibers through the numerous interstices incorporated into their infrastructural designs. When successful, they are purely incidental to local tissue physiology (James, 1983).

TABLE 1 Examples of Early (Prior) Endosteal Implants

Name	Material	Description	Stages	Surface	Primary retention	Length (mm)	Diameter (mm)
Brånemark (Nobelpharma)	Titanium, commercially pure (CP)	Threaded screw	2	Machined	Threading (bone tapping, self tapping)	7, 10, 13, 15, 18, 20	3.75
Core-vent	Titanium alloy	Threaded hollow basket	2	Sand blasted	Threading, core (self-tapping)	7, 10, 13, 15, 18	4.0
TPS screw	Titanium (CP)	Threaded screw	1	Plasma spray	Threading	8, 11, 14, 17, 20	3.5, 4.0
IMZ (Interpore)	Titanium (CP)	Bullet shaped	2	Plasma spray, optional hydroxylapatite	Press fit	8, 10, 13, 15	3.3
						8, 11, 13, 15	4.0
Integral (Calcitek)	Titanium (CP)	Bullet shaped	2	Hydroxylapatite	Pres fit	8, 10, 13, 15	3.25, 4.0
Kyocera (Bioceram)	Single crystal sapphire	Threaded screw	1	Smooth, porous	Threading	E: 19.5, 22, 25 S: 19.5, 23 20.5, 24	3.3, 4.2 3.0, 4.0 4.2, 4.8
Tubingen	Aluminum oxide polycrystal porous	Stepped	1	Aluminum oxide stippled	Press fit	21, modifiable	4.0, 5.0 6.0, 7.0
Stryker	Titanium alloy	Finned	2	Machined, optional hydroxylapatite	Press fit	8, 11, 14	3.5, 4.0 5.0
Bausch and Lomb (Steri-Oss)	Titanium (CP)	Threaded screw, bullet shaped	2	Machined, optional hydroxylapatite	Threaded screw, Press fit	12, 16, 20 8, 10, 12, 14, 16 12, 16, 21	3.5 3.8 4.0

FIG. 9. The Brookdale bar is attached to an underlying subperiosteal infrastructure (see Fig. 6) by four to six permucosal posts. A denture prosthesis is designed with clips that attach to the bar for stabilization.

Relatively high levels of success have been attributed to these subperiosteal implants, particularly the newer mandibular tripodal configurations as well as the pterygohamular maxillary designs (Linkow, 1986; Cranin *et al.*, 1985) (Fig. 11). When CAD/CAM-generated castings were used, slight inaccuracies were sometimes experienced which were treated with

FIG. 10. The undersurface of a denture designed to clip on to a subperiosteal implant bar.

particulate bone substitute materials such as hydroxylapatite, which were used as local fillers (Fig. 12).

Endosteal

Blade Type The blade- or plate-type designs are available in one-piece (with attached abutment) or submergible (with separate to-be-attached abutment) configurations

FIG. 11. The maxillary unilateral pterygoamular subperiosteal implant is used to provide posterior abutments for nonremovable (fixed) bridges in the maxilla. It is designed to fit against the maxillary, palatal, zygomatic, and pterygoid bones, which are reliable sources of cortical support.

FIG. 13. One-piece blade implants such as the Cranin anchor design have been used successfully as distal abutments or pier abutments for fixed (nonremovable) bridges. The entire structure, with the exception of the protruding dental abutment, is placed within the confines of the jawbone. The abutment protrudes to serve as a prosthetic retainer.

FIG. 12. Minor discrepancies that may occur between the subperiosteal implant fabricated on a CAD/CAM model and the jaw upon which it rests are grafted with hydroxylapatite granules, a synthetic bone replacement material. Materials like this (tricalcium phosphate, pmma/pHema) are osteoconductive materials that serve as reliable but nonosseous fillers.

FIG. 14. Submergible blade implants with prosthetic heads that are attached to the implant at the date subsequent to surgery allow for a stress-free healing period.

(Figs. 13 and 14). They are fabricated in a great variety of designs of relatively pure surgical-grade titanium or titanium–aluminum–vanadium alloy. With the aid of clear plastic templates, these may be employed in an almost limitless number of host sites. In addition, several manufacturers supply the surgeon with one- and two-piece titanium blade-form blanks. These may be fashioned and cut to almost any shape or size that the potential surgical site demands. If the implantologist cannot find an implant that will satisfy a need within the broad spectrum of manufactured designs, or believes in the anchor (“shoulderless”) philosophy (Fig. 13), a custom casting may be made by using distortion-free dental and CT scan radiographs to incorporate dimensional accuracy (Cranin, 1980;

Baumhammers, 1972). Cobalt alloy is the biomaterial most often used for such castings.

True osseointegration (a direct bony interface) does not routinely occur when intraosseous slot osteotomies are created for blade implant placement by using high-speed fissure-bur operative techniques. There is a question as to whether two-stage submergible blades fare better than the one-piece implants (particularly since the buried components permit the protrusion of a threaded cervix through the mucosa). Nonetheless, reports from the literature support blade-form endosteal implants with success for periods exceeding 10 years. James and others reported that the mechanism of support is fibro-osseous suspension (integration). They indicated that a sling of connective tissue fibers suspends the implant within its bony crypt, and

FIG. 15. The receptor site for blade implants (such as the one shown in Figs. 13 and 14) is made freehand with a saline-cooled high-speed bur (250,000 rpm). First, a dotted line following the length and position of the implant is made. Then the dots are connected to form the groove receptor site. (See Fig. 4.)

that upon biomechanical stimulation of these fibers caused by mastication, an environment of osteogenesis occurs which creates continual bone anabolism. (James, 1988; Weiss, 1986). These implants, which require a reasonable level of surgical skill to insert, demand the use of freehand, high-speed, saline-cooled capabilities (Fig. 15). They may be used as unilateral posterior abutments for fixed bridge prostheses or in a wide variety of prosthetic functions, such as supports for full coping bar/overdentures or even as single tooth supports. Their prognosis is judged by some to be less predictable because of the support mechanism afforded them—a fibrous sling or hammock that permits micromovement and is accompanied by a slow exteriorization with epithelial downgrowth from the point of permucosal penetration.

Root-Form Types Long-term clinical experience has proven osseointegration to be a reliable modality for treating edentulism, making root-form implants the most popular and compelling implant design. Currently more than 80 companies are manufacturing implants and implant-related products. Most of the root-form implants available today follow the basic principles of design for successful osseointegration, which were outlined by the Swedish group at Goteburg (Albrektsson, 1983) (Fig. 8) (Table 1).

The first factor is the materials and biomaterials used in manufacturing such implants. The Branemark (NobelBiocare) and many other implants are made from commercially pure

(CP) titanium. Upon exposure to air or water, it quickly forms an oxide layer of 8–10 nm at room temperature. This oxide layer makes titanium extremely corrosion resistant, particularly in the biologic environment. The alloyed form of titanium (Ti6Al4V) is also widely used to manufacture these type devices. Titanium alloy has been shown to be as biocompatible as commercially pure titanium and to have superior mechanical properties (Williams, 1977).

The second factor is the design of the implant. It must be constructed to encourage initial stability in its osteotomy. It has been shown that micromovement or displacement of the implant relative to its host site during initial healing can destroy the network of immature preosseous collagenous tissue, which serves as the scaffold for bone development. Such “togging” will lead to fibrous repair instead of bony regeneration (Brunski, 1979). In the root-form type systems initial stability is achieved by the helical shape of the implant, which is inserted in a threaded osteotomy (in cases of less dense bone, the implant itself may be used for threading during the insertion procedure). Other endosteal designs include cylindrical or press-fit configurations, spiral shapes, finned cylinders, sintered balls, and partially hollow cylinders. Cylindrical implants are sometimes coated with either titanium plasma spray or calcium phosphate compounds (hydroxylapatite). These surface treatments offer more surface area and initial retention, which allow for precision of fit of the implants in the osteotomies, prevention of micro motion during the initial healing period and subsequent improved prognoses, particularly in less dense bone. Hydroxylapatite, because of its chemical similarity to osseous tissues, forms an attachment with bone, independent of any mechanical interlocking mechanism. This concept has been described by the term “biointegration” (Kay, 1986; Meffert, 1988; Niznick, 1982; Kirsch, 1986).

The third factor necessitates the use of a surgical technique, which prevents excessive heat generation during preparation of the host site. It has been shown that the heating of bone to a temperature of 47°C or above for over 30 sec causes vascular damage and alters its vitality (Ericsson *et al.*, 1983). To minimize mechanical and thermal trauma, the surgical protocol involves the use of specially designed spiral, helical, or spade drills of graduated lengths and diameters (Cranin, 1991) (Fig. 16). Most bone preparations are carried out at a maximum rotational speed of 2000 rpm and under profuse internal and external irrigation through hollow-core drills.

Finally, another factor for achieving a direct bone-to-implant interface is the suggested technique of maintaining newly placed implants within bone spared from mechanical forces or loads. It has been shown that for successful osseointegration the individual implant should not be loaded for a period of at least 3 months in the mandible and 6 months in the maxilla. Most currently used systems achieve this by producing two-piece designs. As such, these submerged implant systems require two surgical procedures. At the first-stage surgery, the implants (submergible portions) are inserted into the bone and the overlying mucosa is closed, protecting the implants from mechanical loads and oral microbiota. After a 3- to 6-month (or longer in cases of bone grafted sites) period of healing, the second surgical stage of abutment connection is carried out. The bone remodeling process continues after the implant

FIG. 16. A variety of instruments is used to create precise holes within the bone for the root-form implants. Twist drills, bi- and tri-spade drills (two cutting edges and three cutting edges, respectively), as well as bone taps to thread the bone all help to make an exacting atraumatic procedure. This set of color-coded drills designed by Cranin and produced by the Brasseler Corp. is available in its own sterilizable carrier. Each drill is no more than 500 μm greater in diameter than the next in the series. These small increments ensure greater and less traumatic drilling accuracy. The final osteotomies are threaded with the specific bone taps made by the company that supplies the root form implants. They are used at speeds as low as 6 rpm and have hollow cores that allow passage of a bone-cooling irrigant.

is loaded with dental prostheses for an additional period of months to years (Fig. 17). More recently, the concept of immediate loading has gained more popularity. There are a growing number of one-piece, nonsubmerged implant systems available, although the ITI System championed the technique in the 1980s. These are placed in a single surgical procedure and are permitted to protrude into the oral cavity immediately after insertion. Some practitioners follow this philosophy, which permits the implant to be placed into immediate service as a functioning abutment. Clinical longitudinal studies have demonstrated successful osseointegration using such one-stage implantation techniques (Buser *et al.*, 1990; Misch, 1999) (Fig. 18). Among the benefits offered by the one-stage method is a great telescoping of treatment time. In addition, Hruska (Cranin, 1987) introduced an intraoral welding machine that provided the prosthodontist with an instant post-surgical connecting bar permitting the immediate provision of an internally clipped overdenture (Figs. 9 and 10).

In the past 5 years, with the levels of root form implant success becoming so predictable, attention of surgeons have turned to more sophisticated problems such as esthetics. Great attention has been given to the appearance of the completed prosthesis at the gum margin. Whereas pink acrylic had been the medium used to solve the unattractive dark shadows caused by metal crown margins, recent skills have been devoted to the surgical creation and/or preservation of natural gingival papillae and margins with great and rewarding success (Tarnow, 2000).

One of the significant problems encountered by planning teams is a paucity of bone required for the placement of root-form implants, both in height and in width. Advanced techniques in optimizing potential host sites by bone grafting, both autogenous and allogeneic, in granular and block forms have been introduced in the past 15 years (Cranin, 1991, 1999). Significant assistance is offered to the surgeon with use of CT scans taken of their patients with radiopaque markers placed in their mouths. The resultant images delineate with great accuracy the potential host site locations, dimensions, and bone quality (Fig. 19). Recently, surgeons that are more aggressive have discovered the benefits of the zygomatic buttresses as sources for implant retention. The 30+-mm-long implants utilized for these sites are inserted via a palatal-oblique approach and require significant skill in order to be successful (S. Perel, 2000).

Root-form implants are used as abutments for single crown, fixed-cementable bridges, fixed-detachable bridges (anchored by screws), and overdentures. The latter may be retained to the underlying mesostructure bars using Lew attachments (locking bars) (Lew, 1973) (Fig. 20), Hader and similar clips (Fig. 10), "O" rings, and other similar, simple devices, but also may employ the extremely complex technique of retention by spark erosion (Fig. 21).

There are a wide variety of other endosteal implant designs that employ bone anchorage to stabilize loose teeth (endodontic implants), to serve as prosthetic abutments (transosteal implants), and to anchor long-span bridges (with a paucity of natural teeth) to the bone (C-M pins) (Cranin, 1999) (Fig. 22).

Endodontic Stabilizer Designs

Endodontic stabilizers are long pins or screws that are of a small enough diameter to be passed through a tooth root canal. Examples of endodontic stabilizers and pins are shown in Fig. 23. These designs of implants are sometimes placed into teeth that have minimal bone and periodontal ligament support. The stabilizer is intended to improve the mechanical force transfer from the tooth and implant to the bone, to increase the tooth stability, and thereby to enhance long-term usefulness. These devices are used with endodontically treated teeth, and a relatively stable seal at the tooth root apex area is critical to long-term stability.

Stabilizers are fabricated with a mechanically rolled or swaged surface configuration to enhance mechanical strength. These are usually titanium, although some designs utilize titanium and cobalt alloy. Smooth surface designs are also available in single-crystal sapphire (aluminum oxide) ceramic.

Transosseous and Staple Designs

Early transosseous screw or post designs were fabricated from cast cobalt alloy, as shown in Fig. 24. These were placed through the anterior region of the mandible and protruded through the gingival into the oral cavity (Cranin, 1970). These protrusions or abutments (usually bilateral at the location) were used to stabilize standard type, soft tissue supported lower dentures. An extension of this clinical concept the endosteal staple (Small, 1980) incorporated an inferior burden plate that connected the two transosteal threaded pins. Additional pins

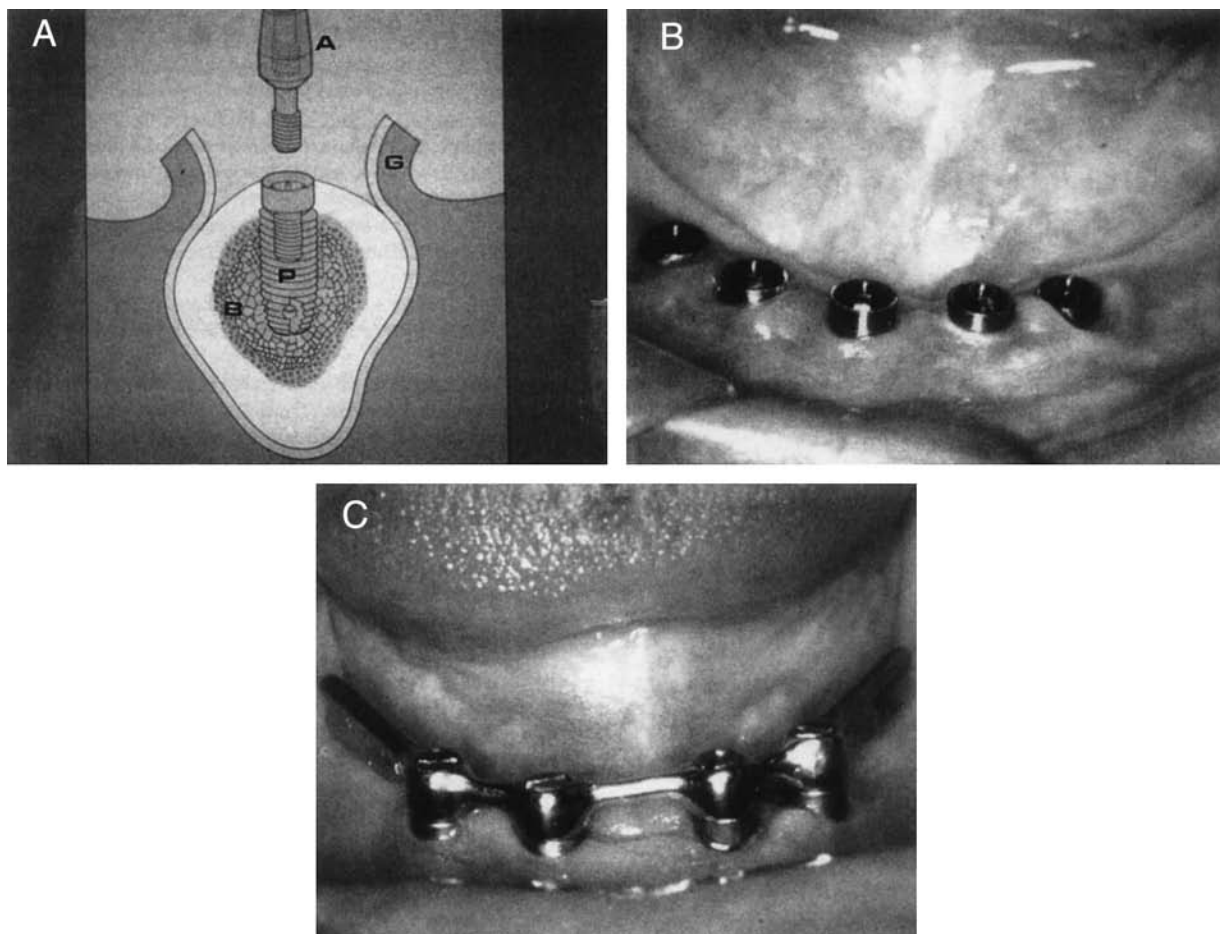

FIG. 17. (A) An abutment is connected to the implant after a 3- to 6-month healing period. The implant (P) rests between the gum (G) while the bone (B) grows into and around the metal structure, granting the firm anchorage known as osseointegration. This cross section shows the gum being opened surgically for placement of the abutment (A). (B) The abutment attaches to the implant, which is buried within the bone. The abutment passes through the gum into the oral cavity. (C) A final anchoring prosthesis such as this bar with four copings is screwed into the implant abutments, which have internally threaded holes. This permits the practitioner to remove this mesostructure bar for evaluation, hygiene, and when necessary, for repair.

and subsequently screws were placed along the plate to penetrate the inferior border of the mandible and thereby provide endosteal support. These designs were fabricated from titanium alloy. Some designs were also fabricated from gold alloy. More recent versions now include bone screw stabilizers and hydroxyapatite coatings to enhance mechanical stability within the bone.

Ramus Frames

The ramus frame implants are also intended for treatment of the edentulous mandibular arch. Several commercially marketed ramus frame designs are available in Fig. 25. The anterior endosteal portion of these devices is placed into the central symphysis of the mandible, while the posterior extensions or blades are implanted into the ascending ramus or distal mandibular regions. The extensions along the posterior (distal) regions, and additional surface tabs were added as design changes in an attempt to enhance resistance to bone resorption and to

progressive settling into the bone of the mandible during long-term use. These devices are utilized as one-stage restorative systems in patient treatments. Many of these devices are placed in patients who are completely edentulous and the patient starts to use the denture the first day after surgery. Thus, the frame-supported lower denture, stabilized by the bone insertions, articulates with a tissue-supported upper denture.

Plates, Screws, and Wires

Bone plates, screws, and wires used in oral and maxillofacial surgery are very similar to those used in orthopedic surgery. On a relative basis, more of the oral surgical implants are fabricated from titanium as compared with orthopedic devices, and, in general, they are smaller in dimension. A wide range of dental design configurations exists that is intended to stabilize both simple and complex craniofacial bone lesions. All commonly used plates, screws, and wires are constructed from metals and alloys (Fig. 26).

FIG. 18. This X-ray shows an implant that was loaded immediately after its insertion. Three days later a prosthetic crown was cemented to it.

FIG. 20. The Lew attachment is a stainless steel, two-piece device (Park Dental Research Corp.) that is embedded into the flange of an overdenture. It serves when in closed position (C) to lock the prosthesis beneath an implant bar, and when the button is pulled out by the patient (O), it serves to release it.

Intramucosal Inserts

One design listed as a dental implant is the mucosal implant series. These are small, mushroom-shaped buttons that are fabricated into the denture base and protrude from the denture surface (Fig. 27). The buttons are located using a surgical procedure so that they penetrate into the adjacent mucosa. Epithelial cells line the crypt around the buttons during healing; therefore

FIG. 19. These cross-sectional images, derived from a CT scan (DentaScan), show a series of cuts through the canin/premolar area of the maxilla. Depth, width, and location of the maxillary sinus are in evidence. In addition, the radiopaque objects in the lower sections indicate the planned location of an implant as delineated by a barium-filled tooth placed in the radiographic template.

FIG. 21. (A) Electron discharge machining or spark erosion techniques were used to mill this mesostructure bar shown attached to implants with fixation screws. (B) The armature or skeleton to which the porcelain is baked and the denture teeth are processed is milled intimately to fit by a precise frictional relationship to the mesostructure bar. (C) The external surface of this structure is prepared to receive the processed prosthesis. (D) The completed spark erosion fabricated mesostructure bar, with a totally porcelain baked superstructure, may be maintained by a frictional relationship or, if additional retention is desired, by the use of strategically related latches, such as Ceka-like attachments. (See color plate)

these systems are not true implants. However, since they are often placed into freshly prepared soft tissue lesions, implant quality materials and surface conditions are required (e.g., most are passivated stainless steel or titanium). As mentioned most are fabricated from type 316L stainless steel or titanium, with some made from aluminum oxide ceramics. The denture base is constructed from poly(methyl methacrylate), which also is used as an implant biomaterial for orthopedic (bone cement) and dental (bone substitute) applications.

TISSUE INTERFACES

Occlusal forces from the mastication of food are transferred from the intraoral prosthesis throughout the implant abutment and neck (connector) and into the implant-to-tissue interface region. These forces are dissipated through the associated tissues, and the quality of functional stability can be correlated with the relative interfacial stability (micromotion)

over time (Brunski, 1988). Two types of interfacial conditions have been described for functional dental implants: fibrous tissue integration (called pseudo-ligament fibro-osteal integration) (Weiss, 1986) and bone tissue integration (called osseous or osteointegration) (Branemark *et al.*, 1977) (Figs. 24A, B).

Osseointegration

The concept of osseous or osteointegration was initially associated with root-form implant designs, two-stage restorative treatments, and a titanium oxide implant to bone interfacial condition (Branemark *et al.*, 1977). This is described as a direct bone-to-biomaterial interface (without fibrous tissue) for a functioning implant at the optical microscopy limits of resolution ($0.5 \mu\text{m}$). A wide range of implant biomaterials and designs have been shown to exhibit this type of interface for functional dental systems (Rizzo, 1988). Proponents support the concepts that (1) greater force can be transferred along

FIG. 22. This thin ridge implant, CM (crete mince) is manufactured in Switzerland. Its maximum width is 2 mm and it is supplied in lengths of up to 20 mm (A). To be effective they must be used in multiples (B).

bone interfaces; (2) direct association or attachment eliminates or minimizes interfacial movement (slip); and (3) periodontal soft-tissue regions are more biomechanically stable.

Interestingly, both osseous and fibrous tissue interfaces have provided functional situations for dental implant devices over 15 or more years (Rizzo, 1988). Clinical trials that have been developed using prospective analysis protocols have provided opinions about the questions related to “which is the best interface.” However, in general, the clinical use of endosteal implants, in terms of sales, demonstrates a strong preference for root-form design titanium and hydroxyapatite type implant systems.

Hydroxyapatite, glass ceramics, porous layers added to metals, and other biomaterial surface modifications have been introduced and developed to enhance bone adaptation to endosteal and subperiosteal implant surfaces (Ducheyne and Lemons, 1988). These surface modifications could result in a more stable implant-to-tissue interface. Clinical data continue to be developed to evaluate relative

FIG. 23. This X-ray shows a transmandibular implant that is anchored by screws to the cortex at the inferior border of the mandible. Adjacent to it are nine endodontic implant stabilizers. These chrome alloy pins are placed through the root canals of teeth with poor bone support and their ends, after passing through the root apices, extend into the surrounding bone, which lends additional retention. They are most successful when cemented into multiple adjacent teeth.

outcomes for different systems, and reports at 10 years show very promising outcomes for multiple design and surface types.

CLINICAL ENVIRONMENT

Repair

As might be expected, bone loss will sometimes be seen around the cervices of root form implants. This phenomenon is known as saucerization (Cranin, 1970). Meffert (1992) established standards for the surgical repair of ailing, failing, and failed implants. The last group was defined as demonstrating mobility and mandated removal. The other two groups, all of which were found to be stable, were essentially salvageable if the prescribed techniques were followed.

Biomechanics

The body of the dental implant contacts the bone and soft tissue interfaces within the submucosal regions. These contact zones within or along the bone surface provides the areas for mechanical force transfer (Bidez *et al.*, 1986). Therefore, the implant-to-tissue interface becomes a critical area for force transfer and thereby the focal point for quality and stability of intraoral function. The implant body is directly connected to the transmucosal (or transgingival) post, which provides the base for the dental bridge abutment. The intraoral prosthesis (crown, bridge, or denture) is attached to the abutment using cement, screws or clips. This arrangement was schematically shown in Fig. 1B.

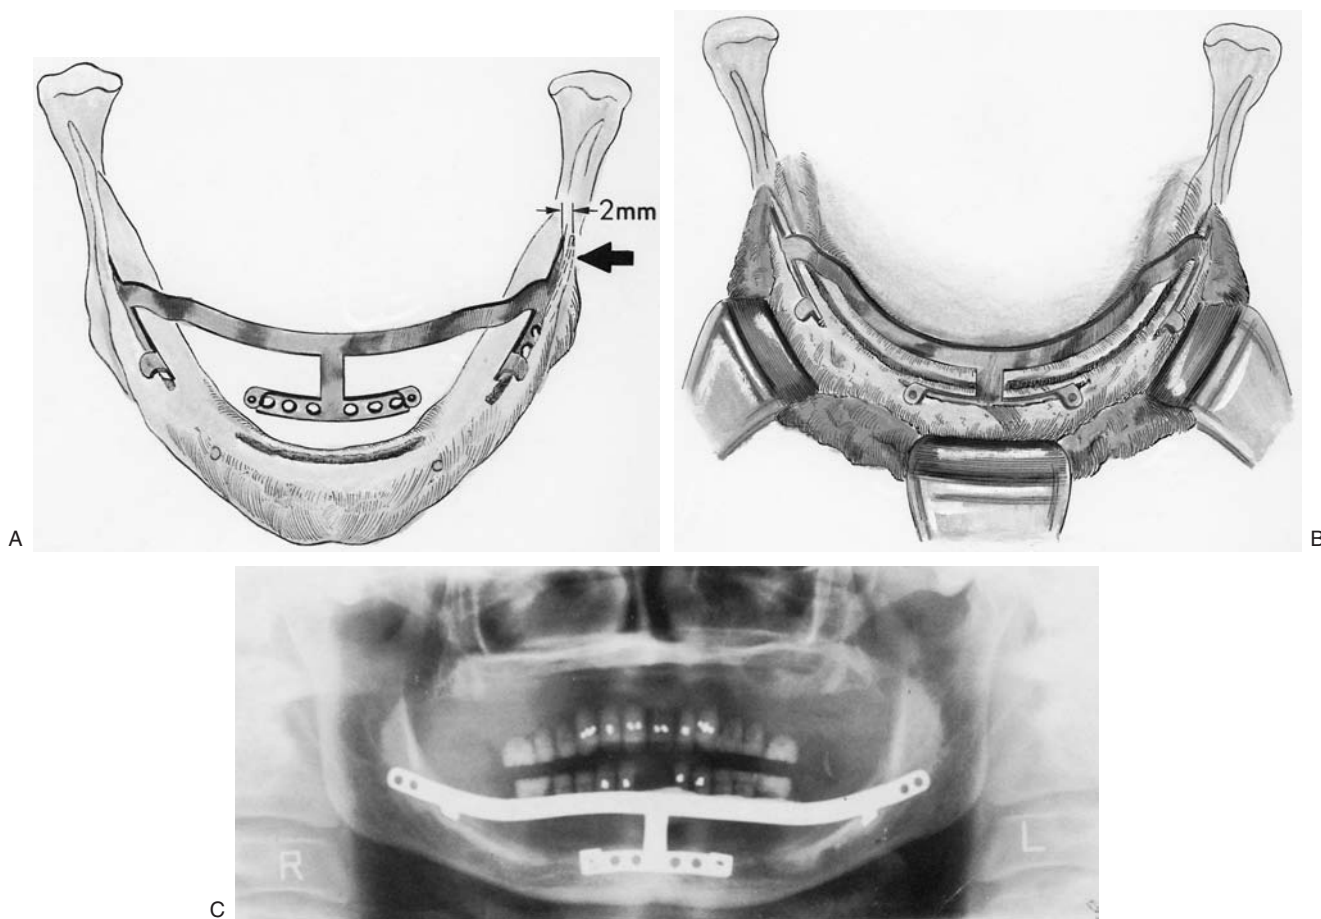

FIG. 24. (A) The ramus frame implant (Roberts and Roberts, 1970) is placed into three blade-type osteotomies. (see Fig. 4.) (B) It is tapped into the precut bone slots until the seating tabs become flush with the surrounding bone. (C) When successful, these implants will survive as retentive devices for overdentures, for many years.

The dental implant device provides a percutaneous connection from the submucosal to the oral environment resulting in a very complex set of conditions (Meffert, 1988). The oral cavity represents a multivariate external environment with a wide range of circumstances (e.g., foods and abrasion, pH, temperatures from 5 to 55°C, high magnitude forces, bacteria). Stability requires some type of seal between the external and internal environments, which of course depends upon both the device and the patient. The most significant reason for this is discovery by Robert James (1974) of hemidesmosomes, i.e., microscopic suction cups that were shown to be responsible for the adhesion of epithelial cells to polished implant cervices, thereby sealing their infrastructures from the onslaught of the challenging oral environment.

Fortunately, the oral environment and the associated tissues are known to be very tolerant and resistant to external challenges.

Crown, Bridge, and Denture Restorations

Intraoral prostheses involve a wide range of metals, ceramics, polymers, and composites. Since many of these intraoral

devices are mechanically or chemically (cemented) attached to the dental implants, biomaterial interactions become a part of the overall restorative treatment. Therefore, each implant modality must be evaluated to ensure that adverse biomaterial of biomechanical conditions are not introduced through incorrect selection (Lemons, 1988). For detailed information, the reader is referred to dental material textbooks (Craig, 1985; Leinfelder and Lemons, 1988; Phillips, 1991; Cranin, 1999; Lemons and Cranin-Prior edition of book).

Fixed Restorations

Most root-form and blade (plate) systems use restorative treatments in which the implant is rigidly attached to the intraoral prosthesis. Some systems provide polyethylene or polyoxymethylene spacers within the core of the implant to enhance mobility through the interposition of lower modulus materials, while others require that occlusal surfaces of the teeth be fabricated from polymer-based restorative materials (Kirsch, 1986; Branemark *et al.*, 1977). These variations result in a wide range of treatments being utilized clinically. In this regard, device retrieval analyses have shown some situations where galvanic coupling of dissimilar alloys (see Chapter 6.3)

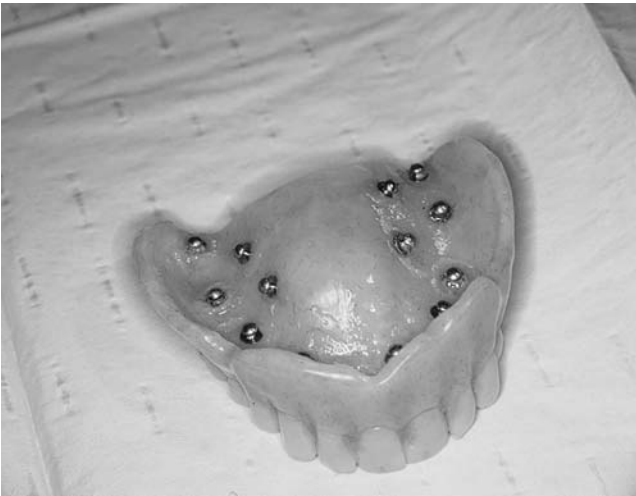

FIG. 25. Intramucosal inserts (Dahl, 1944; Jermyn, 1953) are stainless steel or CP titanium, arrow-head-shaped buttons (Park Dental Research Corp.) that are processed into the tissue-borne surfaces of nonretentive maxillary dentures. The mucosal receptor sites that they lock into offer significant anchorage to them.

or inadequate quality castings that contained porosities and high carbon content have influenced device longevities (Lemons, 1988). At this time, most implant device-related treatment includes a prescription or recommendation for the design and biomaterial of the intraoral prosthesis.

Removable Dentures

The subperiosteal, transosseous, staple, ramus-frame, and mucosal-insert implant designs are associated with removable denture prostheses. The dentures are fastened to the various intraoral connectors or abutments shown in previous figures. The dentures can be attached by a variety of connector types that range from magnets to simple recesses into one of the components. Dentists and dental laboratory personnel have been ingenious in developing these connector systems. In some situations, interlocking devices have evolved to provide what is called “fixed-removable” prostheses.

TRENDS IN RESEARCH AND DEVELOPMENT

The dental implant field has provided a significant contribution to our overall understanding of basic biomaterial and biomechanical properties. The oral cavity provides 28 to 32 candidate implant sites, a necessity for crossing the epithelium to provide functional support, a wide range of anatomical shapes, and an even wider range of environmental conditions. The oral cavity and associated tissues provide a very severe environment for implant biomaterials and designs, and it is interesting to note the trends in research and development within this field.

FIG. 26. These two photomicrographs (original magnification 8×) show the appearance of the bone, connective tissues, and epithelium supporting successful and failing root form, endosteal implants. The histology shows dramatic, stark differences (Cranin *et al.*, 1999).

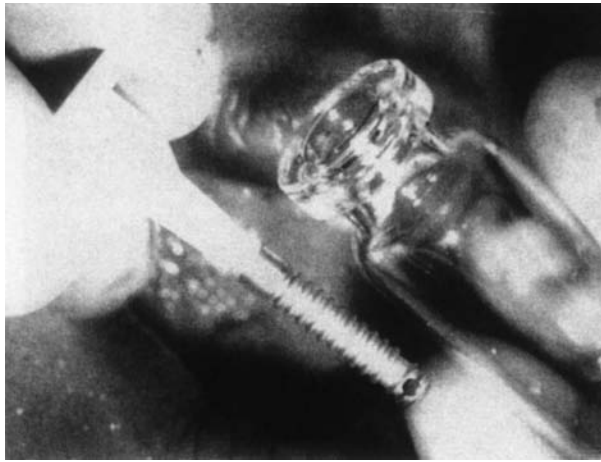

FIG. 27. Root-form implants are packaged within glass or plastic vials sterile and ready for use. Many companies supply the implants attached to their vial covers, which offer easy handling, a primary device for torquing the implant into place, and a method that prevents metallic contamination when other transport instruments might be used.

Conservative Treatment Modalities

In the 1970s, dental implants were judged to be in a longitudinal research and development phase. Typically, they were only used in clinical situations where all other treatments had failed and where bone and soft-tissue health was not compromised for implant-based restorations.

As a result of the reported clinical longevities and the functionalities of several dental implant designs and biomaterials, opinions now reflect the use of implants on a routine basis where they are indicated for dental restoration of normal function. Dental implant-based treatments have moved from the longitudinal research phase in 1970 to a recognized conservative modality in 2003. Important to this change is the quality and quantity of bone and soft tissue available at the time of implant placement. Advances in hard and soft tissue grafting have allowed many patients, who were previously considered poor candidates for dental implants, to undergo oral rehabilitation with the use of dental implants. This trend is expected to continue to provide ever-improved device function and longevity.

GENERAL ASPECTS OF PACKAGING AND PREPARATION

Of the three basic implant types: blades, root forms, and subperiosteals, the first two are usually prefabricated and the last is custom cast. Blades are supplied in titanium or titanium alloy directly from the manufacturer either in sterile packages or in plastic envelopes. Handling them is difficult, because even if they are prepared properly by the maker or user, the benefits of presurgical treatment such as radiofrequency glow discharge, sterility, and freedom from surface lipids or contaminants (e.g., talc from rubber gloves) will be lost owing to the

frequent and sometimes aggressive manipulations necessitated during implantation procedures.

In most instances, root forms are successfully placed on their first insertion, so innovative sterile packaging in small glass or plastic vials is the current method of presentation. These implants need not be touched by the surgeon's fingers and are transferred from package to host site either by the vial covers into which they are inserted and which serve as handles, or in the titanium-tipped forceps, mounting platforms and fixture mounts (Fig. 27).

Because subperiosteal implants are individually cast of cobalt-chromium-molybdenum alloy, the laboratory and the surgical team must treat them individually. They require passivation with dilute acids, defatting using acetone or other organic solvents, ultrasonic cleaning, and, finally, sterilization by autoclaving at 270°F for 20 min (Baier *et al.*, 1986). During surgical insertion, no other metals (stainless steel retractors, suction tips, or seating instruments) should be permitted to touch their surfaces. Baier and co-workers contend that such implants may achieve a more compatible surface condition with the use of radio-frequency glow discharge (RFGD), which sterilizes and creates a surface of maximum wettability. In 1993, Linkow began to use the Ohara technique for casting subperiosteal implants of titanium. They were light, strong, and highly compatible. The problem presented by the technique was that even with a specialized casting machine and method, the metal could not be successfully utilized for complete subperiosteal implants, therefore limiting its benefits.

The implant surgeon, the manufacturer, and the biomaterials scientist, in addition to their basic skills, must acquire a thorough understanding of metallurgy, biocompatibility, and the benefits of proper cleanliness and sterilization so that an appropriate host-site environment will be created to ensure the long-term success of implants.

QUESTIONS

1. What are the most popular metals in use today in dental implantology?
2. How well does bone tolerate invasive procedures? Is heat generated? Are there safe limits to induced temperatures? How can the health of host bone be assured?
3. What are some of the presurgical diagnostic techniques used to assist in planning?
4. Name some of the less frequently used dental implant modalities.

7.9 ADHESIVES AND SEALANTS

Dennis C. Smith

According to a definition of the American Society for Testing and Materials, an adhesive is a substance capable of holding materials together by surface attachment. Inherent in the concept of adhesion is the fact that a bond that resists separation is formed between the substrates or surfaces (adherends) comprising the joint and work is required to separate them.

“Adhesive” is a general term that covers designations such as cement, glue, paste, fixative, and bonding agent used in various areas of adhesive technology. Adhesive systems may comprise one- or two-part organic and/or inorganic formulations that set or harden by several mechanisms.

Commercial adhesive systems are often designed to result in only a thin layer of adhesive for efficient bonding of the two surfaces since thick layers may contain weakening defects such as air voids or contaminants. Such systems may be low-viscosity liquids. In other situations where, for example, the surfaces to be joined are irregular, gap-filling qualities are required of the bonding agent. These systems may be solid–liquid (filled)

adhesives or viscous liquids and are usually referred to as cements, glues, or sealants. Thus, the term “sealant” implies not only that good bonding and gap-filling characteristics are present in the material, but also that the bonded joint is impervious, for example, to penetration by water or air. Since most adhesives, including biomaterials, are used to joint dissimilar materials that are subjected to a variety of physical, mechanical, and chemical stresses, good resistance to environmental degradative processes, including biodegradation, is essential.

The applications of adhesive biomaterials range from soft (connective) tissue adhesives, used both externally to temporarily fix adjunct devices such as colostomy bags and internally for wound closure and sealing, to hard (calcified) tissue adhesives used to bond prosthetic materials to teeth and bone on a more permanent basis. All of these biological environments are hostile, and a major problem in the formulation of medical and dental adhesives is to develop a material that will be easy to manipulate, interact intimately with the tissue to form a strong bond, and also be biocompatible. Over the past two decades, more success at a clinical level has been achieved in bonding to hard tissues than to soft tissues.

The opposing concept to adhesion is *abhesion*, i.e., the deliberate prevention of bonding between surfaces. Such situations may arise in prevention of staining or fouling of surfaces or of adhesions between parenchymatous and surrounding tissue after surgery.

More details on the background to adhesion and adhesives can be found in recent texts (Mittal and Pizzi, 1994; Comyn, 1997; Pocius, 1997; Mittal and Pizzi, 1999). General information on wound closure and surgical adhesives is given in Sierra and Salz (1996) and Chu *et al.* (1997). This chapter does not cover mucosal adhesives such as Polycarbophil or Carbopol.

HISTORICAL OVERVIEW

Wound closure by means of sutures extends back many centuries. The idea of using an adhesive is more recent but dates back to at least 1787 when it was noted “that many workmen glue their wounds with solid glue dissolved in water” (Haring, 1972). Hide glue is similar to gelatin, which itself derives from collagen. Other biological adhesives, such as blood and egg white, have also been known for centuries; however, first attempts to develop adhesives with specific chemical structures began in the late 1940s and 1950s.

Cyanoacrylates

Natural materials such as cross-linked gelatin and thrombin–plasma were investigated, but a major stimulus was provided by the discovery in 1951 of methyl 2-cyanoacrylate by Cooper *et al.* (1972). This clear liquid monomer and its higher homologs (ethyl, butyl, octyl, etc.) were found to polymerize rapidly in the presence of moisture or blood, giving rapid hemostasis and highly adherent films. Extensive clinical and laboratory investigations on the cyanoacrylates took place in the 1960s and 1970s (Matsumoto, 1972), but problems of manipulation and biocompatibility, including reports of cancer in laboratory animals, have limited their current use to surface

applications on oral mucosa and life-threatening arteriovenous situations.

Protein Glues

The discovery of the adhesive properties of the cyanoacrylates prompted numerous studies on synthetic adhesive systems designed to interact with tissue protein side-chain groups to achieve chemical bonding (Cooper *et al.*, 1972). Few systems were found to possess the requisite combination of biocompatibility, ease of manipulation, and effectiveness. As a result of this experience and the more strictly controlled regulatory situation of today, only limited new research is being done on novel tissue adhesives. Work has been reported on synthetic polymerizable systems containing the reactive cyanoacrylate or isocyanate groups (Ikada, 1997; Flagle *et al.*, 1999), but attention has been more focused clinically on materials based on natural origins. Some studies still continue on the gelatin-resorcinol-formaldehyde (GRF) combination (Ikada, 1997) but the main emphasis has been on fibrin glues derived from a fibrinogen-thrombin combination. Other protein- and peptide-based materials have been investigated including fibrin-collagen (Prior *et al.*, 1999), cross-linked albumin (Feldman *et al.*, 1999), and derivatized collagen (DeVore, 1999).

Hydrogels

Light-cured poly(ethylene glycol)-based monomers have been developed to form a series of aqueous hydrogels. These materials can also be used as drug delivery matrices (Coury *et al.*, 1999).

Tooth and Bone Cements

As with soft tissues, interest in adhesive bonding to skeletal or hard tissues as a replacement for, or supplementation to, gross mechanical fixation such as screws has developed mainly in this century and particularly in the past 40 years. Fixation of orthopedic joint components by a cement dates back at least to Gluck (1891) and retention of metal or ceramic inlays and crowns on teeth by dental cements to about 1880. The development of acrylic room-temperature polymerizing (cold-curing) systems for dental filling applications in the 1950s led to their use as dental cements and later to their application for fixation of hip joint components by Charnley and Smith (Charnley, 1960, 1970; Smith, 1971). These situations involved bonding by mechanical interlocking into surface irregularities.

Tooth Adhesives

In the case of tooth restorations, bonding of similar acrylic filling systems using mechanical interlocking resulted in leakage along the bonded interface. This so-called microleakage initiated an intensive effort over the past 40 years to develop adhesive dental cements and filling (restorative) materials (Phillips and Ryge, 1961; Smith, 1991, 1998). This led to the development of poly(acrylic acid)-based adhesive cements, first the

zinc polycarboxylates (Smith, 1967) and then, in 1972, the glass ionomer cements (Smith, 1998), and, to resin bonding systems.

Bonding materials and techniques are now a major component of clinical dentistry (Degrange and Roulet, 2000). Effective clinical bonding of polymerizable fluid dimethacrylate monomers and composite formulations to dental enamel, the most highly calcified (98%) tissue in the body, has been achieved by using phosphoric acid etching of the surface (the "acid-etch" technique). Bonding to tooth dentin is currently achieved by using acidic primer monomeric systems containing functional groups such as polycarboxylate or polyphosphate and hydrophilic monomers such as hydroxyethyl methacrylate (Roulet and Degrange, 2000). Similar materials have been investigated for adhesion to bone that is compositionally similar to dentin (Lee and Brauer, 1989).

Table 1 gives a summary of the compositions of the various materials in current clinical use.

BACKGROUND CONCEPTS

As indicated previously, significant advances in adhesive biomaterials have occurred over the 30–40 years as real progress has taken place in the science and technology of adhesion and adhesives. This development is continuing since the fundamental aspects of the formation of adhesive bonds at interfaces are not yet fully understood even though successful application of adhesives in technically demanding situations has been achieved.

Experience and, to some extent, theory have shown that severe hostile environments such as biological milieu may require specific surface pretreatments for the surfaces being joined in addition to selection of an adhesive with appropriate characteristics (Comyn, 1997). Such surface pretreatments may involve cleaning or etching processes designed to remove contaminants and expose wettable surfaces, and may require the application of primers to achieve specific chemical reactivity at the surface (Mittal and Pizzi, 1999). These procedures are a reflection of the need for intimate interfacial contact between the bonding agent and the adherends in order to form adhesive bonds across the interface. These adhesive forces must hold the materials together throughout the required service life of the joint. However, it must also be appreciated that the factors of the design of an adhesive joint, the applied loads, and the service environment it must withstand will all affect its mechanical performance and life expectancy (Kinloch, 1987; Comyn, 1997; Mittal and Pizzi, 1999).

The establishment of intimate molecular contact between the adhesive and adherend requires, ideally, the adhesive and/or primer to (1) exhibit a zero or near-zero contact angle when liquid, (2) have a low viscosity during bonding, and (3) be able to displace air and contaminants during application. As discussed elsewhere in this volume (Chapters 1.4 and 9.4), surface wetting to achieve these requirements involves an understanding of wetting kinetics and equilibria on clean, high-energy surfaces, the kinetics of spreading of the adhesive including the effects of microroughness, and the minimization of surface contaminants, including moisture, during the bonding process.

TABLE 1 Classification and Composition of Tissue Adhesives

Type	Components	Setting mechanism
Soft-tissue adhesives		
Cyanoacrylate	Butyl or isobutyl cyanoacrylate	Addition polymerization
Fibrin sealants	A. Fibrinogen,	Fibrin clot formation
Factor XIII	B. Thrombin, CaCl ₂	
GRF glue.	Gelatin, resorcinol, formaldehyde	Condensation Polymerization
Hydrogel	Block copolymers of PEG, poly(lactic acid) and acrylate esters	Photoinitiated addition polymerization
Hard-tissue adhesives		
<i>Bone</i>		
Acrylic bone cement	Methyl methacrylate and poly (methyl methacrylate)	Peroxide-amine initiated addition polymerization
<i>Teeth</i>		
Dental cements	Zinc oxide powder, phosphoric acid liquid	Acid-base reaction, Zn complexation
Zinc phosphate		Acid-base reaction, Zn complexation
Zinc polycarboxylate	Zinc oxide powder, aqueous poly (acrylic acid)	Acid-base reaction, metal ion complexation
Glass ionomer (polyalkenoate)	Ca, Sr, Al silicate glass powder aqueous poly (acrylic-itatonic acid) or (acrylic-maleic acid)	Peroxide-amine or photoinitiated polymerization
Resin-based	Aromatic or urethane dimethacrylate monomers, silicate or other glass fillers aqueous poly(acrylic acid-itaconic acid-methacrylate) comonomers	Photoinitiated addition polymerization
Resin-modified glass ionomer	Hydroxyethyl methacrylate aromatic or urethane diamethacrylates, Ca, Sr, Al glass powder	
Dentin adhesive	Etchant: phosphoric acid primer: carboxylate or phosphate Monomers hydroxyethyl methacrylate/water/solvent Bonding agent: urethane or aromatic dimethacrylate monomers	Photoinitiated addition polymerization

Four main mechanisms of adhesion at the molecular level have been proposed (Comyn, 1997; Mittal and Pizzi, 1999): (1) mechanical interlocking, (2) adsorption (including chemical bonding), (3) diffusion theory, and (4) electronic theory. More complex interpretations have been proposed (Schulz and Nardin, 1999) but the validity of each theory is influenced by the system under consideration.

Mechanical Interlocking

This adhesion involves the penetration of the bonding agent into surface irregularities or porosity in the substrate surface. Gross examples of this mechanism include the retention of (a) dental filling materials in mechanically prepared tooth cavities, (b) crowns by dental cements on teeth (Fig. 1), and (c) the fixation of artificial joint components by acrylic bone cement (Fig. 2). Even apparently smooth surfaces are pitted and rough at the microscopic level, and strong bonding can arise with an adhesive that can penetrate at this level. The use of primers (chemical pretreatments) can create surface irregularities or porosities at the microscopic level, or can form porous layers that similarly provide effective micromechanical interlocking. Examples include the etching of dental enamel by 35–40% phosphoric acid (Fig. 3) and primer treatment of tooth dentin with acidic agents (Fig. 4). In each case the unpolymerized bonding agent penetrates 5–50 μm into the surface, creating numerous resin “tags” that provide a strong bond. A further

FIG. 1. Diagrammatic representation of mechanical interlocking by a cement to tooth dentin. Note voids at interface due to imperfect adaptation.

effect of surface roughness may be an increase in the interfacial energy dissipated during joint separation.

Adsorption Theory

This theory postulates that if intimate interfacial molecular contact is achieved, interatomic and intermolecular forces will establish a strong joint. Such forces include van der Waals and hydrogen bonds, donor-acceptor bonds involving acid-base interactions, and primary bond (ionic, covalent, metallic) formation (chemisorption). Numerous studies have suggested that

FIG. 2. Section through femur after removal of stem of hip prosthesis showing mechanical interlocking by bone cement into cancellous bone. (After J. Charnley, personal communication.)

FIG. 3. Dental enamel etched by 30-sec treatment with 35% phosphoric acid showing prismatic structure. Prisms are about 5 μm in diameter.

FIG. 4. Treatment of dentin surface by acidic primer showing demineralised collagen fibers in surface zone.

secondary bonds (van der Waals and hydrogen bonds) alone are sufficient to establish strong bonding. However, where environmental attack is severe (e.g., by water as in biological systems), the formation of primary bonds across the interface seems to be essential (Kinloch, 1987).

Evidence of primary bond formation has been found for commercial adhesives, particularly as a result of the use of chemical primers (e.g., silane coupling agents) on ceramics (Kinloch, 1987; Schulz and Nardin, 1999). In the biomedical field, the poly(acrylic acid)-based dental cements (zinc polycarboxylate and glass ionomer cements) (Fig. 5) have been shown to undergo carboxylate bonding with Ca in enamel and dentin (Smith, 1991, 1998). Silane primers are also used in the bond formation between dental resin adhesives and dental ceramics. Formation of covalent bonds by reaction of acid chloride, aldehyde, or other reactive groups with hydroxyl or

FIG. 5. Diagrammatic representation of setting of zinc polyacrylate and bonding to calcific surface.

amino groups in dentin collagen and/or complexation reactions between dentin Ca and phosphate or carboxyl groups have also been postulated in several reactive polymerizable dentin bonding systems, but no unequivocal evidence for this has yet been presented (Eliades, 1993; Smith, 1998).

Diffusion Theory

This theory states that the intrinsic adhesion of polymers to substrates and each other involves mutual interdiffusion of polymer molecules or segments across the interface. This can occur only when sufficient chain mobility is present. The application of this theory is limited to specific situations. Diffusion of polymers into intimate contact with metallic or ceramic surfaces may in fact result in enhanced adsorption or even micromechanical interlocking as a source of improved bonding. This concept (and others) have led to the idea of an "interphase" that is formed between adhesive and substrate and influences bonding behavior (see below).

Electronic Theory

Electronic theory postulates that electronic transfer between adhesive and adherend may lead to electrostatic forces that result in high intrinsic adhesion. Such interactions may arise in certain specialized situations, but for typical adhesive-substrate interfaces, any electrical double layer generated does not contribute significantly to the observed adhesion (Kinloch, 1987; Schulz and Nardin, 1999).

Weak Boundary Layer

A theory that has an impact on the foregoing adhesion mechanisms is the concept of weak boundary layers at the surface of materials to be bonded, either intrinsic or formed by contamination of the adherends. Such layers may result in the formation of an interphase between adhesive and substrate that may exhibit reduced or altered bonding behavior. Such behavior has led to extensive investigation of cleaning procedures and adhesion primers to optimize the bond (Mittal and Pizzi, 1999).

The evidence presently available suggests that for most biological adhesives, adsorption phenomena or micromechanical interlocking account for the bond formation and behavior observed. Since few practical surfaces, especially tissues, are completely smooth and nonporous, it is likely that both mechanisms exist in practical clinical situations, with one or the other predominating according to the type of adhesive system, surface preparation technique, and bonding environment.

COMPOSITION AND CHARACTERISTICS OF ADHESIVE BIOMATERIALS

Soft-Tissue Adhesives

Most soft-tissue adhesives are intended to be temporary. That is, they are removed or degrade when wound healing is sufficiently advanced for the tissue to maintain its integrity.

FIG. 6. Structures of methyl cyanoacrylate and methyl methacrylate.

Effective adhesion can be obtained on dry skin or wound surfaces by using wound dressing strips with acrylate-based adhesives. However, on wound surfaces that are wet with tissue fluid or blood, the adhesive must be able to be spread easily on such a surface, provide adequate working time, develop and maintain adhesion, desirably provide hemostasis, facilitate wound healing, and maintain biocompatibility. Positive antimicrobial action would be an additional advantage (Ikada, 1997).

Few, if any, systems comply with all these requirements. Currently, there are two principal systems in widespread clinical use—cyanoacrylate esters and fibrin tissue adhesives. Another glue based on a gelatine–resorcinol–formaldehyde combination still receives limited use. An interesting but still experimental system based on polypeptides from marine organisms (mussel adhesive) does not seem to have developed into practical use. These materials have been reviewed (Sierra and Salz, 1996; Chu *et al.*, 1997). More recently a family of synthetic implantable resorbable hydrogel has been developed (A. Coury, 1999, personal communication) that show promise as sealants for the lung and other sites.

Cyanoacrylate Esters

These esters are fluid, water-white monomers that polymerize rapidly by an anionic mechanism in the presence of weak bases such as water or NH_2 groups. Initially, methyl cyanoacrylate (Fig. 6) was used but in the past two decades isobutyl and *n*-butyl cyanoacrylate have been found more acceptable. The higher cyanoacrylates spread more rapidly on wound surfaces and polymerize more rapidly in the presence of blood. Furthermore, they degrade more slowly over several weeks in contrast to the methyl ester, which hydrolyzes rapidly yielding formaldehyde that results in an acute inflammatory response.

These materials achieve rapid hemostasis as well as a strong bond to tissue. However, the polymer film is somewhat brittle and can be dislodged on mobile tissue and the materials can be difficult to apply on large wounds. Because of adverse tissue response and production of tumors in laboratory animals, cyanoacrylates are not approved for routine clinical use in the United States, although a commercial material based on *n*-butyl cyanoacrylate is approved by several other countries.

The current uses are as a surface wound dressing in dental surgery, especially in periodontics, and in life-threatening applications such as brain arteriovenous malformations. Reports of sarcomas in laboratory animals (Reiter, 1987), late complications after dura surgery (Chilla, 1987), evidence of

in vitro cytotoxicity (Ciapetti *et al.*, 1994), and lack of regulatory approval have restricted their further use in spite of work on synthesis of new types of cyanoacrylate.

Fibrin Sealants

Fibrin sealants involve the production of a synthetic fibrin clot as an adhesive and wound-covering agent. The concept of using fibrin dates back to 1909 but was placed on a specific basis by Matras *et al.* in 1972. The commercial materials first available (Tisseel, Tissucol, Fibrin-Kleber) consisted of two solutions that are mixed immediately before application to provide a controlled fibrin deposition. Later a “ready-to-use” formulation (Tisseel Duo) was introduced (Schlag and Redl, 1987).

The essential components of these solutions are as follows:

Solution A:	Solution B:
Fibrinogen	Thrombin
Factor XIII	CaCl_2

The fibrinogen is at a much higher concentration (~70 mg/ml) than that in human plasma. On mixing the two solutions using a device such as a twin syringe with a mixing nozzle a reaction similar to that of the final stages of blood clotting occurs in that polymerization of the fibrinogen to fibrin monomers and a white fibrin clot is initiated under the action of thrombin and CaCl_2 . Aprotinin, an inhibitor of fibrinolysis, may also be included in solution A. The composition may be adjusted to promote hemostasis, for example, or to minimize persistence of the clot to avoid fibrosis.

There are now several commercial products available in Europe, Japan, and Canada; none is presently approved for use in the United States (MacPhee, 1996). Fibrinogen for these commercial materials is manufactured from the pooled plasma of selected donors using processes such as cryoprecipitation. The material is subjected to in-process virus activation and routinely screened for hepatitis and HIV. To minimize these risks recent processes produce the fibrinogen in a “closed” (single-donor) blood bank or utilize the patient’s own blood. This autologous fibrin glue is preferred but its quality is partly determined by the fibrinogen level in the donor plasma (Ikada, 1997). Other complications include formation of antibodies and thrombin inhibitors as well as potential risks of BSE (bovine spongiform encephalopathy) if bovine thrombin is used. More recently, human-derived thrombin has been employed.

Fibrin sealant has four main advantages: (1) it is hemostatic, (2) it adheres to connective tissue, (3) it promotes wound healing, and (4) it is biodegradable with excellent tissue tolerance (Sierra and Salz, 1996; Ikada, 1997; Scardino *et al.*, 1999). The adhesive strength is not as high as that of cyanoacrylates but is adequate for many clinical situations. Thorough mixing of the ingredients and application techniques or devices that allow uniform spreading are essential to success.

The material has been used in a wide variety of surgical techniques for hemostasis and sealing involving thoracic–cardiovascular, neurologic, plastic, and ophthalmic surgery and as a biodegradable adhesive scaffold for meshed skin grafts in burn patients (Sierra and Salz, 1996; Ikada, 1997; Feldman

et al., 1999). A symposium has reviewed current clinical uses (Spotnitz, 1998). An auxiliary aspect of fibrin sealants is their use as a delivery vehicle at local sites for antibiotics and growth factors (Sierra and Salz, 1996).

Attempts to modify fibrin sealant have been directed toward (a) improvements in ease of application and control of setting by use of a one-component light-activated product (Scardino *et al.*, 1999), (b) improvements in strength and performance by addition of fibrillar collagen (Sierra and Salz, 1996), and (c) development of a formulation containing gelatin (Ikada, 1997).

Gelatin-Resorcinol-Formaldehyde Glue

This glue was developed in the 1960s by Falb and co-workers (Falb and Cooper, 1966; Cooper *et al.*, 1972) as a less toxic material than methyl cyanoacrylate. The material is fabricated by warming a 3:1 mixture of gelatin and resorcinol and adding an 18% formaldehyde solution. Cross-linking of the gelatin and resorcinol by the formaldehyde takes place in about 30 seconds.

The material was used in a variety of soft-tissue applications but technical problems and toxicity have limited its application in recent years to aortic dissection (Ikada, 1997). In attempts to overcome the toxicity and potential mutagenicity/carcinogenicity of the formaldehyde component, modified formulations have been developed in which other aldehydes such as glutaraldehyde and glyoxal (Ennker *et al.*, 1994a, b) are substituted for the formaldehyde. Favorable results with this material (GR-DIAL) have been reported (Ennker *et al.*, 1994a, b). Concerns with toxicity remain, however, and this material has not received FDA approval for commercial use. Less toxic gelatin cross-linking agents have been investigated *in vitro* without substantial improvement.

The three foregoing types of adhesives have received extensive clinical trial in Europe and Japan. Fibrin sealant is the most widely used material currently. However, all of these systems have significant deficiencies. This is illustrated by their relative characteristics listed in Table 2 (Ikada, 1997).

Bioadhesives

Bioadhesives are involved in cell-to-cell adhesion, adhesion between living and nonliving parts of an organism, and

adhesion between an organism and foreign surfaces. Adhesives produced by marine organisms such as the barnacle and the mussel have been extensively investigated over the past 30 years because of their apparent stable adhesion to a variety of surfaces under adverse aqueous conditions. These studies have shown that these organisms secrete a liquid acidic protein adhesive that is cross-linked by a simultaneously secreted enzyme system. The bonding probably involves hydrogen bonding and ionic bonding from the acidic groups (Waite, 1989).

The adhesive from the mussel has been identified as a polyphenolic protein, molecular weight about 130,000, which is cross-linked by a catechol oxidase system in about 3 minutes. A limiting factor in the practical use of this material is the difficulty of extraction from the natural source. The basic unit of the polyphenolic protein has been identified as a specific decapeptide (Waite, 1989; Green, 1996). Recombinant DNA technology and peptide synthesis have been used in attempts to produce an affordable adhesive with superior properties. Little information has been reported on the performance (including biocompatibility) of these materials. Green (1996) investigated their potential in ocular sites.

Hydrogel Sealants

A new approach is the development of synthetic sealants based on poly(ethylene glycol) (PEG) hydrogels that are derived from original work of Sawhney, Pathak, and Hubbell (1993). A family of fully synthetic implantable, resorbable hydrogels intended for use as surgical sealants has been developed (Ranger *et al.*, 1997; Alleyne *et al.*, 1998; Tanaka *et al.*, 1999; Moody *et al.*, 1996), for barrier coatings (West *et al.*, 1996) and for drug delivery matrices (Lovich *et al.*, 1998). The hydrogels (Focal Inc.) are formed by *in situ* deposition of aqueous formulations based on specialized macromers followed by photopolymerization to highly cross-linked structures.

The macromers are reactive block copolymers consisting of a water-soluble core such as polyoxyethylene flanking biodegradable oligomers such as poly(lactic acid) or poly(trimethylene carbonate) and polymerizable end caps such as acrylate esters (Sawhney *et al.*, 1993). Control of the physical properties and degradation rates is achieved by specifying the molecular structures and concentration of the reactants in the formulation (Goodrich *et al.*, 1997). Photopolymerization can be effected with ultraviolet or visible light using appropriate photoinitiators. Typically, the initiator system eosin Y-triethanolamine is employed with visible illumination in the 450–550 nm range.

In most applications for these hydrogels, strong bonding to tissue is required. This is achieved by use of a two-part sealant system consisting of primer and topcoat. Strong, durable bonding to a wide variety of internal tissues has been demonstrated (Coury *et al.*, 1999).

Published reports to date have shown these hydrogels to be effective as sealants for the lung (Ranger *et al.*, 1997), dura mater (Alleyne *et al.*, 1998), and blood vessels (Tanaka *et al.*, 1999; Moody *et al.*, 1996) and as local drug-delivery depots (Lovich *et al.*, 1998). Commercialization of the formulations

and associated delivery devices for sealant applications has commenced.

Hard-Tissue Adhesives

Bone Cement

As previously noted, attachment of prostheses to calcified tissues (bone, tooth enamel, dentin) can be achieved by gross mechanical interlocking to machined surfaces. Thus, room temperature-polymerizing methyl methacrylate (Fig. 7) systems are used for fixation of orthopedic implants (e.g., acrylic bone cement; see Chapter 7.7) and for dental restorations. The former, in a closed system, have been relatively successful. However, conditions are much more stringent in the mouth because of the changing environment, thermomechanical stresses on the bond, and the presence of oral bacteria that result in marginal leakage at the tooth-filling interface and renewed tooth decay. Thus, considerable development of new dental cements and adhesive systems has occurred in recent years in the attempts to provide a leak-proof bond to attach fillings, crowns, and veneers to the tooth (Fig. 8).

Dental Cements

Dental cements are, traditionally, fast-setting pastes obtained by mixing solid and liquid components. Most of these materials set by an acid-base reaction and more recent resin cements harden by polymerization (Smith, 1988, 1991, 1998). The compositions of these materials are given in Table 1. The classes and typical mechanical properties are given in Table 3.

Zinc phosphate cement is the traditional standard. This material is composed primarily of zinc oxide powder and a 50% phosphoric acid solution containing Al and Zn. The mixed material sets to a hard, rigid cement (Table 1) by formation of an amorphous zinc phosphate binder. Although the cement is gradually soluble in oral fluids and can cause pulpal irritation, it is clinically effective over 10 to 20 year periods. The bonding arises entirely from penetration into mechanically produced irregularities on the surface of the prepared tooth and the fabricated restorative material. Some interfacial leakage occurs because of cement porosity and imperfect adaptation (Fig. 1), but this is usually acceptable since the film thickness is generally below 100 μm .

Poly(carboxylic acid) cements were developed in 1968 (Smith, 1967, 1998) to provide materials with properties comparable to those of phosphate cements but with adhesive properties to calcified tissues. Zinc polyacrylate (polycarboxylate) cements are formed from zinc oxide and a polyacrylic acid solution. The metal ion cross-links the polymer structure via carboxyl groups, and other carboxyl groups complex to Ca ions in the surface of the tissue (Fig. 5). The zinc polycarboxylate cements have adequate physical properties, excellent biocompatibility in the tooth, and proven adhesion to enamel and dentin (Smith, 1991) but are opaque. The need for a translucent material led to the development of the glass-ionomer cements (Smith, 1998).

The glass ionomer cements are also based on polyacrylic acid or its copolymers with itaconic or maleic acids, but utilize a calcium aluminosilicate glass powder instead of zinc oxide (Smith, 1998). In this case, the cements set by cross-linking of the polyacid with Ca and Al ions from the glass together with formations of a silicate gel structure. The set structure and the residual glass particles yield a stronger, more rigid cement (Table 1) but with similar adhesive properties to the zinc polyacrylate cements. Both cements are widely used clinically.

TABLE 3 Properties of Dental Cements and Sealants

Material	Strength (MPa)			Fracture toughness K_{1C} MN ^{-3/2}
	Compressive (MPa)	Tensile (MPa)	Modulus of elasticity (GPa)	
Zinc phosphate	80–100	5–7	13	~0.2
Zinc polycarboxylate	55–85	8–12	5–6	0.4–0.5
Glass ionomer	70–200	6–7	7–8	0.3–0.4
Resin sealant unfilled	90–100	20–25	2	0.3–0.4
Resin sealant filled	150	30	5	
Resin cement	100–20	30–40	4–6	
Composite resin filling material	350–40	45–70	15–20	1.6

In recent materials, the polyacid molecule contains both ionic carboxylate and polymerizable methacrylate groups and is induced to set, by both an acid–base reaction and visible light polymerization. These dual-cure cements are widely used clinically. Adhesive bonding but not complete sealing is obtained because of imperfect adaptation to the bonded surfaces under practical conditions. A further development involves glass-filled photopolymerized carboxylated methacrylate polymers (resin-modified materials) that are closer to composite resin materials (Smith, 1998).

Resin cements are fluid or paste-like monomer systems based on aromatic or urethane dimethacrylates (Fig. 9). Silanated ceramic fillers may be present to yield a composite composition. The two-component materials polymerize on mixing through a two-part organic peroxide–tertiary amine initiator–activator system in about 3 minutes. More recent are one-component materials containing diketone polymerization initiators that achieve polymerization in about 30 seconds by exposure to visible (blue) light energy. Dual-cure systems are also available. These set materials are strong, hard, rigid, insoluble, cross-linked polymers (Table 1). Bonding is achieved by mechanical interlocking to surface roughness. In recent materials, reactive adhesive monomers may also be present (see below), also conferring a presumed chemisorption mechanism.

Enamel and Dentin Adhesives

Enamel and dentin bonding systems are similar polymer–ceramic composite formulations to resin cements but are more complex systems containing reactive monomers. Their use usually involves first an acidic pretreatment of the tooth surface, then an unfilled bonding composition (primer resin) to achieve good wetting of the tooth surface, followed by a filled bonding agent for the bulk of the bond. These materials are used to attach composite resin restorative materials, ceramic veneers, and orthodontic metal and ceramic brackets to enamel and dentin surfaces. Because of the different composition and physical properties of enamel and dentin (see Chapter 3.4) more complex and greater demands are placed on multi-purpose adhesive systems intended for both tissues. Clinical application of these systems are reviewed by Roulet and Degrange (2000).

Enamel Bonding

Bonding to enamel is achieved by pretreating the surface with 35–50% phosphoric acid for 30–60 seconds as described earlier (Fig. 3). This resulting washed and dried surface is readily wettable and penetratable by resin cements and bonding agents. The resulting resin tags (5–50 μ m long) in the surface of the tissue result in efficient micromechanical interlocking with a potential tensile bond strength of about 20 MPa, equivalent to cohesive failure in the resin or in the enamel.

Dentin Bonding

Bonding to dentin currently involves pretreatment of the prepared (machined) surface with acidic solutions (phosphoric, nitric, maleic acids) or ethylenediaminetetraacetic acid (EDTA) to remove cutting debris (the smear layer). This procedure opens the orifices of the cut dentinal tubules and creates microporosity in the surface (Fig. 4). A primer treatment is then applied that comprises a reactive monomer system (Fig. 10) containing a carboxylate function or a polyphosphate function, depending on the type of product. These primers also contain hydrophilic monomers such as hydroxyethyl methacrylate (HEMA) and may also contain water.

The function of the primer is to penetrate the demineralized dentin surface and facilitate wetting by an unfilled dimethacrylate bonding resin that is subsequently applied. Polymerization of this treatment layer by visible-light activation results in micromechanical bond formation by penetration into the dentin and surface tubules, so forming the so-called hybrid layer (Nakabayashi *et al.*, 1991) or resin-interdiffusion zone (Van Meerbeek *et al.*, 1992). Chemical interaction with the hydroxyapatite and/or proteinaceous phases of the dentin surface may also occur. However, direct chemical evidence has not yet been provided for the postulated interactions (Eliades, 1993; Degrange and Roulet, 2000; Smith, 1998). Under the best conditions, initial tensile bond strengths of 15–25 MPa can be obtained depending on test conditions. The long-term durability of these bonds under oral conditions is being investigated (Roulet and Degrange, 2000).

NEW RESEARCH DIRECTIONS

As a result of the experience of the past two decades, the problems involved in developing an adhesive system for both soft and hard tissues have been addressed and identified. A practical limitation in many systems remains ease of manipulation and application. For example, as noted earlier, the effectiveness of the fibrin sealant is critically dependent on proper mixing of the ingredients and uniform application. It has proved difficult to reconcile short- and long-term

biocompatibility needs with chemical adhesion mechanisms that use reactive monomer system.

Where relatively temporary (less than 30 days) adhesion is required, as in wound healing, systems based on natural models that allow biodegradation of the adhesive and interface and subsequent normal tissue remodeling appear to merit further development. For longer term (years) durability in both soft and hard tissues, hydrophilic monomers and polymers of low toxicity that can both diffuse into the tissue surface and form ionic bonds across the interface seem to be the most promising approaches. Evidence has been obtained of the need for

FIG. 10. Reactive monomer structures for bonding to calcific tissues. (M-R = monomer portion of molecule. (After Asmussen, E., Aranjó, P. A., and Pentsfeld, A., 1989, *Trans. Acad. Dent. Mater.* 2: 59.)

hydrophobic–hydrophilic balance in adhesive monomer systems (Nakabayashi *et al.*, 1991), and the use of hydrophilic monomers such as hydroxyethyl methacrylate in commercial materials has facilitated surface penetration.

Recent development trends in soft-tissue adhesives appear to reflect these approaches. Newer materials (Chu, 1997) comprise cross-linked collagen materials (Colcys), light-cured polymerizable and biodegradable polyethylene glycols (FocaSeal), as noted earlier, photopolymerized derivatized collagen (DeVore, 1999), a bioresorbable hemostatic collagen-derived matrix with thrombin (FloSeal), and serum albumin cross-linked with a derivatized poly(ethylene glycol) sealant. The development of synthetic peptides and materials based on human recombinant components are being investigated.

On calcified surfaces, the use of hydrophilic electrolytes such as the polycarboxylates has demonstrated that proven ionic bonding *in vitro* can also be achieved *in vivo* (Smith, 1998). An advantage of such systems is that surface molecular reorientations can improve bonding with time (Peters *et al.*, 1974). Encouraging preliminary results have been obtained with new glass ionomer hybrid systems and there is considerable scope for the future developments of modified polyelectrolyte cements. Analogous materials based on polyphosphonates are being developed.

The development of more efficient adhesives and sealants that, in addition to enhancing the durability of current applications, would permit new applications such as osteogenic bone

space fillers, percutaneous and permucosal seals, and functional attachment of prostheses is still a challenging problem for the future.

7.10 OPHTHALMOLOGICAL APPLICATIONS

Miguel F. Refojo

Light that penetrates into the eye is partially refracted in the cornea, passes through the aqueous humor and the pupil (the opening in the center of the iris), is further refracted in the crystalline lens, passes through the vitreous humor, and converges on the retina (Fig. 1). Diverse polymeric devices, such as spectacles, contact lenses, and intraocular implants, are used to correct the optical function of the eye. The materials used in spectacle lenses are outside the scope of this chapter. Contact lenses, however, being in intimate contact with the tissues of the eye, are subject to the same regulations that govern the use of implant materials, and they are included in this chapter with other biomaterials used to preserve and to restore vision such as intraocular implants.

CONTACT LENSES

General Properties

Contact lenses are optical devices that must have good transmission of visible light. Pigments and dyes are added to some contact lenses for cosmetic effect. Contact lenses also may have ultraviolet (UV) light-absorbing additives, usually copolymerized in the contact lens material, to protect the eye from the harmful effects of UV light. UV light not absorbed by the normal crystalline lens is harmful to the retina and may contribute to the clouding of the lens (cataract) (Miller, 1987).

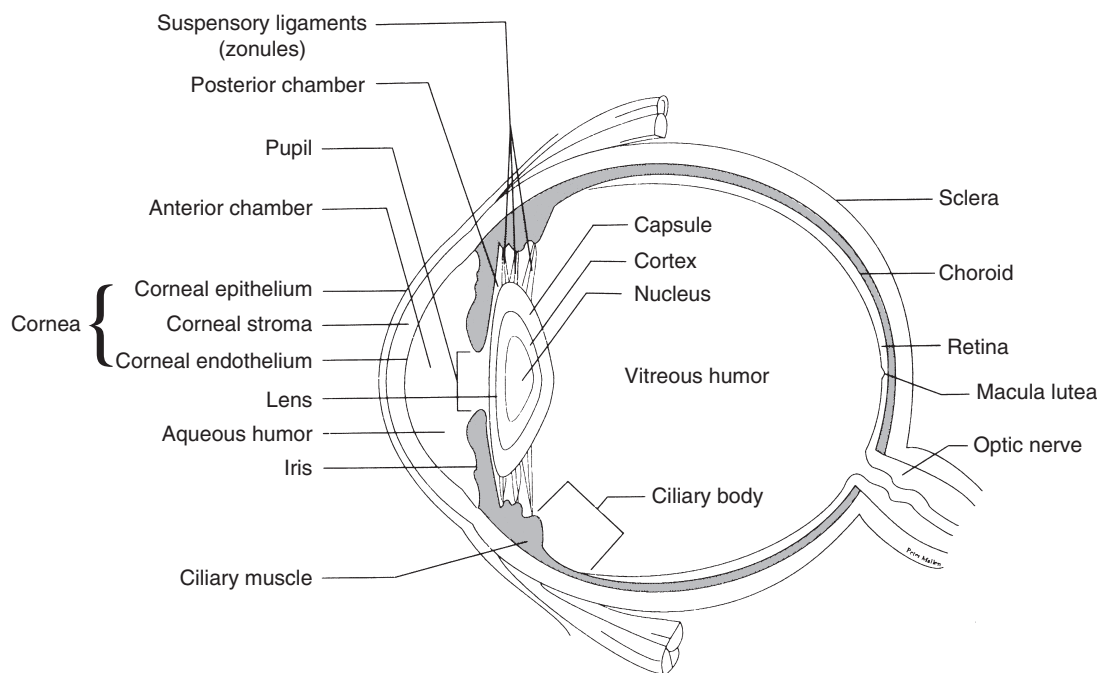

FIG. 1. Schematic representation of the eye.

The principal properties sought in contact lens materials, in addition to the required optical properties, chemical stability, and amenability to manufacture at reasonable cost, are high oxygen transmissibility (to meet the metabolic requirements of the cornea), tear-film wettability (for comfort), and resistance to accumulation on the lens surfaces of mucus/protein/lipid deposits from the tear film and other external sources. Contact lenses also must be easy to clean and disinfect (Kastl, 1995).

Most of the available contact lenses were developed with the most important property of oxygen permeability in mind. The oxygen permeability coefficient, P , is a property characteristic of a material. [$P = Dk$, where D is the diffusivity, in cm^2/sec , and k is the Henry's law solubility coefficient, in $\text{cm}^3(\text{O}_2\text{STP})/[\text{cm}^3(\text{polymer}) \text{ mm HG}]$]. For a given contact lens, its oxygen transmissibility (Dk/L) is more important than the Dk of the material; oxygen transmissibility is defined as the oxygen permeability coefficient of the material divided by the average thickness of the lens (L , in cm) (Holden *et al.*, 1990).

For oxygen permeability, the ideal contact lens would be made of polydimethylsiloxane. For better mechanical properties and manufacture, most silicone elastomeric lenses have been made of diverse poly(methyl phenyl vinyl siloxanes). Because of its hydrophobic character, to be useful, a silicone rubber lens must be treated in an RF-plasma reactor or other suitable procedure to make its surface hydrophilic and tolerated on the eye. (see Chapter 2.4, "Thin Films, Grafts, and Coatings"). Nevertheless, the silicone rubber lenses have not been successful for general cosmetic use, not only because of surface problems and comfort, but principally because they have a strong tendency to adhere to the cornea.

There are currently a wide variety of contact lens materials with diverse physical properties that determine the fitting characteristics of the lens on the eye (Lai *et al.*, 1993).

Soft Hydrogel Contact Lenses

There are essentially two kinds of hydrogel contact lenses (Refojo, 1996). The most common are the original homogeneous hydrogels (see Chapter 2.5), and the newest kind that are made of heterogeneous hydrogels that consist of a water-poor hydrophobic phase of siloxane moieties dispersed within a water-rich hydrophilic phase similar to the standard hydrogels. These heterogeneous hydrogels have highly enhanced oxygen transmissibility compared with the standard hydrogels of similar hydration (Alvord *et al.*, 1998).

Standard Hydrogel Contact Lenses

The standard hydrogel lenses are made of slightly cross-linked hydrophilic polymers and copolymers. The original hydrogel contact lens material was poly(2-hydroxyethyl methacrylate) (HEMA) (Wichterle and Lim, 1960); at equilibrium swelling in physiological saline solution it contains about 40% water of hydration. (Hydration of hydrogel contact lenses is customarily given as a percentage of water by weight, on a wet basis.)

The soft hydrogel contact lenses (SCL) are supple and fit snugly on the corneal surface. Because there is little tear exchange under these lenses, most of the oxygen that reaches the cornea must permeate through the lens. The oxygen permeability coefficient of the standard hydrogel materials increases

exponentially with the water content. These hydrogel materials have a hypothetical limit in oxygen permeability that approaches the oxygen permeability of pure water.

The oxygen transmissibility of the rather thick original PHEMA hydrogel contact lenses was soon found to be insufficient for normal corneal metabolism. Therefore, new hydrogel contact lenses were developed with higher water content or with a water content similar to that of PHEMA but more amenable to fabrication in an ultrathin modality. This takes advantage of the law of diffusion which, applied to contact lenses, will guarantee that for any lens type under the same conditions of wear the oxygen flux through the lens will double when the thickness is halved.

Other conventional hydrogel contact lens materials include HEMA copolymers with other monomers such as methacrylic acid, acetone acrylamide, and *N*-vinylpyrrolidone. Commonly used materials are also copolymers of *N*-vinylpyrrolidone and of glyceryl methacrylate with methyl methacrylate. Newer hydrogel contact lenses are made of poly(vinyl alcohol) and a copolymer of HEMA with a methacrylate of phosphorylcholine (Formula 1). The poly(vinyl alcohol) lens (CIBA) is a daily disposable lens. The other lens (omafilcon A, Proclear, Biocompatibles Inc.) has 59% hydration and apparently better water retention than other conventional hydrogel lenses.

A variety of other monomers and cross-linking agents are used as minor ingredients in many commercial standard hydrogel contact lenses (Lai *et al.*, 1993) (Table 1).

Hydrogel lenses have been classified by the Food and Drug Administration (FDA) in four general groups: I, low water (<50% H₂O), nonionic; II, high water (>50% H₂O), nonionic; III, low water, ionic; and IV, high water, ionic. The ionic character is usually due to the presence of methacrylic acid, which is highly hydrophilic and enhances hydration but is also responsible for higher protein binding to the contact lenses. High water of hydration is a desirable property for good oxygen permeability, but it carries some disadvantages such as friability and protein penetration into the polymer network. Physiologically and optical, untrathin low-water-content contact lenses can perform very well as daily-wear lenses.

As a result of temperature changes and water evaporation, all hydrogel contact lenses dehydrate to some degree on the eye. Higher-water-content lenses dehydrate more than low-water-content lenses, and thin lenses dehydrate more easily than thick lenses (Refojo, 1991). An important advantage of the use of high-water-content, thin hydrogel contact lenses is their relatively high oxygen transmissibility. However, a drawback of these lenses is that as they dehydrate on the eye, they induce corneal epithelium injuries by a mechanism still unclear.

The transparent cornea does not contain blood vessels. Therefore, the cornea, to maintain its metabolism and transparency, uses oxygen from the ambient air when the eye is open (partial pressure O₂ about 160 mm Hg at sea level), and when the eye is closed from the blood vessels of the palpebral conjunctiva (partial pressure O₂ 55 mm Hg). The ideal contact lens should not be a barrier to the passage of oxygen to the cornea. The standard hydrogel contact lenses are used preferably for daily wear (open eye), but some with higher oxygen transmissibility are used for up to 1 week extended wear (day and night) (Holden *et al.*, 1984).

Siloxane-Hydrogel Contact Lenses

Striving to enhance the oxygen transmissibility of the soft contact lenses, while maintaining the comfort of the standard hydrogel lenses, the contact lens industry developed a new kind of siloxane-hydrogel contact lenses with sufficiently high oxygen transmissibility to allow their use for up to 1 month extended wear. These lenses are made essentially by copolymerizing hydrophilic monomers, similar to those used in the standard hydrogel lenses, with macromers of methacrylate, or vinyl, end-capped polydimethylsiloxanes (Formulas 2 and 3 (Künzler, 1996; Refojo, 1996), and/or with methacrylates of tris(trimethylsiloxy)silane (TRIS-like) (see Formula 5). The siloxane macromers and the TRIS-like monomers are functionalized with hydrophilic groups to make them compatible with the hydrophilic components of the hydrogel. In these hydrogels, the oxygen permeation takes place mainly through the siloxane-rich phase and to a relatively lower degree through the water of hydration of the hydrogel. Because the relatively high content of siloxane moieties on the surface of these materials, the lenses must be treated in an RF-plasma reactor or

other suitable procedure to make their surface hydrophilic and tolerated on the eye, as was mentioned above for the silicone elastomeric lenses. The two commercial siloxane-hydrogel contact lenses are PureVision (balafilcon A, Bausch & Lomb), which at 36% water has O_2 permeability about of $110 \times 10^{-11} \text{ cm}^2 \text{ (STP) cm}^2 / (\text{cm}^3 \text{ sec mm Hg})$, and Focus Night & Day (lotrafilcon A, Ciba Vision Corp.) that at 24% water has oxygen transmissibility of about 175×10^{-11} . Both of these lenses compare very favorably with the oxygen permeability of standard hydrogel contact lenses (Young and Benjamin, 2003). The lotrafilcon polymer contains a macromer similar to that given in Formula 4, but with a silicone block inserted at the midpoint of the perfluoropolyether block. On the other hand, the balafilcon polymer contains a siloxanyl methacrylate similar to that in Formula 5, but with a hydrophilic urethane group inserted between the alkyl and methacrylate moieties.

Rigid Contact Lenses

The rigid contact lenses fit loosely on the cornea and move with the blink more or less freely over the tear film that separates the lens from the corneal surface. The mechanical properties of rigid contact lenses must be such that any flex on the lens provoked by the blink must recover instantaneously at the end of the blink.

The original rigid contact lenses were made of poly(methyl methacrylate) (PMMA), which is an excellent material in almost all respects except for lack of permeability to oxygen. Several materials that were specially developed for the manufacture of rigid gas-permeable (RGP) contact lenses are copolymers of methyl methacrylate with a siloxanylalkyl methacrylates, most often methacryloxypropyltris

Flexible Perfluoropolyether Lenses

The only perfluoropolyether lens that reached the market, but which is not longer available, was made from a copolymer of a telechelic perfluoropolyether (Formula 4) (which imparts high oxygen permeability) with vinylpyrrolidone (which imparts wettability) and methyl methacrylate (which imparts rigidity). This flexible, nonhydrated contact lens, made by the molding procedure, had a high oxygen permeability and, because of its high fluorine content, was claimed to be more resistant to coating by tear proteins than are other contact lens materials.

This methacrylate end-capped perfluoropolyether can be also used to make highly oxygen-permeable hydrogels.

(trimethylsiloxy)silane (Formula 5). To compensate for the hydrophobic character imparted to the polymer by the high siloxane content of these copolymers (required for oxygen permeability), the copolymer also contains some hydrophilic comonomers. The most commonly used hydrophilic comonomer in rigid lenses is methacrylic acid. There are also minor ingredients and cross-linking agents.

A diversity of RGP contact lenses, consisting of different but closely related comonomers used in a variety of proportions to obtain the most desirable properties, are commercially available (Table 2). However, any subtle change in the chemistry of a contact lens material might strongly affect its clinical performance. As a general rule, the oxygen permeability coefficient of these original RGP siloxanylalkyl methacrylate contact lens materials is inversely proportional to the density (Refojo, 1994).

The development of the fluorine-containing RGP contact lenses was the realization that the fluoroderivatives may improve oxygen permeability and resistance to deposit formation on the lenses. Thereafter, the contact lens chemists included fluoroalkyl methacrylates or a similar fluorine-content monomer as an additional ingredient in the siloxanylalkyl methacrylate-*co*-methyl methacrylate RGP contact lens materials. These perfluoroalkyl-siloxanylalkyl-methyl methacrylate contact lenses have high oxygen permeability and, supposedly, better surface properties than the non-fluorine-containing rigid contact lenses, but their Dk is not directly related to their density like that of the original RGP contact lenses. Some RGP contact lenses made of siloxanylalkylmethacrylates with styrene derivatives (Menicon) have high enough oxygen transmissibility to be used for extended wear (Benjamin and Cappelli, 2002).

Cellulose acetate butyrate (CAB) was also used as a rigid oxygen-permeable contact lens material. However, CAB has not only relatively low oxygen permeability compared with the siloxanyl-alkyl methacrylate copolymers but also low scratch resistance, and it tends to wrap with humidity changes.

Other copolymers have been used as contact lens materials are isobutyl and isopropyl styrene, with hydrophilic comonomers of the type of HEMA or vinylpyrrolidone.

CORNEAL IMPLANTS

The cornea is an avascular tissue that consists of three principal layers (Fig. 1). The outermost layer, which itself consists of about five cellular layers, is the epithelium. The central and main portion of the cornea is the stroma, a collagenous connective tissue that is 78% hydrated in its normal state. Normal corneal hydration is disrupted by hypoxia and injury to the limiting epithelial and endothelial membranes. The endothelium is the innermost single layer of cells, which by means of a "pump-leak" mechanism is mostly responsible for maintaining normal corneal hydration. Swelling, tissue proliferation, and vascularization may compromise the transparency of the cornea. There are several types of corneal implants that replace all or part of the cornea (Refojo, 1986a; Abel, 1988).

Epikeratophakia and Artificial Epithelium

To correct the optics of the eye after cataract extraction, the surgeon may perform an epikeratophakia procedure which consists of transplanting a slice of donor cornea. The transplanted tissue heals into a groove carved into the recipient corneal surface and is reepithelialized with the recipient corneal epithelium (Werblin *et al.*, 1987) (Fig. 2). A modification of this technique attempts to obtain similar results with an artificial material that would heal into the donor cornea and be able to grow the epithelium of the donor cornea on its surface (Evans *et al.*, 2003).

An epithelium that has become irregular through swelling and proliferation has been replaced by the artificial epithelium made of a hard PMMA contact lens glued with a cyanoacrylate

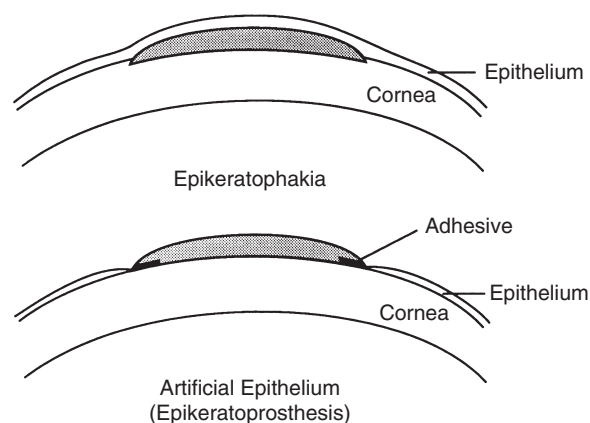

FIG. 2. Schematic representation of superficial corneal implants. (Top) In the epikeratophakia procedure the corneal epithelium is removed before the implant is placed on the stromal surface and epithelium grows over the implant. (Bottom) The artificial epithelium or epikeratoprosthesis is a contact lens glued to a deepithelialized cornea. Ideally, the epithelium should not grow over or under the glued-on lens.

adhesive to the corneal stroma (Fig. 2). This procedure has not been successful mainly because of failure of the glue to maintain a tight attachment of the prosthesis to the corneal stroma and also because of epithelium penetration between the prosthesis and the cornea.

Plastic Corneas

Corneal transplants from donor eyes are usually highly successful. In the instance of transplant failure, an opaque cornea can be replaced with an artificial cornea (keratoprosthesis) (Barber, 1988). These are usually through-and-through corneal implants, consisting of a central optical portion and some modality of skirt that fixes the prosthesis to the recipient cornea (Fig. 3). Another plastic cornea model is the “collar-button” type that holds the optical cylinder of the prosthesis to the recipient cornea by means of front and back plastic plates (Nouri *et al.*, 2001). Many materials have been tested to make all or part of these devices, but most artificial corneas implanted in patients have been made of PMMA. The main problem with through-and-through keratoprostheses is common to all kinds of implants that are not fully buried in the recipient tissue: faulty tissue–prosthesis interface, epithelium downgrowth, retrocorneal membranes, and tissue ulceration and infection around the prosthesis. The most feasible solution to these problems would be the development of a material for the optical portion of the keratoprosthesis that would accept growth and attachment of transparent epithelium on its surface. Also needed are biomaterials that would heal into the recipient corneal tissue (Chirila *et al.*, 1998a).

Artificial Endothelium

The corneal endothelium has been replaced, but not very successfully in the long term, by a silicone-rubber membrane

FIG. 3. (Top) Schematic representation of a through-and-through artificial cornea (keratoprosthesis), that consists of an optical cylinder that penetrates the opaque tissue. The prosthesis has an intrastromal rim that holds the prosthesis in the cornea. (Bottom) Schematic representation of the artificial corneal endothelium that consists of a transparent membrane sutured to the posterior part of the a cornea denuded of its endothelium. This membrane acts as a barrier to the inflow of aqueous fluid into the corneal stroma.

that passively controls corneal hydration (Fig. 3). Unfortunately, this procedure was unsuccessful because the membrane served as a barrier not only to water but also to the nutrients that the cornea normally receives from the aqueous humor.

Intracorneal Implants

Ophthalmic surgeons may use diverse polymeric devices to correct the optical function of the eye. Thus, intracorneal implants can be used instead of spectacles or contact lenses to correct nearsightedness and farsightedness (Fig. 4). Some intracorneal implants are made of hydrogel materials tailored to have high permeability to metabolites and able to correct severe myopia (McCarey *et al.*, 1989). The stromal cells (keratocytes) and the epithelium receive their nutrients from the aqueous humor and also release waste products in the same direction. Therefore, some previously used intrastromal lens implants that were made of PMMA and polysulfone, which are impermeable to metabolites, resulted in the ulceration and vascularization of the overlying stroma. A newer development is the intrastromal ring of PMMA or silicone rubber that obviates the corneal nutritional problem of the lens implants. More recently the intracorneal implant consists of two 180° narrow segments of PMMA that change the corneal curvature and, hence, the eye's optical power. These implants can make the corneal curvature steeper, increasing the refractive power, or flatter, decreasing the refractive power (Fink *et al.*, 1999).

FIG. 4. Schematic representation intracorneal implants used to change the curvature of the cornea in refractive keratoplasty. (Top) An intrastromal hydrogel intracorneal implant. (Bottom) An intrastromal corneal ring, that in a newer version is implanted as two 180° PMMA segments.

FIG. 5. Schematic representation of two typical models of aqueous humor drainage implants for glaucoma. (Yamanaka and Refojo, 1990).

IMPLANTS FOR GLAUCOMA

Polymeric devices are used to control abnormally high intraocular pressure in otherwise intractable glaucoma (Krupin *et al.*, 1988). These devices consist essentially of tiny silicone tubes that transport the aqueous humor—which normally maintains the physiological intraocular pressure and flows in and out of the eye in a well-regulated manner—from the anterior chamber to some artificially created space between the sclera and the other tissues that surround the eyeball. This artificial space is maintained by one or more end plates connected to the anterior chamber by the silicone tubing (Fig. 5). The artificial space fills with the aqueous humor and forms a bleb from which the aqueous humor is absorbed into the blood circulation. The most common materials used in the end plates are silicone rubber and polypropylene, although other materials have also been investigated (Ayyala *et al.*, 1999). Tissue proliferation, or capsule formation, takes place around all implanted biomaterials and may retard or even stop the outflow of aqueous humor from the bleb.

INTRAOCULAR LENS IMPLANTS

Intraocular lenses (IOLs) are used after cataract extraction to replace the opaque crystalline lens of the eye (Apple *et al.*, 1984), and are dealt with in Patel's chapter (7.11).

IMPLANTS FOR RETINAL DETACHMENT SURGERY

A retina detached from its source of nutrition in the choroidal circulation ceases to be sensitive to light. The choroid is the vascular layer between the retina and the sclera (Fig. 1).

In cases of retinal detachment, the surgeon must reattach the retina to restore vision. Retinal detachment could result from traction of a retracting vitreous humor or from seepage of liquefied vitreous through a retinal hole between the retina and the choroid. Retina surgeons can often restore vision to these eyes with vitreous implants and scleral buckling materials (Refojo, 1986b) (Fig. 6).

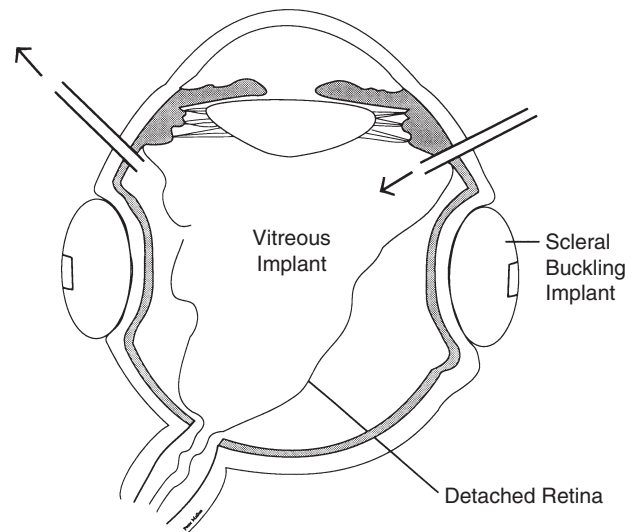

FIG. 6. Schematic representation of an eye with a detached retina. The retina can be pushed back into its normal place by injecting a fluid in the vitreous cavity (inside arrow) while the subretinal fluid is drained (outside arrow). A scleral buckling implant (the drawing represents is an encircling implant) is placed over retinal tears to counteract the traction on the retina of a shrinking vitreous and to reapproximate the retina to the underlying tissues.

Vitreous Implants

Vitreous implants are desirable in certain difficult cases of retinal detachment surgery (Refojo, 1986b). Physiological saline solution, air, sulfur hexafluoride, perfluorocarbon gases, and low-molecular-weight perfluorocarbon liquids frequently are injected into the vitreous cavity during vitreoretinal surgery. These fluids may perform well only as short-term retinal tamponade agents. Hyaluronic acid solutions and many other hydrophilic polymers have been investigated for long-term vitreous replacement without much success (Chirila *et al.*, 1998b). Therefore, for long-term vitreous replacement the only substance used at this time, as last resort and with variable results, in silicone oils of high viscosity (1000 to 5000 centistokes). (Giordano and Refojo, 1998). Retinal toxicity, oil emulsification, glaucoma, and corneal clouding are some of the complications of intraocular silicone oils. These complications may be avoided by removing the oil after choroidal-retinal adhesion has been achieved, but oil removal involves further surgery, is difficult to achieve completely, and carries the risk of recurrence of retinal detachment.

Scleral Buckling Materials

The scleral implants are used for the external treatment of retinal detachment. By indentation of the sclera these implants bring together the detached retina and the underlying choroidal layer (Schepens and Acosta, 1991). Scleral buckling materials for retinal detachment surgery must be soft elastic. Solid silicone rubber and silicone sponge have been used successfully for many years. An acrylic hydrogel made of a copolymer of 2-hydroxyethyl acrylate with methyl acrylate has also been used for scleral buckling and improves the rate of infection resulting from the use of the sponge and the potential for long-term pressure necrosis of the more rigid solid silicone-rubber implants (Refojo, 1986b). However, long-term biodegradation of the acrylic hydrogel resulted in complications due to implant swelling (Roldán-Pallarés *et al.*, 1999).

SURGICAL ADHESIVES

As in most applications of polymers as biomedical implants, in ophthalmology any polymeric device must be as free as possible of residual monomer. However, in the unique case of the cyanoacrylate surgical adhesives, the monomers are applied directly to the tissues and almost instantaneously polymerize and adhere tenaciously to the tissues. (See Chapter 7.9, "Adhesives and Sealants.") The cyanoacrylate adhesives have been used in many diverse applications in the eye but have been particularly useful in corneal perforation and ulcer, as well as in gluing artificial epithelium to the corneal surface and repairing retinal detachments (Refojo *et al.*, 1971).

7.11 INTRAOCULAR LENS IMPLANTS: A SCIENTIFIC PERSPECTIVE

Anil S. Patel

INTRODUCTION TO OPTICS OF THE EYE, CATARACTS, AND INTRAOCULAR LENS IMPLANTS

Vision is considered to be our dominant sense. We see in the brain through optic nerves, which carry information of the optical image formed in the eye. The physiological optics of the eye for formation of the image, the photochemical transduction in the neurosensory retina at the optical image plane, and the subsequent neural processing in the retina and the brain are quite complex and beyond the scope of this chapter (LeGrand and El Hage, 1980). As an introduction, a brief description of optical imaging of the eye is necessary.

The eye is schematically illustrated in Figure 1 of Section 7.10. The average healthy adult eye is about 24.2 mm long axially from anterior surface of the cornea to the retina. It can be considered as a camera with the cornea and the natural crystalline lens as its two lenses, while the iris forming the pupil is an aperture between them, and the retina is the imaging plane. The image of an outside object of interest

is formed on the retinal photoreceptors by the fixed refractive power of the cornea in combination with the variable refractive power of the natural lens, permitting imaging of any object at various far and near distances from the eye. The fixed refractive power of the cornea is about 43 diopters, which is about 70% of the total refractive power of the eye. The refractive power of the natural lens is about 20 diopters for seeing far objects. For seeing near objects, it increases as required to an upper limit, which gradually diminishes with age. When young, the refractive power of the natural lens can increase by up to 14 diopters, but by about the age of 42, this capability is less than the 3 diopters required for near reading distance. The physiology of variable refractive power of the natural lens is as follows.

As shown in Figure 1 of Section 7.10, the natural lens has a capsular bag containing a nucleus surrounded by the cortex. It is attached by the suspensory ligaments called zonules to the ciliary muscle. For an average healthy eye, the refractive power of the cornea and its natural lens are, in combination, adequate to form a focused image on the retina for any object at 20 feet or greater distance when the ciliary muscle is relaxed. In this physiologically relaxed condition of the eye, the zonules are in tension, and the natural lens is also in tension, providing about 20 diopters of required refractive power for distant vision. For seeing an object at any nearer distance, the ciliary muscle appropriately contracts radially and moves anteriorly, thereby relaxing the zonules, which in turn relaxes the natural lens. This results in the needed change in the shape of the lens, and thus increases its refractive power as required for near vision. This complex mechanism, which results in the ability to increase the refractive power of the natural lens for near vision, is called accommodation (Kaufman, 1992). This ability gradually diminishes with age as the lens grows and eventually become less than 3 diopters required for near reading distance, and the eye is considered presbyopic. This presbyopia of the eye is treated with eyeglasses, contact lenses, or evolving refractive surgery in order to restore the ability to see near objects.

Further aging of the lens results in loss of its clarity as opacities begin to appear in its structures, and the optical image formation deteriorates. Eventually, such a compromised natural lens is unacceptable and is called cataractous since it is transformed to an unacceptable structure for the primary function—to allow formation of a clear image on the retina (U.S. Department of Health and Human Services, 1983). This normal aging process related to cataract formation eventually leads to blindness and is the leading cause of blindness in the world. In the developed world, depending upon the need for vision, cataract surgery is carried out much more promptly before the total blindness stage when the degradation in the vision by the cataractous lens reaches an unacceptable level (AAO, 1989). During a relatively safe and short-duration surgery, not only is the cataractous lens removed, but in its place a biomaterial medical device called an intraocular lens (IOL) is implanted to provide the clear optical imaging function of the normal lens (Alpar and Fechner, 1986). While currently, worldwide, an estimated 10 million IOLs are implanted, primarily in the developed world and emerging countries, the lack of resources and rapid increase in life expectancy accounts

for estimated 20 million cataract-related blind people in the underdeveloped world. Cataract blindness is preventable by a simple surgical procedure using the IOL implant, and the number of such procedures is expected to grow. Even then, cataracts are expected to remain the leading cause of blindness with an estimated 40 million cases by the year 2020 (Brian and Taylor, 2001).

WHY ARE IOLS SUCCESSFUL?

Within a span of only 30 years, the number of cataract surgeries and IOL implantations has rapidly expanded for sound reasons, both in terms of improvements in surgical procedure and visual outcome from the patient's perspective, as summarized below.

Prior to IOL implantation, thick spectacles of about 10 diopters refractive power were needed to attempt to restore the function of the natural lens after cataract surgery. Imaging by such external spectacle lenses and the cornea creates a 25% magnification of the resultant image on the retina compared with imaging by the natural lens and the cornea. Thus, when a cataract develops in one eye of the patient, its functional restoration by cataract surgery and a spectacle lens is unacceptable to the brain since, for fusion of images of the two eyes, the brain requires them to be no more than 6% different in size. Thus, restoration of vision by spectacles after cataract removal required waiting for maturation of cataracts in both eyes before surgeries were carried out to achieve equal image sizes for both eyes. This resulted in significantly poor vision in the unoperated cataractous eye for a prolonged period before cataract surgery was done. Additionally, cataract surgery 30 years ago was associated with other risks and poor visual outcome (as compared in Table 1), and was thus relatively discouraged until too late an age, when the compromised vision was totally unacceptable in a relatively advanced state of dysfunction, compared with today's practice in the developed world. Binocular vision with spectacles also had a significantly reduced field of vision and severe astigmatism on account of the required large size of the incision for cataract surgery.

The size of the optic of the IOL and its intraocular location eliminated image size magnification and reduced visual field problems, which were present for the spectacles. Foldable IOLs encouraged development of small-incision, safer, cataract surgery techniques without surgically induced astigmatism, and thus achieved quicker and better vision after cataract surgery (Apple *et al.*, 2000a). Table 1 captures all the reasons for the overwhelming success of IOLs, where needed resources are available.

EMERGING FUNCTIONAL VARIATIONS OF IOLS

As a replacement of the cataractous natural lens, the majority of currently used IOLs are monofocal IOLs of fixed refractive spherical dioptric power, and thus cannot correct existing astigmatism as needed for some eyes, or restore accommodation as was provided by the pre-presbyopic natural lens. Toric IOLs, multifocal IOLs, and emerging accommodative

IOLs are relatively recent developments, and they will be discussed later as IOLs with emerging variations of the optical function (Sanders *et al.*, 1992; Maxwell and Nordan, 1990; Samaloni, 2002).

The eye with its natural lens is called the phakic eye. The eye after removal of the natural lens, either clear or cataractous, is called an aphakic eye. The eye with replacement of the natural lens with an IOL is called a pseudophakic eye. An ophthalmic implant placed in a phakic eye without removal of its natural lens, for example, an additional IOL in order to correct refractive error, is called a phakic IOL (Obstbaum, 2003). Surgical implantation of a phakic IOL is a form of refractive surgery that provides needed refractive correction in a myopic or hyperopic eye as an option to eyeglasses or contact lenses or corneal refractive surgery such as LASIK. The current status of phakic IOLs will also be discussed later as a variation of optical function.

Thus, the IOL as an ophthalmic intraocular implant is now evolving to provide a variety of optical functions. The biomaterials for such variety of IOLs have been many, and new materials are emerging in order to meet the requirements of their various optical functions and designs.

BIOMATERIALS FOR IOLS

Biomaterial selection for IOLs is based on specialized requirements to maintain a stable, clear path for optical imaging as well as long-term safe acceptance as a permanent implant by the unique biology of the eye (Ratner, 1998; Mamalis, 2002). Additionally, the selected biomaterial is required to meet IOL design objectives such as targeted incision size for insertion and needed mechanical fixation, typically via anchoring components called loops or haptics. The haptics permit the IOL to achieve stable location within the eye and also permit the targeted optics design to achieve the functional goal for the IOL. Figure 1a–d illustrates various lens haptics.

Historical Beginning of Poly(methyl methacrylate) (PMMA) as an IOL Material

Harold Ridley of London, in 1949, was the first to implant an IOL made from a PMMA sheet originally formulated for canopies of the British Royal Air Force airplanes (Ridley, 1951). His selection of the material was based on an accidental implantation of pieces of the canopy in pilot's eyes, which were observed by him to be quietly tolerated without noticeable inflammatory reaction or other unacceptable biological consequence. Also, since it remained optically transparent, he chose this Imperial Chemical Industry's PMMA formulation, known as Perspex CQ (Clinical Quality), to create a biconvex 10.5-mm diameter disk-shaped IOL, a historical first. This Ridley IOL was too big and bulky, weighing about 110 mg in air, compared with current IOLs, weighing about 20 mg on average (Patel *et al.*, 1999). It was difficult to mechanically fixate such a bulky IOL in the eye, and serious surgical and postoperative complications led to discontinuation of its use.

TABLE 1 Why Are IOLs Successful? Comparison of Cataract Surgery in the Developed World for Restoration of Vision 30 Years Ago with Spectacles and Today with Foldable IOLs

30 years ago	Foldable IOL today	Improvements (2000+)
<ul style="list-style-type: none"> • Ten days of hospitalization • Use of general anesthesia or retrobulbar injection in the back of the eye with long needle • Large >12-mm incision requiring significant stitching and resultant astigmatism • Use of alpha-chymotrypsin enzyme to weaken zonules and cryoextraction of the entire cataractous lens through the large incision • No protection of cornea and intraocular tissues during surgery • Thick spectacles to restore function of the natural lens resulting in a 25% image magnification, which is incompatible with monocular cataract surgery; also resultant reduced field of vision • Overall unsatisfying vision achieved several months after surgery; anxiety and fear of cataract surgery 	<ul style="list-style-type: none"> • Same-day outpatient surgery in a few hours • Use of topical drops and intracameral anesthetic or peribulbar injection if needed • Small 3-mm incision requiring no stitching • Use of ultrasonic phacoemulsifier and irrigating/aspirating instruments to break up and remove the nucleus and cortex, leaving behind the capsular bag with an anterior opening for insertion of IOL in the bag • Use of a viscoelastic biomaterial to protect the corneal endothelium and other intraocular tissues • No restriction on monocular cataract surgery • Satisfying vision next day after surgery; minimal anxiety and fear of cataract surgery and IOL implantation 	<ul style="list-style-type: none"> • Convenience and cost • Lowered risk and complications • No stitching-related surgically induced astigmatism • Significantly reduced complications of retinal detachment, excessive inflammation, and infection • Significantly reduced risk of losing corneal clarity and inflammation of the uveal tissues • No delay in cataract surgery in the first eye since IOL provides natural unchanged size of image; also unchanged field of vision • Minimal duration of compromised vision and interruption from occupation; prompt restoration of excellent vision

This concept of the IOL implantation is recognized as a pioneering breakthrough. Also, PMMA remained the dominant IOL material for the next 40 years until the 1990s when foldable IOLs of other materials emerged.

Evaluation of Monofocal IOL Designs and Biomaterials

Although the Ridley IOL was unacceptable, it stimulated many other surgeons, who created several generations of monofocal IOL designs with a much smaller optic made of PMMA and a variety of fixation means and materials (Apple *et al.*, 1989).

The anatomical confines of the eye's anterior chamber (AC) were selected for fixation of IOL. Several AC-IOL designs emerged between 1952 and 1962 with a relatively heavy footplate extension of the optic, which rested in the angle formed by the peripheral iris structure and the collagen fibers of the scleral tissue at the junction with the cornea (Choyce, 1958; Strampelli, 1961). While fixation of the IOL was ensured by these AC-IOL designs, the unique biocompatibility needs of the nearby cornea and iris uveal tissue were revealed. Contact of the IOL with the cornea, for example by rubbing, damaged the corneal endothelium and resulted in loss of corneal clarity. The uveal tissue responded with chronic inflammation. Since exact anatomical sizing was difficult, mis-sized AC-IOLs aggravated the foregoing complications by protrusive erosion or loose rotation within the anterior chamber (Ellingson, 1978). These AC-IOL designs were abandoned, and iris-fixated or -supported designs

emerged between 1959 and 1973 (Binkhorst, 1959). These iris-supported IOLs introduced fixation using several biomaterials attached to the PMMA optic. Fixation structures were shaped as round loops of various materials including nylon 6, nylon 66, and polypropylene suture materials. Even platinum-iridium loops and titanium clips were used. Nylon suture degenerated in the eye (Kronenthal, 1977). Metal loops or clips were heavy, causing injury to the iris and hemorrhage within the anterior chamber (Shephard, 1977). Only iris-supported IOL designs with polypropylene loops created by Cornelius Binkhorst seemed viable. His two-loop iridocapsular IOL was implanted with the loops supported by the iris while the optic was captured by the capsular opening (Alpar and Fechner, 1986). The nucleus and the cortex of the cataractous lens were removed earlier during the surgery through this opening. This method of cataract surgery is called extracapsular cataract extraction (ECCE). Prior to this surgical technique, removal of the entire cataractous lens using an enzyme to weaken the zonules and a cryoextractor was more prevalent. This method of cataract surgery is called intracapsular cataract surgery (ICCE). Iridocapsular supported Binkhorst two-loop IOL implantation after ECCE gave encouraging results, but with the passage of 6 to 10 years, late decompensation of cornea occurred, often requiring corneal transplantation. Also, erosion of the iris, IOL dislocation with dilation of the pupil and difficulty of implantation discouraged its use (Nicholson, 1982; Obstbaum, 1984). The Binkhorst two-loop iridocapsular IOL with ECCE is considered the forerunner of current capsular-fixated posterior chamber IOL (PC-IOL) with ECCE using phacoemulsification.

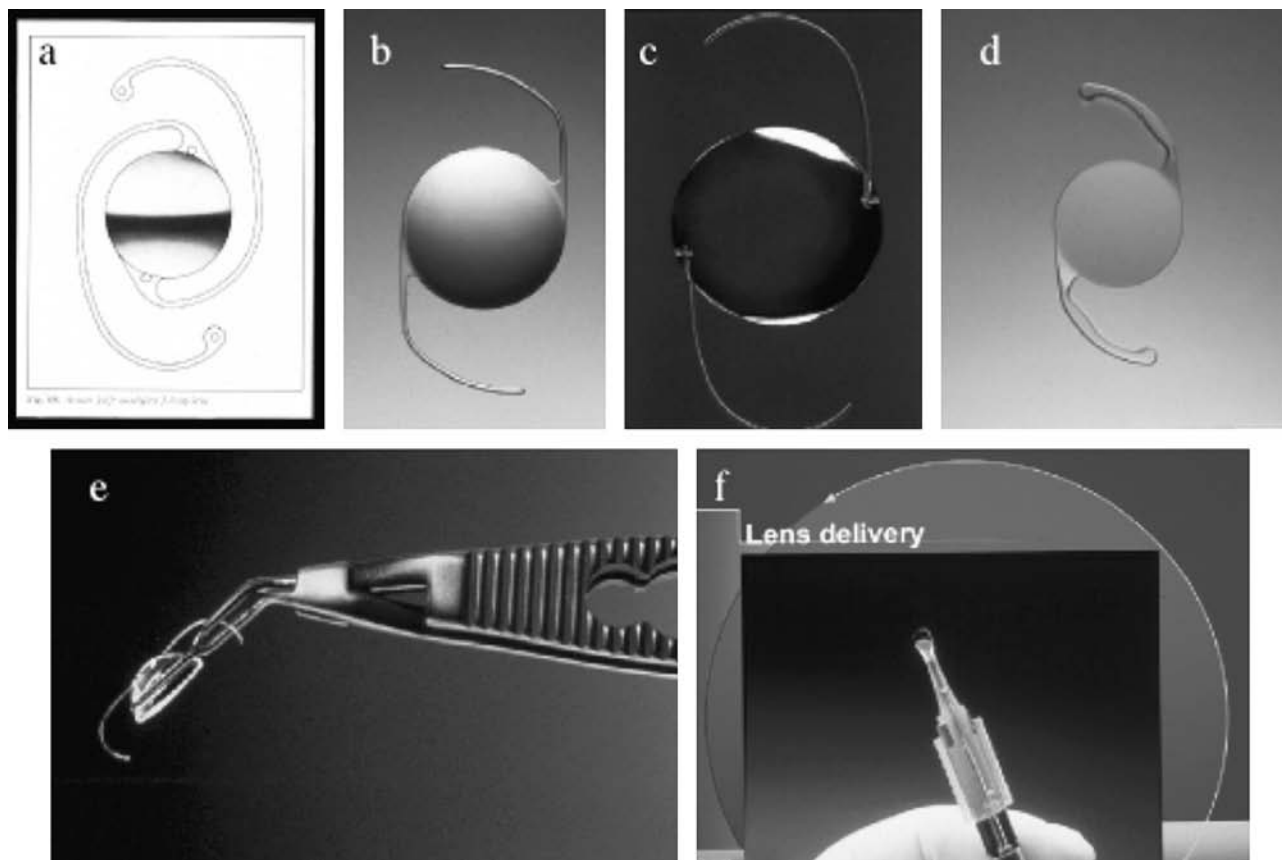

FIG. 1. IOL transition occurring in developed world is best illustrated here: (a) Past: three-piece PMMA IOL; (b) Current: single-piece PMMA IOL; (c) Past: single-piece foldable IOL; (d) Current: single-piece foldable IOL; (e) Past: insertion forceps held folded IOL; (f) Current: folded IOL emerging from an injector tip cartridge.

Failure of iris-supported IOL led to revisiting AC-IOLs in the 1970s and 1980s with a thinner footplate and the evolution of haptics, much thinner and somewhat flexible extensions of the optic, for fixation. These haptics were an integral part of the IOL made from the same PMMA material, or the haptic could be formed using other biomaterials. Polypropylene suture material, extruded monofilament from other PMMA formulations, and polyamide materials were used for haptics. Even these newer AC-IOL designs gave unsatisfactory long-term outcomes with undesirable corneal decompensation, chronic uveal inflammation, and eventual glaucoma (Apple *et al.*, 1987). Many AC-IOLs with finely looped haptics were associated with micro movement and rubbing with sensitive tissues of the anterior chamber, resulting in loss of corneal endothelial cells, iris chafing, and adhesions around the haptics. While the latest AC-IOL design with a one-piece PMMA optic with integral open haptics, which were wider and yet somewhat flexible, improved the results by avoiding the complications just discussed, the search intensified for fixing the IOL in the posterior chamber where the natural lens is located.

Finally, the search for a PC-IOL led to an IOL by Stevens Shearing in 1979 with a PMMA optic and two J-shaped

polypropylene haptics designed for placement behind the iris in the anatomical space called the ciliary sulcus, in front of the posterior capsule (Shearing, 1979; similar to Fig. 1c). Soon, a variety of shapes of haptics emerged with a different degree of flexibility and contact area for ease of implantation and stable fixation. Also, PMMA monofilament as a haptic material replaced polypropylene after some concern for its degradation was raised (Apple *et al.*, 1984). The PC-IOL designs achieved such success that manufacturing processes even created one-piece PMMA IOLs with integral flexible haptics (Fig. 1a,b).

PC-IOL implantation required the ECCE cataract surgery method, and, while large numbers of IOLs were implanted with this method from 1977 to 1992, several refinements emerged to address complications of the sulcus-fixated PC-IOL. Inflammation on account of iris chafing, decentration of the IOL when one haptic was fixated in the sulcus and the other unintentionally went into the bag, and posterior capsule opacification emerged as unacceptable complications of the sulcus-fixated IOL. Placement of the entire IOL (both haptics and the optic) within the capsular bag avoided iris chafing, reduced inflammation, and improved central fixation. C-shaped haptics and the surgical technique of opening the capsular bag by manually

controlled tearing called anterior curvilinear capsulorrhexis provided reliable implantation of the PC-IOL in the capsular bag with good centration (Grimbel and Neuhann, 1990). As a result, a large number of surgeons with varying skill levels began to implant PC-IOLs.

By the early 1980s, Perspex CQ PMMA was replaced by most IOL manufacturers with differing PMMA formulations with UV chromophore additives in order to protect the retina from damage by UV radiation.

Viscoelastic materials, such as sodium hyaluronate, were introduced and used to protect the corneal endothelium and other intraocular tissues (Miller and Stegmann, 1982). Even coatings for IOLs and surface modifications for IOLs were investigated in order to minimize damage to corneal endothelium due to accidental touch during insertion into the eye, as well as to minimize foreign-body reaction on the surface of the IOL. Heparin surface-modified PMMA IOLs were introduced, but since they did not solve the posterior capsular opacification complication and also required a longer incision than needed for foldable IOLs, their use was minimal and short-lived (Phillipson *et al.*, 1990; Winther-Nielsen *et al.*, 1998).

The ECCE method of cataract removal, which is required for PC-IOL implantation, retains the entire capsular bag except the capsulorrhexis-excised anterior capsule face. There is a region near the equator of the lens capsule where the residual lens epithelial cells (LEC) with potency for mitosis and migration remain. These LEC proliferate and migrate and spread onto the anterior capsule as well as onto the posterior capsule and even potentially on the IOL surface. These LEC cells undergo morphological changes reducing their transparency resulting in anterior capsule opacification (ACO) and posterior capsular opacification (PCO), as well as contraction of the capsular bag (Kruger *et al.*, 2001; Amon, 2001). PCO is the complication that reduces clarity of the optical path and degradation of the quality of image formation to the extent that it is also called "secondary cataract" formation. While making an adequate opening in the cloudy posterior capsule by a Nd-YAG laser beam without surgically opening the eye restored the clarity of the optical path and the image quality on the retina, there are several disadvantages of this surgical procedure. They include the cost of the procedure, the degraded vision prior to it, the possibility of damaging the lens, and the potential for inducing retinal detachment because of the shock wave created by the focused laser. These disadvantages stimulated approaches to prevent PCO after PC-IOL implantation in the capsular bag. The shape of the optic was changed from convexo-plano to biconvex, and haptics were angulated to achieve complete contact of the posterior surface of the PC-IOL to the posterior capsule. Ridges were also added on the posterior surface to stop migration of LEC without much success. Thus, Nd-YAG laser-created posterior capsulotomy remained a necessary procedure for "secondary cataracts" due to PCO. The rate of need for this posterior capsulotomy depends on the type of IOL material and design, success in surgical removal of much of the cortical contents of the lens, age-related vigor of remaining LEC, and other inflammatory stimulating factors. With some foldable IOL materials, as discussed later, and using the latest surgical techniques for ECCE

with phacoemulsification, the PCO formation rate and the posterior capsulotomy as a necessary second surgical procedure have been significantly reduced.

Rationale and Emergence of Soft Biomaterials for Foldable IOLs

While PC-IOLs of PMMA material were implanted in very large numbers in the early 1980s, another ECCE surgical method drew attention. A probe with a titanium needle that is axially oscillated by an ultrasonic instrument achieved removal of the cataractous nucleus by fragmenting and aspirating it. Cortical material was aspirated out by another probe as a component of the instrument system known as an ultrasonic phacoemulsifier. It also provided necessary simultaneous irrigation into the eye to prevent collapse of the anterior chamber and damage to the cornea. Advancement in this technology with further refinement in the surgical techniques resulted in eyes with less inflammation postoperatively. Also, the incision length required to enter and remove the cataract by this technology is only 3 mm compared with an approximately 9-mm incision required for the manual ECCE extraction method for removal of the nucleus of the cataract. This reduction in incision length resulted in significant reduction in surgically induced astigmatism. Additionally, ECCE using the phacoemulsifier spared mechanical trauma to intraocular tissue encountered during manual ECCE extraction method, thus minimizing tissue irritation and inflammation.

Postoperative large astigmatism induced by the relatively large 9-mm incision required for manual ECCE was degrading the optical image formation and resultant vision (Luntz and Livingston, 1977). While it was managed by surgical and suturing techniques and by appropriate eyeglass correction, it was recognized that the surgically induced astigmatism by a 3-mm incision to enter the eye for ECCE by phacoemulsification was negligible, but subsequent enlargement to insert the PMMA IOL with the preferred 6-mm diameter optic size increased the surgically induced astigmatism (Kohnen *et al.*, 1995; Olson and Crandall, 1998). A soft biomaterial for designing foldable IOLs for insertion through a 3-mm incision was needed to eliminate this surgically induced astigmatism. Additionally, foldable IOL insertion through a 3-mm incision after ECCE with phacoemulsification promised elimination of the need for stitching, and retention of the minimal post surgical inflammation provided by this method of cataract surgery (Gills and Sanders, 1991).

In the early 1980s, a transparent polysiloxane, a formulation originally created for other industrial applications, was used as a biomaterial for foldable IOLs by Starr, Inc. (Mazzocco *et al.*, 1986). In the subsequent 15 years, several formulations of polysiloxane with different refractive indexes, mechanical properties, and UV transmission characteristics emerged from other companies. PolyHEMA, a hydrogel material for contact lens, was also used as a biomaterial for foldable IOLs, but fixation was difficult and it produced unacceptable postoperative complications after Nd-YAG posterior capsulotomy.

In 1994, the first new soft biomaterial for IOLs was introduced by Alcon Laboratories Inc.; as AcrySof IOL. This

TABLE 2 Types of Biomaterials for IOLs in the Market or Clinical Investigation by Leading and Newly Emerging Manufacturers

Manufacturer	Type of IOL	Biomaterials
Advanced Medical Optics	Monofocal IOLs Foldable IOLs: Monofocal Multifocal	PMMA with UV absorber Proprietary polysiloxane with UV absorber Proprietary copolymer of acrylates with UV absorber (hydrophobic), Sensar IOL, PMMA monofilament haptics
ALCON	Monofocal IOLs Foldable IOLs: Monofocal Foldable IOLs: Toric Multifocal Phakic Foldable: Blue Blocking Monofocal IOLs	PMMA with UV absorber PMMA monofilament haptics for three-piece IOLs Proprietary copolymer of acrylates with UV absorber (hydrophobic) ACRYSOFT [®] IOL, PMMA monofilament haptics for three-piece IOLs Same as above Same as above with yellow bondable dye
Bausch and Lomb	Monofocal IOLs Foldable monofocal IOLs Phakic AC IOL	PMMA with UV absorber Proprietary polysiloxane with UV absorber Proprietary copolymer of acrylates with UV absorber (hydrophilic). Hydroview [®] IOL PMMA with UV absorber
C&C Vision	Foldable accommodative IOL—movement based	Proprietary polysiloxane with UV absorber as optic and polyamide haptics, Crytalens [®] AT-45
Calhoun Vision	Foldable monofocal light Adjustable power IOL	Proprietary photopolymerizable polysiloxane macromers dispersed within polymerized polysiloxane matrix
CIBAVision	Prefolded monofocal IOL Phakic AC-IOL Phakic PC-IOL	Proprietary copolymer of acrylates with UV absorber (hydrophilic), Memory [®] lens that unfolds upon hydration and warming in the eye Same as above with PMMA footplate covered by the copolymer, Vivarte [®] IOL Proprietary polysiloxane with UV absorber, PRL, IOL
CORNEAL Laboratories	Foldable monofocal IOLs	PMMA with UV absorber Proprietary polysiloxane with UV absorber Proprietary hydrogel
Human Optics, AG	Foldable accommodative IOL—movement based	Proprietary copolymer of acrylates with UV absorber (hydrophilic)
IOL TECH Laboratories	Foldable monofocal IOL Foldable phakic AC-IOL	Proprietary hydrogel with UV absorber (28% water content) Same as above
Medenium	Foldable monofocal IOL Foldable phakic PC-IOL	Proprietary copolymer of acrylates with UV absorber (hydrophobic), Matrix [®] IOL Same as given above as CIBAVision PRL [®] IOL
Ophtec	Phakic AC-IOL Toric phakic IOL	PMMA with UV absorber Iris-fixated Artisan [®] IOL
Pfizer (Pharmaclia)	Monofocal IOL Foldable monofocal IOLs Multifocal IOL	Heparin surface-modified PMMA with UV absorber Proprietary polysiloxane with UV absorber PMMA with UV absorber
Rayner IOL Ltd., (Manufacturer of Ridley IOL)	Monofocal IOL Foldable monofocal IOLs	PMMA with UV absorber Proprietary copolymer of acrylates with UV absorber (hydrophilic)
STARR Surgical	Foldable monofocal IOL Foldable toric IOL Foldable phakic PC-IOL	Proprietary polysiloxane with UV absorber, also proprietary hydrogel, Collamer [®] IOL Same as that for Collamer [®] , known as Implantable Contact Lens (ICL)

biomaterial was specifically created to meet the desired optical, mechanical, and biological properties for foldable IOLs (Anderson *et al.*, 1993). This copolymer of phenylethyl acrylate and phenylethyl methacrylate with a cross-linking agent and a bonded UV absorbing chromophore provided a higher refractive index of 1.55. This allowed the design of a thinner foldable IOL from this hydrophobic soft acrylate material. Its tailored mechanical properties resulted in slow unfolding of the IOL, unlike the rapid, uncontrolled, springlike opening of early silicone IOL with plate haptics. Early three-piece AcrySof IOLs with PMMA monofilament C-shaped haptics were folded and inserted using forceps, similar to three-piece silicone IOL designs (Fig. 1e). Subsequently IOL injectors were developed and are currently used for most of the foldable IOLs (Fig. 1f). Also, AcrySof IOL is now available as a single-piece foldable IOL with integral haptics of the same biomaterial as optic.

The AcrySof IOL soon became the most widely used foldable IOL, and millions of these IOLs had been implanted globally with overall satisfactory outcomes. Besides being a small-incision IOL, it unfolds gently in the eye, remains well centered, and postoperatively results in “quieter” eyes without significant inflammation. Some glistening, which is judged cosmetic, and edge-related optical photic phenomena are reported and now have been minimized through improvements. The newer generation of silicone foldable IOLs and other hydrophobic as well as hydrophilic soft acrylate foldable IOLs also emerged (see Table 2) (Apple *et al.*, 2000a). This success for soft, foldable IOLs, and in particular, AcrySof, is attributed not only to the above-discussed good short-term postoperative results, but also, most importantly, to long-term reduction in PCO formation and the needed Nd-YAG posterior capsulotomy (Hollick *et al.*, 1999). The Nd-YAG capsulotomy rate for AcrySof IOL is <5%, the lowest thus far reported for all IOLs (Apple *et al.*, 2001). Scientific investigations have explained this, based on both the properties of its biomaterial and its design. These investigations are still ongoing with other foldable IOL materials and designs. The surface property of the material and the square-edge design of the optic are attributed as factors for reduction of PCO (Linnola, 1997; Linnola *et al.*, 2000).

In addition to several proprietary hydrophobic soft acrylates and polysiloxanes, several hydrophilic soft acrylates and newer hydrogels have also been introduced as foldable IOLs. But their disadvantages such as greater tendency for fibrotic membrane formation over the anterior surface of the IOL, ACO, and postoperative surface or deep calcification, higher PCO rates, and lack of proven advantage over hydrophobic soft acrylates or polysiloxane IOLs have reduced their acceptance (Koch *et al.*, 1999; Apple *et al.*, 2000b; Werner *et al.*, 2001; Izak *et al.*, 2003).

Currently, hydrophobic acrylates and polysiloxane foldable IOLs are predominantly used in developed countries. Special insertion tools have been designed and used to implant them through a 3-mm incision, the same as required for ECCE cataract extraction by phacoemulsifier.

Though the AcrySof IOL is widely used, many surgeons find silicone IOLs also as acceptable for most cataract patients without other ocular pathology, especially when the cost of the IOL is a consideration. Silicone IOLs are made by several

manufacturers. Concern has been expressed about optical complications associated with silicone oil adhesion on silicone IOLs if the use of silicone oil is required in the future for vitreoretinal surgery (Kaushik *et al.*, 2001; Khawly *et al.*, 1998). IOLs fabricated from other soft hydrophobic acrylates are also now emerging in the market.

Monofocal IOLs with fixed spherical refractive power, discussed earlier, remain the dominant IOL implant for replacement of the cataractous lens. Transition from hard PMMA IOLs to soft foldable IOLs for small-incision cataract surgery has mostly occurred in the developed world. This was primarily driven by improved postoperative results for the patients. Therefore this transition is also expected in the developing world when the necessary resources and skills are available.

IOLS WITH VARIATIONS OF THE OPTICAL FUNCTION

Monofocal Toric IOLs

Since monofocal IOLs with spherical refractive power do not correct preexisting corneal astigmatism, it is corrected either surgically by certain techniques during the cataract surgery or postoperatively using sphere-cylindrical power spectacles. With the same biomaterials as used for monofocal IOLs, toric IOLs with toric optics have recently emerged as another alternative for the more precise correction of significant preexisting corneal astigmatism. The axis of the cylinder for the spherocylindrical optic of the monofocal toric IOL is marked on the IOL for necessary proper alignment during the cataract surgery. Postoperative rotation of a toric silicone IOL with plate haptics (from Staar Surgical) has been widely reported since it is difficult to size it for needed fixation in the capsular bag (Leyland *et al.*, 2001). Such rotation significantly compromises the optical objective of the toric IOL. Another toric IOL design with flexible haptics (from Alcon Inc.), that can provide improved stable fixation has been clinically investigated with much better results without significant rotation (Lane, 2003).

Multifocal IOLs

Since monofocal IOLs optically focus on an object at only one chosen distance with a relatively narrow depth of focus, postoperatively, patients are required to wear spectacles for other distances. Even though almost all elderly cataract patients are accustomed to wearing spectacles because of their presbyopia prior to cataract, the investigation of the opportunity to eliminate spectacles using multifocal IOLs began in the 1980s. With the same biomaterials as for monofocal IOLs, several multifocal optical designs using refractive optical zones or diffractive optical structures have been investigated, implementing simultaneous optical imaging for objects located at a distance as well as near (Maxwell and Nordan, 1990). This optical design principle is called simultaneous vision and has the potential for halo and other unwanted optical consequences depending on the optical design. Multifocal IOLs with refractive optical zones are sensitive to pupil size in terms of their optical performance. The FDA-approved Array Multifocal IOL

by AMO, Inc., has a radial array of alternating variable optical power to provide both distant and near optics for any pupil size (Steinert *et al.*, 1999). Although for pupils of 3-mm diameter or larger such a design does provide multifocal vision, the near vision is reported to be suboptimal for a smaller pupil size. Also, halos appear with nighttime driving when the pupil is larger, and these remain a potentially unacceptable complication for some patients (Haring *et al.*, 2001).

Earlier, the 3M Corporation, and, more recently, Pharmacia Corporation (now merged with Pfizer, Inc.), introduced a diffractive optic design that provides pupil-size-independent distant and near optics, but still retains potentially unacceptable halos with nighttime driving. With better understanding of the cause of such halos, a unique optical design that combines a limited central diffractive optical zone with refractive optics beyond it was introduced by Alcon, Inc., as the AcrySof Multifocal IOL to minimize nighttime halo and retain pupil-independent optics for daytime (Dublineau, 2003).

The simultaneous vision principle based multifocal IOLs demands a more accurate selection of the necessary IOL power in order to achieve spectacle-free vision postoperatively. Also, since the vision achieved is not an actual accommodation, it is called pseudoaccommodation.

Applications of multifocal IOLs for treatment of presbyopia, hyperopia, and myopia are currently being clinically investigated in certain suitable patients. For treatment of any one of these refractive errors of the eye, its noncataractous, clear natural lens is surgically removed and is replaced by a multifocal IOL (Packer *et al.*, 2002). This lensectomy is carried out by the same surgical procedure as is required for cataract surgery. Unpredictability of achieving necessary targeted refraction and acceptance of unavoidable optical effects of the simultaneous vision optics of multifocal IOLs remain key hurdles for its widespread use for treatment of refractive errors.

Phakic IOLs

Currently, for correction of refractive errors of myopia or hyperopia, treatment alternatives include spectacles, contact lenses, and a variety of corneal refractive surgery procedures including LASIK. As another modality of treatment, the phakic IOL, which is an IOL to correct the refractive error of the eye, is placed in the phakic eye in addition to the natural crystalline lens. Phakic IOLs have been clinically investigated for many years with continuous improvement to achieve long-term safety and, it is hoped, widespread use. Unique designs with newer biomaterials are currently being investigated for achieving this goal.

For correction of myopia, the angle-supported phakic AC-IOL designs of PMMA, similar to earlier AC-IOLs for cataract surgery, resulted in complications of damaged corneal endothelial cells and pupil ovalization. More flexible, soft and foldable phakic AC-IOL designs of hydrophobic soft acrylate material (Alcon's AcrySof Phakic AC-IOL) and of hydrogel material (Cibavision's Vivarte Phakic AC-IOL), when properly sized, are reported to have improved acceptable results in ongoing long-term clinical investigations (Knorz, 2003; Henahan,

2001). Iris-fixated phakic AC-IOLs of PMMA (Ophtec's Artisan Phakic AC-IOL), when properly implanted, also have been reported to have acceptable results, but the surgery requires special surgical techniques (Maloney *et al.*, 2002). Additionally, long-term safety data for the cornea and the iris are not yet available with well-controlled studies. The anterior chamber of the hyperopic eye is anatomically relatively small and thus less suitable for a phakic AC-IOL.

Phakic posterior chamber IOL designs using silicone and hydrogel materials are placed between the iris and the natural lens to correct myopic and hyperopic refractive errors. They have been clinically investigated over the past few years. Their anatomical placement has potential for iris chafing and related complication of pigmentary glaucoma. Also, cataractogenesis of the natural lens by either metabolic disturbances or accidental touch of a surgical instrument is reported, especially with silicone phakic PC-IOLs (Sanchez-Galeana *et al.*, 2003). A hydrogel phakic PC-IOL (Starr's ICL), after several design iterations in its final design, is reported to have fewer complications, and U.S. FDA approval is expected (Sanders *et al.*, 2003).

Accommodative IOL

In order to provide true accommodation after cataract surgery, as well as to treat refractive errors of myopia, hyperopia, and presbyopia, a safe and effective accommodative IOL with 3 or more diopters of accommodation ability to replace the cataract or the natural lens has been long sought after.

Designs implementing the concept of forward movement of the optic of the IOL to achieve accommodation were pursued by C&C Vision, Inc., of the United States and Human Optics of Germany (Samalo, 2002). The Crystalens AT-45 of C&C Vision is a silicone IOL with polyamide haptics and two hinges that permit axial forward movement of the optic for accommodation and subsequent backward movement for disaccommodation (Cumming *et al.*, 2001). Although only 1 to 2 diopters of such movement-based accommodation is reported, the results remain variable and without scientific understanding of factors responsible for such movement. Since there is no other significant safety issue, even this limited success is encouraging.

In order to achieve a greater magnitude of accommodation, a mechanically coupled pair of optic-based accommodative IOL was investigated in an animal model by Hara in Japan, and then by Sarfarazi in United States (Hara *et al.*, 1992). Recent results in monkey eyes by Sarfarazi are encouraging for this approach, which does not require any new materials for the design (Sarfarazi, 2003).

Another concept under investigation in animal models requires removal of the contents of the natural cataractous or clear lens through the smallest possible anterior capsulotomy and subsequently filling it by appropriate silicone polymer to achieve the needed geometrical shape and optical power (Haefliger *et al.*, 1987). Other gel biomaterials have also been investigated, but a host of surgical, biological, and optical issues remain as hurdles to this approach to restore accommodation using the natural capsular bag, zonules, and ciliary muscle for a physiology-based truly

accommodative IOL. In another variation of this approach, Nishi of Japan has reported implantation of a silicone-filled balloon as an IOL into the mostly intact capsular bag to achieve 4 to 8 diopters of accommodation in monkey eyes (Nishi *et al.*, 1993). Thus, a search for truly accommodative IOL may challenge interdisciplinary resources, including newer biomaterials for some of the above concepts.

Adjustable Power IOLs

For achieving the targeted postoperative refraction for any pseudophakic eye, careful measurement of the axial length of the eye and refractive power of its cornea are required before IOL implantation surgery. Subsequently, using one of many available IOL power selection mathematical formulas, the necessary IOL power is selected by the surgeon for implantation. Errors in this procedure and deviation of the actual axial position of the IOL from that anticipated by the formula result in postoperative residual refractive error. Most of the time, postoperative spectacle correction to address this error is acceptable, but occasionally excessive error requires explanation of the IOL to address unacceptable imbalance of refraction between the two eyes. Also, to achieve the goal of spectacle-free vision with multifocal IOLs or phakic IOLs, achievement of targeted refraction is more critical and necessary. Thus, for many years, concepts for a postoperative adjustable power IOL have been investigated. Several concepts requiring surgical reentry into of the eye were investigated, but did not result in products because of concern for safety and cost. A new, unique biomaterial-based light adjustable IOL by Calhoun Vision, Inc., is being pursued clinically in the human eye (Schwierling *et al.*, 2002). This approach is attractive since it does not require surgical reentering of the eye for adjustment of the refractive power of the already implanted IOL. This new biomaterial technology consists of an IOL, which is implanted as a polymerized silicone matrix containing nonpolymerized silicone macromers with an attached photoinitiator dispersed within it for subsequent staged photopolymerization (Maloney, 2003). The IOL is implanted as per current practice for IOL power selection for the targeted refraction. Postoperatively, the achieved refraction is measured. Depending upon sign and magnitude of the refractive error, for necessary adjustment of power of the IOL, the IOL is judiciously exposed to long UV radiation from a slit-lamp based light delivery instrument leading to partial photopolymerization. Spatial intensity distribution is used for either exposing the central optical zone, to increase the power of the IOL, or exposing the peripheral optical zone, to decrease the power of the IOL. After the required duration for redistribution of the remaining unpolymerized macromers in the IOL, the patient is reexamined for the consequent change in the shape, and, hence, power of the IOL toward the targeted correction of the refractive error. If the IOL power adjustment is not achieved, the procedure of partial polymerization is repeated with needed adjustment until targeted refraction is achieved. At this stage, as a final step, the entire optic is exposed with UV radiation for complete "lock-in" of the shape of the IOL. After the safety of this IOL was established in rabbit eyes, currently it is under clinical investigation required to establish safety and

efficacy in terms of accuracy, precision, reproducibility, and acceptance of resultant optical shapes.

Yellow-Tinted Blue Blocking IOL

Menicon and Hoya Corporations of Japan, for their PMMA IOLs, and recently Alcon, Inc., for its AcrySof IOL, have each incorporated a yellow dye into their IOL materials in order to block visible blue light in addition to complete blocking of UV radiation. The AcrySof Natural IOL mimics the UV-visible transmission of a 53-year-old human natural lens (Cionni, 2003). The scientific rationale for such a yellow-tinted IOL is to prevent unnatural excessive blue color perception, and to protect the more susceptible aging retina after cataract surgery. Blue light can be toxic to the retina and is considered one of the potential risk factors of age-related macular degeneration, a serious sight-threatening disease.

OVERALL SUMMARY AND FUTURE OF IOLS

In a relatively brief span of a few decades, IOLs have emerged as one of the most successful biomaterial-based implants. They are considered a safe and effective means to prevent the leading cause of age-related degradation of vision, cataracts, that eventually leads to functional blindness. Currently, an estimated 10 million IOLs are implanted annually for cataract replacement, mostly in the developed world, and in some regions of the developing world where resources are available. If the prevailing rate of cataract surgery in the United States is projected for the approximately 6 billion population of the world, then it is estimated that 45 million IOLs are needed annually! Few ophthalmologists and little money have led to delayed (or no) cataract treatment in the developing world, resulting in a tragic backlog of 20 million cataract-related blind people. Thus, with expected continuous global development and simultaneous increases in population as well as life expectancy, and with increasing demand for good vision, the future of IOLs for cataract surgery is assured.

The successful developments of IOLs were outcomes of interdisciplinary team efforts by creative surgeons, scientists, and engineers in both academia and industry. Starting from a biomaterial selection based on accidental implantation of pieces of PMMA from the canopies of fighter airplanes, a variety of newer biomaterials have been specifically created to achieve the various designs and functional goals of IOLs, as outlined in Table 2. Creative interactions and an understanding of the opportunities and issues of biomaterials, optical and mechanical designs, and evolving surgical techniques, along with improved understanding of the unique biology of the eye, have spearheaded the sophistication we see in modern IOLs. These efforts are expected to continue to achieve development of truly accommodative IOLs with the capability of mimicking the physiological function of the natural lens. Multidisciplinary efforts will also continue to achieve improved phakic IOLs to correct refractive error of presbyopia, myopia, and hyperopia. When long-term safety and efficacy are demonstrated, phakic IOLs or truly accommodative IOLs have the potential to replace the current alternatives

of spectacles, contact lenses, and a variety of corneal refractive surgery procedures, including LASIK. Thus, globally, the number of IOLs required for all functional goals could be manyfold greater than the given projection for IOLs needed for cataract replacement.

Further opportunities for improved optical designs of IOLs for correction of corneal aberration have just started with the Pharmacia Tecnis IOL (now Pfizer) (Mester *et al.*, 2003). With further understanding of the optical needs for achieving optimum vision, eventually a custom IOL may evolve for each individual eye for all of the projected functions of IOLs for aphakic and phakic eyes (Kohnen, 2003). Achievement of these goals will require advances in biomaterials for IOLs and biomaterials scientists working closely with physicists, chemists, engineers, surgeons, regulatory affairs experts, and business people. The success of IOLs in improving vision worldwide genuinely showcases the strength of the biomaterials endeavor and the highly multidisciplinary nature of this field.

QUESTIONS

1. What are the advantages of IOL implantation over spectacles for correction of vision after removal of cataract? What other improvements have been achieved in cataract surgery over the past 30 years?
2. Which was the first biomaterial selected for IOL implant? What was the basis for this selection?
3. What is the rationale for foldable IOLs? Which foldable soft hydrophobic materials are preferred over soft hydrophilic materials and why?

7.12 BURN DRESSINGS AND SKIN SUBSTITUTES

Jeffrey R. Morgan, Robert L. Sheridan, Ronald G. Tompkins, Martin L. Yarmush, and John F. Burke

Every year approximately 12,000 people die from severe burns and thermal injury. Most of these deaths are due to the catastrophic problems that ensue when the skin's integrity is disrupted. The major lethal problems are massive fluid losses and microbial invasion. Prompt replacement of the integrity of the skin is a cornerstone of therapy for these patients, but lack of available natural skin makes this an almost impossible task for those patients with very large burns.

The outlook for those who have suffered serious burns has improved dramatically over the past 20 years, in terms of both survival and postinjury quality of life. Twenty years ago a 30% burn was a serious threat to life and smaller burns resulted in protracted hospitalization and disability. Today such injuries are routinely managed with hospital stays measured in days, followed by prompt return to work or school. These improvements arose after the value of early excision and immediate autograft closure of full-thickness wounds was recognized and widely adopted. However, in those with large injuries, these favorable outcomes have not been realized because of the inability to accomplish immediate definitive wound closure. Until a durable and reliable skin replacement has been developed, these patients will continue to require protracted acute hospitalizations and find their reconstructive options limited by a shortage of autograft. The modern search for a suitable skin substitute has been under way since the 1940s, with steady progress as the principles of wound healing and the functions and properties of the skin became better understood. This chapter reviews those principles and examines their application as they relate to the search for the ideal skin substitute for patients with massive burns.

BRIEF HISTORY OF ADVANCES IN BURN TREATMENT

Burn patients die for two reasons: burn shock during the first few postinjury days and, in those who survive burn shock, wound sepsis during the first few postinjury weeks. Burn shock resulting from the diffuse capillary leak triggered by the burn wound, which results in inadequate circulating volume and progressive hypotension and eventual shock. The necrotic skin and subcutaneous tissue predictably become infected over the first postburn week, with resulting systemic inflammation and progressive sepsis. Recognition of these processes and the development of effective interventions have had a profound impact on the natural history of the injuries.

The exaggerated fluid requirements of burn patients were first understood in the 1930s. Various fluid resuscitation formulas were developed and refined over the ensuing 30 years. Although there is still room to improve fluid resuscitation techniques and to modify the physiology behind the high volume requirements, burn shock has been almost eliminated as a cause of death, except in those with cardiovascular disease or massive injuries.

Traditional burn management was expectant. Even in the 1950s and 1960s, when fluid resuscitation was becoming very effective, burn wounds were treated with various salves while the eschar (necrotic skin and fat) became colonized with bacteria, liquefied, and separated from the underlying viable tissue. This resulted in the regular occurrence of wound sepsis and nearly universal death in those with larger wounds. At this time there was therefore no need for a skin substitute. The odor from the liquefying wounds led to the separation of burn patients from other parts of the hospital. In the 1970s, the favorable impact of early identification and excision of full-thickness wounds with immediate skin graft placement on underlying viable tissue was recognized (Burke *et al.*, 1974). These procedures are not simple and were initially practiced only in those with small injuries, where truncated hospital stays and enhanced functional outcomes were noted. Those with large injuries continued to die; there was still no need for a skin substitute. With better availability of blood banks and intensive care units, burn excision is now practiced in those with large injuries where enhanced survival and shortened stays have been reported. However, closure of the massive wounds thus generated has become a very difficult clinical problem.

PRINCIPLES OF WOUND COVERAGE AND HEALING

Hospitalization of the massively burned patient is divided into four general phases: initial evaluation and resuscitation, initial wound excision and biologic closure, definitive wound closure, and rehabilitation and reconstruction. Currently, even those patients who suffer very large injuries can be expected to recover and become reintegrated with family and community. Length of hospital stay can be roughly estimated as 8 days + 0.8 days per percent burn and, in those with large injuries, is primarily limited by the absence of a reliable permanent skin substitute.

To understand the requirements necessary to replace lost skin, we must first understand the general mechanism of wound healing. Burn injuries result in loss of skin structure to varying degrees (Tompkins and Burke, 1989). Usually burns are first degree (the loss of the epidermal layer), second degree (the loss of the epidermal layer and a portion of the dermis), or third degree [the loss of tissue through the dermis, including the hair follicles and sweat glands, and extending into the hypodermis (subcutaneous) layers] (Fig. 1). Occasionally, as often seen in electrical injuries, a deep, full-thickness wound is referred to as a fourth-degree burn, which is defined as extending downward through the subcutaneous tissues to involve tendon, bone, muscle, and other deep structures.

FIG. 1. First-, second-, and third-degree burns and the depth of a split-thickness skin graft.

Second-degree burns can generally be classified as either superficial or deep. The interface between the epidermis and dermis is not linear, but consists of many papilla formed by the rete pegs of the epidermis. Also the skin varies in thickness at different locations on the body. In superficial injury, enough of the deep epidermal or superficial dermal layers may remain to allow spontaneous healing of the wound by reepithelialization. Other sources of epidermal cells are the epidermal appendages, including the hair follicles, sweat glands, and sebaceous glands. These wounds can be treated by simple dressings without topical antibiotics and will heal spontaneously within 10 to 14 days. Deep second-degree burns have completely destroyed the epidermis and extend further into the dermis, with large amounts of necrotic tissue being present. Both the fluid and bacterial barriers are severely compromised, putting the patient at a much higher risk. These wounds, if allowed to heal on their own (because the dermis has been grossly distorted or destroyed), result in hypertrophic scarring, with nonoptimal functional and cosmetic results. These types of wounds should be treated as if they were third-degree burns to allow for faster and better healing.

A third-degree burn is defined as having damaged the skin all of the way through the dermis and into the subcutaneous tissue. The wound is freely permeable to fluids, proteins, and bacteria. The constant proteinaceous exudate

from these wounds, combined with an abundance of necrotic skin above, make an ideal medium for bacterial growth. In these injuries, all the dermis and all of the epidermal cells within the wound have been destroyed, including those in the epidermal appendages. Dermis cannot regenerate, so it must be replaced, whereas epidermis can regenerate; however, without replacement, epidermal cells must migrate from the distant wound edges. Therefore, prompt debridement of the wound followed by autografting or other methods of wound coverage is the treatment of choice. Small third-degree wounds (those of less than 2 cm) may be allowed to heal spontaneously by ingrowth from the wound edges, but this process requires at least 6 weeks; the wound may never heal completely and always results in a generous scar.

When a patient suffers a third-degree burn, the necrotic layer of tissue that was once viable skin is referred to as the "eschar." This layer is removed surgically and any of the underlying dermis and hypodermis is then covered. If the freshly excised open wound is not immediately closed either with skin or skin replacement, then "granulation tissue" is formed by the local invasion of small blood vessels and fibroblasts from beneath the wound's surface. Granulating wounds become reddened with these new vascular structures, and if no grafting is performed and the wound is simply allowed to spontaneously heal, the continued invasion of fibroblastic tissue

FIG. 2. A dermatome used to harvest split-thickness skin grafts.

will eventually form a hypertrophic scar through the unorganized deposition of collagen. New epidermis seen around the edges of the wound is usually inadequate for reepithelialization in all but the smallest injuries. Myofibroblasts, specialized fibroblastic cells with the contractile properties of smooth muscle, invade the wound and begin to pull the edges inward and result in contractures and restriction in movement of the surrounding skin and its structures. This process can result in severe deformation of the surrounding features and is particularly troublesome in places such as the face, neck, and limbs. In some cases of massive wounds, even contraction of the wound will fail to bring the edges of the wound together, and the center of the wound remains open permanently.

Clearly the best coverage for the wound is natural skin taken from the individual himself (an autograft) to avoid specific immunological incompatibility. If the burn injury is anywhere from 35 to 50% of the total surface area of the body, it is frequently possible to transplant partial-thickness skin grafts from other noninjured areas of the patient. These grafts are usually about 0.3 to 0.5 mm thick and include the epidermal layer and a thin portion of the underlying dermis. They are harvested from the donor site using a reciprocating blade such as an electric dermatome or a hand-held knife (Fig. 2). The graft is placed on the freshly excised wounds and survives by simple diffusion of nutrients for the first 72 hours until neovascularization of the graft occurs. The graft must be placed on a wound bed free of dead tissue, infection, hemorrhage, or significant exudate or it will not survive. Wounds that have been freshly excised of all dead tissue offer the best short- and long-term results in all instances because granulation tissue prompts an inflammatory process that eventually results in exacerbation

FIG. 3. A skin meshing device.

of scar formation. The epidermis at the donor site where the graft was originally harvested regenerates in 2–3 weeks from the deep epidermal elements (hair follicles and sweat glands) which were left behind, leaving a thinner, less functional dermis because the dermis removed by the graft will not regenerate. Even in small burns there is a considerable price to the patient when a split-thickness graft is harvested. The threat of infection and hypertrophic scar formation is always present and the harvesting of a split-thickness skin graft always leaves a permanent scar and often unwanted pigment changes resulting in permanent cosmetic deformity.

Many times the graft is “meshed,” which involves passing the graft through a mesher which makes many small linear incisions in the graft (Fig. 3). These incisions allow the graft to be gently spread and expanded in size. By increasing the edge area of the epithelium, meshing allows the graft to cover from 1.5 to 9 times its initial area, although 1.5 to 3 expansions are most common. The mesh also allows fluids (tissue exudates and blood) to drain from the bed, which helps to increase the likelihood of graft survival. Unfortunately the mesh pattern is usually visible for extended periods of time after healing because the dermis does not properly regenerate within the interstices and therefore meshing makes the cosmetic results less desirable than with nonmeshed grafts.

WOUND COVERAGE AND SKIN SUBSTITUTES

Once an assessment has been made of the severity of the wound, decisions can be made as to the course of treatment and the appropriate types of materials that can be used to achieve closure of the wound. For first-degree and superficial second-degree burns the choice of medication or wound coverage is a never-ending source of discussion. However, as long as wounds are carefully monitored for infection and kept clean and moist, most medications and membranes will perform well. Topical medications range from petrolatum through antibiotic- or antiseptic-containing aqueous or ointment preparations

TABLE 1 Partial Listing of Some Commonly Used Topical Wound Medications and Their Principal Characteristics

Medication	Selected characteristics
Silver sulfadiazene	Broad spectrum, painless
Aqueous silver nitrate	Broad spectrum including fungi, electrolyte issues
Mafenide acetate	Broad spectrum, penetrates eschar
Petrolatum	Bland and nontoxic
Various debriding enzymes	Selected utility
Various antibiotic ointments	Selected utility

through debriding enzymes. A partial listing of available topical medications and their characteristics is given in Table 1. When properly used by knowledgeable persons in a program of burn care that includes regular wound evaluation, cleansing, and monitoring, all can be effective.

Wound membranes and substitutes either provide transient physiologic wound closure or can contribute to definitive wound closure (Fig. 4). Physiologic wound closure implies down-regulation of the intense inflammatory reaction characteristic of an open wound as well as a degree of protection from mechanical trauma, vapor transmission characteristics similar to skin, and a physical barrier to bacteria. Temporary membranes can contribute to the creation of a moist wound environment with a low bacterial density and have been used as a dressing on clean superficial wounds while they await

epithelialization. All synthetic membranes are more or less occlusive. If a membrane dressing is placed over devitalized tissue, submembrane purulence can occur in the closed space with potentially disastrous results. There are a large number of such membranes in common use, some of which are listed in Table 2.

TEMPORARY SKIN SUBSTITUTES

There are four common uses for temporary skin substitutes: (1) as a dressing on donor sites to facilitate pain control and epithelialization from skin appendages, (2) as a dressing on clean superficial wounds for the same reasons, (3) to provide temporary physiologic closure of deep dermal and full-thickness wounds after excision while awaiting autograft availability or healing of underlying widely meshed autografts, and (4) as a “test” graft in questionable wound beds. There are many temporary substitutes and membranes in common use (Pruitt and Levine, 1984), classes of which will be described next.

Allografts from Cadavers

Split-thickness human allograft, procured from organ and tissue donors, remains the standard by which other temporary skin covers are judged. This tissue is procured, processed, stored, distributed, and tracked by skin banks. Although commonly used after refrigeration for 7 days or less, it is quite

FIG. 4. Various wound covers, clockwise starting at the bottom left-hand corner: meshed split-thickness autograft, TransCyte, Epicel, cryopreserved cadaver allograft, Biobrane, split-thickness autograft, EZ Derm, and Integra Dermal Regeneration Template.

TABLE 2 Partial Listing of Some Commonly Used Wound Membranes and Their Principal Characteristics

Membrane	Selected characteristics
Temporary	
Porcine xenograft	Adheres to coagulum, excellent pain control
Biobrane ^a	Bilaminar, fibrovascular ingrowth into inner layer
Split-thickness allograft	Vascularizes and provides durable temporary closure
Various semipermeable membranes	Provides vapor and bacterial barrier
Various hydrocolloid dressings	Provides vapor and bacterial barrier, absorbs exudate
Various impregnated gauzes	Provides barrier while allowing drainage
Allogeneic dressings	Provides temporary cover while supplementing growth factors
Permanent	
Epicel ^b	Provides autologous epithelial layer
Integra ^c	Provides scaffold for neodermis, requires delayed thin autograft grafting
AlloDerm ^d	Consists of cell-free human dermal scaffold, requires immediate thin autograft

effective when cryopreserved according to well-established protocols designed to maximize cell viability. Cryopreserved skin can be made widely available through express mailing. When viable split-thickness allograft skin is applied to a clean excised wound, the tissue vascularizes and provides durable biologic cover until it is recognized as foreign by the host. This process generally results in loss of the allogeneic epithelium approximately 3 weeks after application in most burn patients. An added benefit to allografts that undergo revascularization is that, like autografts that revascularize, bacterial counts in the wound drop dramatically. Allografts at least provide temporary physiologic wound closure and allow time for reepithelialization of a donor site, but all allografts must eventually be replaced by autograft. When donor sites for autografts have reepithelialized it is possible to reharvest autograft from the same site; however, there is a limit to the number of times that a donor site can be reharvested because the dermis cannot regenerate and repeated removal of even thin layers of dermis will leave a donor area with unsatisfactory function. When modern screening techniques are followed, the risk of disease transmission by cadaver allografts is very low.

Allografts of Cultured Cells and Collagen

Using technology for the culture of skin cells that is described in detail later in this chapter, it is possible to culture large numbers of cells and to incorporate these cells into a composite skin substitute. Typically, discarded tissues, such as foreskins, are used as the starting source of cells. Cells from a 1-cm² piece of skin can be expanded to prepare approximately 1600 m² of certain types of cultured skin grafts, like the one described here. Since these cells did not originate from the patients to whom they will ultimately be transplanted, they are also allografts.

A cultured allogeneic composite graft with both an epidermal layer of cultured epidermal keratinocytes and a dermal

analog of cultured dermal fibroblasts in a collagen gel has been developed based on work by Eugene Bell and colleagues (Bell *et al.*, 1981). To prepare these grafts, cultured allogeneic fibroblasts of the dermis are mixed with a solution of purified bovine collagen type 1. This solution is allowed to gel and the surface of this gel is seeded with cultured allogeneic epidermal keratinocytes. When the surface of this bilayered skin equivalent is exposed to the air, the epidermal keratinocytes stratify, differentiate, and form a cornified layer much like the epidermis of normal skin. This cultured allograft (Apligraf, Organogenesis, Inc.) is approved for use in the treatment of diabetic foot ulcers and venous leg ulcers (Fig. 5). The allograft helps provide temporary wound closure and seems to stimulate local healing events that lead to closure of the ulcer.

A slightly different composite graft using cultured allogeneic skin cells is also commercially available (OrCel, Ortec International, Inc.). Fibroblasts and keratinocytes isolated from foreskins are grown *in vitro* and seeded on opposite sides of a bilaminar matrix of bovine collagen. The epidermal surface of the bilaminar matrix is a nonporous collagen gel, so keratinocytes seeded on the surface are able to form an epidermal cover. The opposite side or dermal side of the bilaminar matrix is a porous collagen sponge, so fibroblasts seeded on this surface are able to disperse and penetrate the sponge. These allogeneic composite grafts are matured *in vitro* (10–14 days). This product is approved for use on fresh, clean split-thickness donor sites in burn patients.

Xenografts

The most common source of xenograft (i.e., a graft from a different species) for temporary wound closure is the domestic swine. Typically high-quality frozen hides of 1 to 2-year-old animals are obtained from a reliable slaughterhouse. Split-thickness grafts (unmeshed and meshed) of desired sizes are

FIG. 5. The manufacturing process and close-up of Apligraf.

harvested from these hides. The final grafts, which have non-viable epidermal and dermal layers, are sterilized and stored frozen (Mediskin I, Brennan Medical, Inc.). Alternatively, the epidermis of the grafts is removed and the porcine dermis is subjected to aldehyde cross-linking to increase strength and durability. These grafts can be stored at room temperature (EZ Derm).

Porcine xenograft is used for the temporary coverage of clean wounds such as superficial second-degree burns and

donor sites. Its use has been favorably reported in patients with toxic epidermal necrolysis, and it has been combined with silver to suppress microbial colonization of wounds. Porcine xenografts, at best, only adhere to the wound bed with a fibrous interaction, but this can temporarily close a wound. The grafting success rate is lower than that with fresh cadaver allograft. The porcine grafts must be immobilized for several days to allow bonding of the graft to the wound bed by growth of fibroblasts into the dermal layer of the graft. As with any

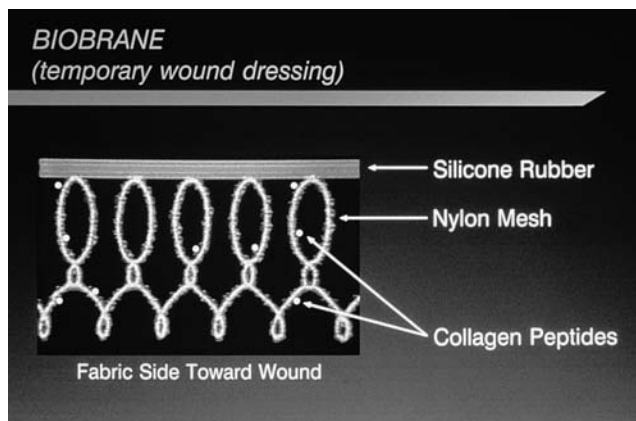

FIG. 6. Diagram of Biobrane.

skin replacement procedure, the wound bed must be debrided thoroughly and be free of significant bacterial contamination. Although porcine xenograft does not vascularize, it will adhere to a clean superficial wound and can provide excellent pain control while the underlying wound epithelializes. Because xenografts will ultimately separate from the wound bed, they must be removed and replaced with autograft material.

Synthetic Membranes

There are a number of monolayer semipermeable membrane dressings that are designed to provide vapor and bacterial barriers and to control pain while the underlying superficial wound or donor site heals. These can be used with good effect on clean superficial wounds as well as split-thickness donor sites. There is one bilayer synthetic membrane in general use at present. This product (Biobrane, Mylan Laboratories, Inc.) is a biosynthetic wound dressing constructed of a silicon film that forms a barrier to water loss and microbial invasion (Fig. 6). Partially embedded within the silicon film is a nylon fabric that has been covalently cross-linked with hydrophilic type I porcine collagen. The wound bed comes into contact with this complex three-dimensional fabric, which helps promote clotting in the nylon matrix and adherence of the membrane to the wound bed. The membrane stays attached to the wound until reepithelialization occurs. Biobrane is flexible enough to deform, maintaining adequate contact with the contours of the wound while still having the mechanical stability necessary for ease of handling and durability as a dressing. Biobrane is not biodegradable and serves at best only as a temporary closure material, lasting up to a month. This and other membranes like it have been used to good effect in clean superficial burns and donor sites.

Hydrocolloid Dressings

Hydrocolloid dressings are semioclusive dressings that combine a synthetic membrane or foam with a hydrocolloid. Elastomers and adhesives such as polyurethane provide a membrane that is conformable and lightly adhesive to the

FIG. 7. Photograph of TransCyte.

wound while providing a barrier to moisture loss and microbial invasion. To capture the exudate produced by many wounds, the polyurethane is combined with a hydrocolloid such as carboxymethylcellulose that forms a gel when it absorbs liquids. The gel helps to provide a moist environment that may enhance wound healing, and the semioclusive nature of the membrane helps to alleviate pain. Since the moisture-capturing capacity of the hydrocolloid can be saturated, hydrocolloid dressings are changed every 3–5 days. Although, like monolayer membranes, they are often associated with submembrane fluid collections, they can be used to good effect in selected superficial wounds.

Cells Combined with Synthetic Membranes

A hybrid product of cultured cells and synthetic polymers has also been produced as a temporary substitute. This product (TransCyte, Smith & Nephew) is commercially available for the treatment of burns (Fig. 7). A nylon mesh, coated with porcine dermal collagen, is bonded to a thin silicon membrane. These membranes are inserted into a cassette-like bioreactor containing culture medium. The nylon matrix is seeded with allogeneic fibroblasts that grow within the three-dimensional nylon mesh. During this growth, the cells deposit additional collagen, extracellular matrix proteins, and growth factors. When growth is complete, the culture medium is removed from the bioreactor, replaced with a freezing solution, and the entire cassette is frozen. The product is shipped and kept frozen. For use, the product is thawed, the freezing solution decanted, and the membrane removed and placed on the wound so that the fibroblast side contacts the wound. After the freeze and thaw process, the allogeneic fibroblasts are no longer viable. This product is used as a temporary cover for surgically excised full-thickness and deep partial-thickness as well as clean superficial burn wounds. The intended use of this product is as an alternative to cadaver allografts. The silicon layer and nylon matrix are translucent, making it possible to visually monitor the wound bed for the possibility of microbial infections. Since the nylon mesh is not biodegradable, this product must eventually be removed.

Areas of Research

One promising area of research is the identification of growth factors that promote wound healing by stimulating cell proliferation and/or cell chemotaxis. The genes encoding many of the growth-factor proteins that are secreted by cells in the wound environment have been identified and large amounts of these proteins have been produced by recombinant DNA technology. Several of these growth-factor proteins are being tested as ointments or incorporated into biomaterials for sustained delivery to wounds. A gene therapy approach is also being investigated as another means to achieve sustained delivery of growth factors. Cultured keratinocytes have been genetically modified to secrete high levels of wound-healing growth factors and are being tested in preclinical studies (Eming *et al.*, 1998).

PERMANENT SKIN SUBSTITUTES

Although no ideal substitute exists at present, there are a number of skin substitutes that may contribute to the permanent reconstitution of the dermis, epidermis, or both. This is an area of active investigation that is of particular importance for the massively burned patient.

Autografts of Sheets of Cultured Keratinocytes

Using methods pioneered by Howard Green and colleagues, keratinocytes, the principal cell of the epidermis, can be grown in large numbers from a small piece of freshly harvested skin ($\sim 25 \text{ cm}^2$) (Green *et al.*, 1979). This full-thickness biopsy of skin is procured from an unburned area and sent to a company

(Epicel, Genzyme BioSurgery, Inc.) that specializes in cultured skin. The biopsy is minced, and the pieces treated with specific enzymes to disaggregate the tissue into single cells. The resulting cell suspension is plated in culture flasks along with a "feeder layer" of murine fibroblasts that have been treated with a nonlethal dose of radiation that prevents them from multiplying. The murine fibroblasts provide insoluble matrix proteins that facilitate the clonal growth of keratinocytes as well as other growth factors. The flasks also contain a rich culture medium that contains numerous factors which stimulate the growth of keratinocytes, such as fetal calf serum, epidermal growth factor, insulin, hydrocortisone, and cholera toxin. Within a few days after plating the cell suspension, small colonies of two to four cells form and eventually expand into larger multicell layered colonies of keratinocytes (Fig. 8). To expand cell numbers even further, these primary cultures of keratinocytes can be treated with trypsin and the resulting cell suspension passed to more culture flasks for secondary cultures. To ready the cells for transplantation, the keratinocyte colonies are grown to confluence by letting the colonies merge into one continuous sheet of cells that covers the entire surface of the flask. This also results in dislodgement of the murine fibroblasts. The resulting sheets of keratinocytes are removed from the dishes as intact sheets by treatment with the enzyme dispase. The thin sheets of cells, which are 30 cm^2 in size and approximately two to eight cells thick, are attached to petrolatum gauze for ease of handling and shipped back to the hospital. The company specializing in this procedure can now deliver 192 sheets of cultured epithelium within 21 days of receiving the biopsy. Depending on the size of the patient, this is equivalent to 45% of the total body surface area.

Since the patient's own skin is used in the process, the cultured cells are autologous and the resulting epithelial sheet

FIG. 8. Stained colonies of cultured keratinocytes at various stages of growth and close-up of Epicel, a sheet of cultured keratinocytes.

is an autograft that is capable of permanent engraftment. Cultured epidermal sheets have been used widely for the treatment of very large burns with mixed results and, at times, suboptimal rates of engraftment. When compared to the performance of standard split-thickness autografts, the gold standard of graft performance, autografts of cultured epithelial sheets have several deficiencies. The cell sheets are thin and fragile and thus are sensitive to mechanical dislodgement, dehydration, and microbial destruction. Moreover, since the cell sheets lack a dermis, cosmetic, functional and durable properties of engrafted epithelial sheets is not ideal.

Analog of the Dermis as Part of a Bilayered Skin Replacement

Ioannis Yannas and John Burke developed a bilaminar skin replacement with an outer layer of Silastic and inner layer of collagen sponge (Burke *et al.*, 1981; Yannas *et al.*, 1982a). They performed extensive design and optimization steps to produce a skin replacement that had a synthetic epidermal layer with performance characteristic similar to native epidermis and a dermal layer that acts as a biodegradable scaffold to facilitate vascularization and population by normal healthy host fibroblasts. This material is approved by the FDA for burn treatment and is commercially available (Integra Dermal Regeneration Template, Integra LifeSciences, Inc.; Figs. 9, 10). The outer Silastic layer is 0.1 mm thick and provides the bacterial barrier needed while maintaining the proper water flux through the membrane. In order to prevent the swelling of the wound bed and the accumulation of fluid between the graft and its bed, all grafts must be permeable to moisture.

The exact permeability must be controlled, as too large a water flux of moisture will result in dehydration of the wound surface and disruption of the wound-graft interface, whereas too small a water flux will cause the accumulation of exudative fluid beneath the graft and lift it from the wound bed. Flux through the Silastic membrane is 1 to 10 mg/cm²/hr, which is similar to that of normal epidermal tissue. The Silastic layer also provides the mechanical rigidity needed to suture the graft in place, preventing movement of the material during wound healing.

A principal component of the dermal analog of this material is collagen. Collagen is an excellent material owing to many of its unique properties. Collagen is a polypeptide compound, hydrophilic in nature, and subject to degradation by distinct classes of extracellular enzymes. The substance is very well studied, allowing for the control of many key physical parameters, including the small strain viscoelastic properties and the rate of degradation (which can be controlled either by cross-linking the collagen fibers or by incorporation of other materials in the suspension). A fairly pure form can be extracted in large amounts from many commercial sources. Collagen is inherently low in antigenicity and exerts a hemostatic effect on the fragile and vascular wounds. Collagen can be formulated in many different ways from gels to films, depending on the properties desired and methods for application. Cross-linking the collagen fibers increases the tensile strength, but unfortunately it also tends to make the fibers stiff and brittle. The permeability of collagen materials may be controlled by their thickness, but mechanical properties must be considered if the material becomes too thick. By incorporating dilutants, the Young's modulus of collagen can be varied over a range

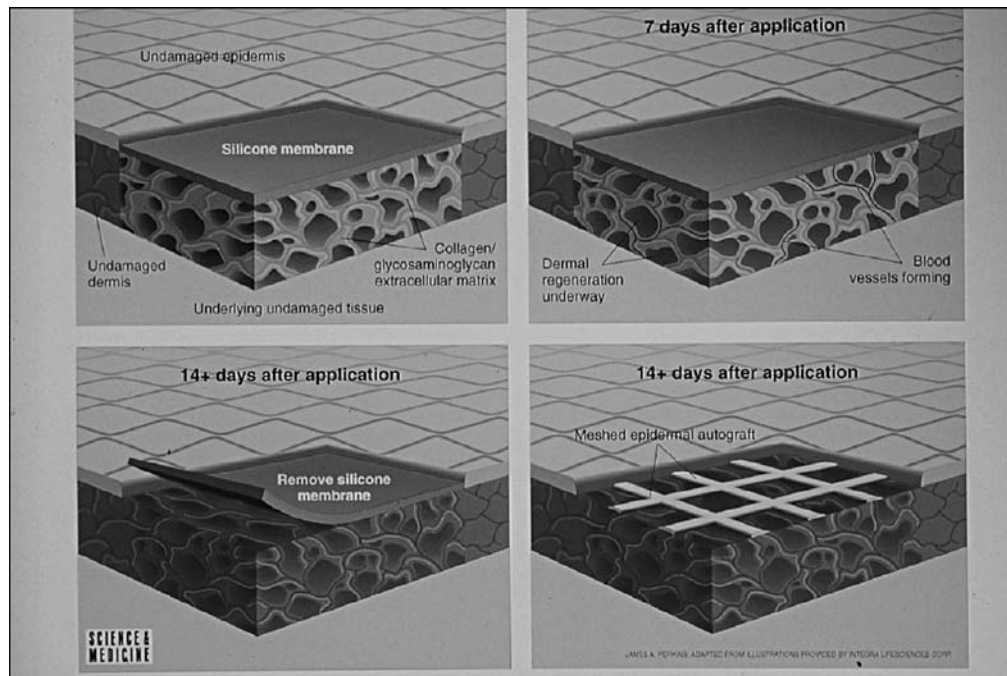

FIG. 9. Schematic of Integra Dermal Regeneration Template placed in an excised burn wound.

FIG. 10. Manufacturing process of Integra Dermal Regeneration Template. Bovine tendons are cleaned, frozen, processed into a slurry with glycosaminoglycans, and freeze dried into sheets.

of 10^5 . A problem noted with collagen was that by increasing the cross-linking (in order to add strength) the compound became stiff and brittle. This could be overcome by incorporating a second macromolecule, a glycosaminoglycan (GAG) into the membrane (discussed next).

Another property of collagen is that it naturally adheres to the wound initially because of its binding with fibrin. The collagen–chondroitin 6-sulfate adheres to the wound within minutes (in contrast to collagen sponge), and neovascularization can be observed within 3–5 days. The strong attachment of the collagen–GAG to the wound is evident by measuring the peel strength of the graft, which is 9 N/m at 24 hours and increases to 45 N/m by 10 days. Successful adherence of the artificial skin to the wound results in physiologic wound closure and its beneficial effects.

The dermal analog of the Integra Artificial Skin is actually a mixture of fibers of collagen (isolated from bovine tendon) and chondroitin 6-sulfate, a type of glycosaminoglycan (GAG) isolated from shark cartilage. During the manufacturing process, the collagen fibers and GAGs are coprecipitated and this slurry is poured into metal pans, frozen using a controlled-rate freezer and then freeze dried (Fig. 10). This process creates a collagen/GAG sponge with controlled pore size (Chamberlain and Yannas, 1999). Proper pore size facilitates

optimal ingrowth of fibrovascular cells. An impermeable graft without pores would not provide any means for such migration. Since most of the epithelial and mesenchymal cells found in the wound bed are on the order of $10\ \mu\text{m}$ in diameter, pores consistent with that order of magnitude would allow free access into the graft material. Pore size of the membrane was shown to be exquisitely sensitive to the method of drying. Dagalakis *et al.* (1980) showed that instantaneous freezing followed by slow sublimation at constant low temperatures was necessary to ensure the maximum mean pore size.

Also influencing final pore size was the inclusion of GAGs. Glycosaminoglycans are found in significant quantity in the ground substance of extracellular matrix and may contribute up to 30% by dry weight of this intercellular region. GAGs consist of a family of macromolecules (molecular weight from 10^5 to 10^6) that share the characteristic of having multiple long polysaccharide chains covalently bound to a core protein by a glycosidic bond. In contrast to glycoproteins, these compounds have a significant quantity of carbohydrate and exhibit behaviors closer to those of a polysaccharide than to those of protein. Each of the various GAGs has its own unique repeating disaccharide that forms the long carbohydrate chains. In the case of chondroitin 6-sulfate, the sugar is *N*-acetylgalactosamine (Fig. 11). The molecules are highly charged and polyanionic

FIG. 11. Repeating disaccharide of chondroitin 6-sulfate.

in nature. They have multiple properties, including the ability to change the mechanical properties of their environment. Hyaluronic acid, which is found in the synovial fluid of joints, contributes to lubrication. For the artificial skin or skin replacement developed by Yannas and Burke, the GAG chondroitin 6-phosphate was chosen because of its important properties: (1) low antigenicity; (2) nontoxic breakdown products; (3) ability to decrease the rate of collagen breakdown; and (4) ability to increase the strength of collagens while making them more elastic. When examined by electron microscopy, the pore structure of the collagen-GAG sponges was significantly more open than that of GAG-free collagen and one could control the pore size by adjusting the collagen-GAG mixture. Bonding of chondroitin 6-sulfate to the collagen is required because at neutral pH the GAG will dissociate from collagen and elute from the material in the absence of cross-linking.

Cross-linking of the sponge was shown to contribute to pore size as well as strength, elasticity and importantly, the rate of degradation. In their design, Yannas and Burke sought to balance the rate of degradation with the time required for cellular regeneration. To balance these terms, they estimated that the time constant for biodegradation (t_b) should be on the same order of magnitude as the time required for the wound to heal (t_h), approximately 25 days, or

$$(t_b)/(t_h) \sim 1$$

Since t_h is constant for any patient, the design of the graft was controlled for t_b . They reasoned that if the graft degraded too quickly, the wound would effectively be left uncovered. On the other hand, if the graft remained intact for long periods of time after the wound was healed, then scar formation and incorporation of the device into the wound would become problems.

Cross-linking of the collagen and GAG was performed using glutaraldehyde. The coherent membrane was removed from the glutaraldehyde and placed in distilled water to remove any unreacted aldehydes. If the membrane was freeze dried, it was first necessary to partially cross-link the collagen in a 105°C vacuum oven. After this step, it was possible to immerse the membrane in a glutaraldehyde solution without it collapsing; the remainder of the cross-linking was then carried out in the standard manner. The amount of cross-linking, which in turn affects the strength, elasticity, and pore size of the membrane, was controlled by adjusting several parameters. The time the membrane remained in the vacuum oven determined the initial retention of GAG by the membrane;

the second step of cross-linking by glutaraldehyde was carried out under acidic conditions (pH 3.2), although they slow the cross-linking process because the GAG forms an unstable ionic complex with collagen at neutral pH. By adjusting the concentration of glutaraldehyde in the mixture, it was possible to tightly control the molecular weight between cross-links (M_c , an inverse measure of cross-link density) between a very loose network ($M_c = 30,000$) and a very tight one ($M_c = 10,000$). This processing resulted in a collagen-GAG complex with $8.2 \pm 0.8\%$ GAG by weight, a pore volume fraction of $96 \pm 2\%$, and a mean pore size of $50 \mu\text{m} \pm 20 \mu\text{m}$.

The final step in the production is the addition of the Silastic layer. The Silastic layer was applied as a liquid monomer, and curing takes place at room temperature on the surface of the collagen after exposure to ambient moisture. The final bilayer copolymer composite is then stored at room temperature either in 70% alcohol or after being freeze dried. Integra LifeSciences provides this material as 10×25 cm aseptic sheets packaged in 70% isopropyl alcohol, which are stored at 2–8°C prior to use.

This off-the-shelf product is used for the coverage of freshly excised full-thickness burns. In 2 to 3 weeks when the dermal analog has revascularized, the outer silicone membrane is removed and replaced with an ultrathin epithelial autograft. Procuring thin autografts has several advantages because donor sites heal faster with less morbidity and repeat harvesting of these sites can be performed sooner. Initial reports of this material were successful, and postmarketing trials are in progress. Histological cross sections of wounds closed with this artificial skin show complete replacement of bovine collagen at 7 weeks with remodeled human dermis. Minimal evidence of hypertrophic scar formation has been noted, and the grafted areas are more supple than those areas simply covered with meshed autograft. This artificial skin is the only long-term dermal replacement with a large experience with burn patients (Heimbach *et al.*, 1988). Although submembrane purulence must be watched for and promptly treated, the material is likely to play an important role in the management of serious burns.

Acellular Allogeneic Dermis

Cadaver skin has been processed to yield an acellular product that is used as an analog of the dermis. Split-thickness cadaver skin is treated with a high-salt solution and the allogeneic epidermis is removed and discarded. This deepdermalized dermis is further treated with a solution containing a detergent to eliminate dermal cells and to inactivate any possible pathogens such as viruses. The resulting acellular dermis has no cells but has bundles of collagen and elastin fibers organized as both reticular and papillary dermis. The undulating papillary surface has many of the proteins of the basement membrane such as laminin, and collagen types IV and VII that are important for the attachment and migration of epidermal keratinocytes. The acellular dermis also has basement membrane proteins that line the channels previously occupied by dermal blood vessels. The material is further washed in a freezing medium and freeze-dried under controlled conditions to

avoid disruption of the matrix proteins. This acellular dermis, which is commercially available (AlloDerm, LifeCell, Inc.) is supplied as a freeze-dried sheet (meshed or unmeshed) approximately 200 cm². Prior to use, acellular dermis is rehydrated in normal saline, becomes soft and pliable, and can be secured with sutures if necessary.

Acellular dermis has been widely used as an implant in oral and reconstructive surgery, whereas for burns, there has been limited use. Acellular dermis has been used for the treatment of full-thickness wounds by applying it to a clean vascularized wound bed and overlaying the acellular dermis with a thin (0.003 to 0.006 inch) split-thickness autograft. Thin autografts, with minimal dermis, are recommended since excessive dermal tissue can interfere with graft take. The grafts are dressed to prevent infection and dehydration. Since the acellular dermis has had its cells removed, the primary targets of immune rejection are lost and acellular dermis is not rejected like conventional cadaver allografts. Rather, the acellular dermis acts as a scaffold for the ingrowth of fibrovascular cells and the thin autograft reepithelializes the surface. Clinical experience with this material in acute and reconstructive burn wounds is still early and limited, but appears favorable.

Permanent Skin Substitutes in Development

Most investigators have come to the conclusion that the ideal skin substitute for the patient suffering from large burns will provide for immediate replacement of both lost dermis and lost epidermis. Both elements are required for optimal function and skin appearance; however, a reliably successful composite substitute that performs as well as split-thickness autograft has not yet been developed. Much exciting work is underway and such a device might very well revolutionize burn care.

Yannas and Burke have extended their studies by seeding the dermal analog of their bilayer skin replacement with autologous keratinocytes obtained from the patient. A small sample of skin is removed from the patient and the top cornified layer of the epidermis is discarded. The basal proliferative cells are then dissociated from one another with trypsin, and suspended in growth medium. These cells are introduced into the dermal analog, either by direct injection or by centrifugal force (this entire procedure can be accomplished in the guinea pig model in under 4 hours). The keratinocytes proliferate and form sheets of keratinized cells. Functional skin replacement has been achieved in guinea pigs in under 4 weeks (Yannas *et al.*, 1982a).

Cultured cells have also been combined with the collagen-GAG dermal analog and tested in burn patients with some success. The surface of the dermal analog has been laminated with a thin layer of collagen and this surface seeded with cultured autologous epidermal keratinocytes (Boyce and Hansbrough, 1987). In addition, the porous underside of the dermal analog is seeded with cultured autologous dermal fibroblasts. When grown at the air/liquid interface, the epidermal keratinocytes stratify and form a cornified layer. This composite skin graft of biomaterials and autologous cells has been tested in a limited clinical trial for the permanent

closure of full-thickness burns with some success, and further investigations of this potentially exciting technology continue.

CONCLUSIONS

There are two major categories of skin substitutes and wound coverings: temporary and permanent. If a wound is superficial and will heal in reasonable time and produce acceptable cosmetic results, then this wound may benefit from coverage with a temporary skin substitute. As a group, temporary skin substitutes all provide a barrier to microbial invasion, help prevent fluid loss, serve to control pain, and provide coverage while healing is taking place under the substitute. There are a variety of temporary substitutes available that are widely used with good success. Depending on their specific use, these temporary substitutes are fabricated from a variety of synthetic materials, purified naturally occurring biomaterials, and processed tissues as well as cultured cells of the skin. These are often combined to produce hybrid devices that have two or all of these components. Since these are temporary skin replacements, allogeneic cells from unrelated donors are used to allow for the large-scale production of these devices prior to use.

Deep third-degree burns will not heal on their own and so require permanent skin closure. The gold standard for the permanent closure of these wounds is the split-thickness autograft obtained from an unburned area of the same patient. However, for the massively burned patient, these donor sites are limited. These patients have a desperate need for a permanent skin replacement. Temporary skin substitutes used to close wounds on these patients can help to provide additional time for the healing of donor sites that can be reharvested. However, hospitalization is prolonged and cosmetic and functional outcomes are not ideal. Permanent skin replacements are being developed from synthetic materials, purified naturally occurring biomaterials, and processed tissues as well as cultured cells of the skin. Since these are permanent skin replacements, it is important that autologous cells from the patient be used with one or more of these components. Promising permanent skin replacements are presently being developed and evaluated; however, the ideal skin replacement for this group of patients does not yet exist.

7.13 SUTURES

Mark S. Roby and Jack Kennedy

INTRODUCTION

A suture is a strand of material that is used to approximate tissues or to ligate blood vessels during the wound-healing period. The use of linen suture as early as 4000 years ago makes these biomaterials one of the earliest recorded medical devices (Chu, 1991). Over the years, a variety of other materials have been used with catgut and silk being the most prevalent until the development of synthetic fibers during the 1950s. It is worth noting that catgut-based sutures used by Galen to treat wounded gladiators around 150 A.D. are still in use today (Barrows, 1986).

One class of sutures, the synthetic absorbable sutures, comprise the fastest-growing segment of the suture market and represent an area of considerable development. For these reasons, the following discussion will focus more on this class of sutures.

CLASSIFICATION

Sutures can be classified according to three characteristics—origin, absorption profile and fiber construction (Table 1).

TABLE 1 Classification of Sutures

Characteristic	Categories
Origin	Natural Synthetic
Absorption	Absorbable Nonabsorbable
Fiber construction	Multifilament Braid Monofilament

Table 2 summarizes the major types of sutures, general applications, and representative products and manufacturers.

Origin

Natural sutures are based on fibers derived from animals or plants. The two most important natural sutures are catgut based on animal collagen and silk spun by the silkworm. Synthetic sutures are based on manmade polymers or metals. Manmade polymers include many common textile fibers such as PET, nylon, polypropylene, and PTFE as well as those based on α -hydroxy acids.

Absorption

Originally, an absorbable suture was one that lost a significant portion of its mechanical strength over a period of 2 months while a nonabsorbable suture was one that maintained a significant portion of its strength longer than 2 months (Swanson and Tromovitch, 1982). However, this period has been extended to three months for certain synthetic absorbable monofilaments and up to a year for a new braided suture developed since that time (Chu, 1997a; Guttman and Guttman, 1994), further blurring the line between absorbable and nonabsorbable materials.

In the case of absorbable sutures, it is important to distinguish between the loss of mechanical strength and the absorption and elimination of the material from the body. A suture may lose its tensile strength over a relatively short period of time, for example weeks, but require months or even years to absorb completely and be eliminated from the body. The tensile strength loss profile is an important parameter in suture selection since mechanical support is necessary during the critical wound-healing period.

The primary mode of degradation for natural materials is enzymolysis, whereas for synthetic absorbable materials it is hydrolysis (Capperault and Bucknall, 1984; Chu, 1985; Salthouse and Matlaga, 1976; Singhal *et al.*, 1988; Zhong *et al.*, 1993). However, there are several reports indicating that enzymes may play a role in the degradation of synthetic absorbable materials (Chu and Williams, 1983; Williams, 1982). Most likely enzymes play a greater role in the degradation and elimination of the hydrolysis by-products from synthetic absorbable sutures (Salthouse and Matlaga, 1976; Singhal *et al.*, 1988).

TABLE 2 Types of Sutures

Suture type	Generic structure	Major clinical application ^a	Type ^b	Representative product	Representative manufacturer
Natural materials					
Catgut	Protein	Plain: Subcutaneous, rapid-healing tissues, ophthalmic	T	Surgical Gut	Ethicon
		Chromic: Slower-healing tissues	T	Chromic, Plain Gut	Syneture
Silk	Protein	General suturing, ligation	T	Mild Chromic Gut	Syneture

^bT, twisted monofilament; M, monofilament; B, multifilament braid.

Fiber Construction

Sutures are fabricated into fibers in order to maximize the resulting strength. For materials that possess a high tensile modulus, yarns composed of low-denier filaments are fabricated into a multifilament braid in order to achieve adequate suppleness. Materials that possess a tensile modulus of about 500 kpsi or less can be fabricated into monofilaments with acceptable handling characteristics although the optimum range is about 350 kpsi or less. Catgut is a twisted multifilament with a polished outer surface that handles similarly to and is therefore often classified as a monofilament.

Because a suture is required to pass through tissues with minimal friction, coatings are normally applied to multifilament braids to increase the surface lubricity. Like the suture itself, coatings can be based on absorbable or nonabsorbable materials.

GENERAL CHARACTERISTICS

Sutures can be characterized by a number of different properties, all of which can be categorized into three groups—physical, handling, and biological (Table 3). There is no one

TABLE 3 Suture Properties and Definitions

Characteristic	Definition
Physical	
Dimensions	Size (diameter) and length
Tensile strength	Maximum tensile stress that can be applied to the strand
Knot-pull strength	Maximum tensile stress that can be applied to the ears of a knot
Needle attachment force	Force required to separate the needle and strand
Knot security	Force that a knot can withstand before slipping or untying
Coefficient of friction	Force required to slide a strand across itself
Stiffness	Force required to bend a strand to a predetermined angle
Memory	Tendency of a strand to return to its original shape
Creep	Deformation of a strand or knot over time when subjected to a constant load
Swelling	Tendency of a strand to swell in tissues
Capillarity	Degree to which a liquid is transported along a strand
Handling	
Knot tie down	Ease with which a knot can be slid down a strand
First throw hold	Force that a "surgeon's knot" (double turn) can withstand before slipping
Tissue drag	Force required to pass a strand through tissue
Package memory	Degree to which a suture retains its package configuration
Suppleness	The "feel" of a suture
Biological	
Tissue reaction	Cellular response to a strand
Tensile strength loss	The loss of tensile strength as a function of time
Absorption	Enzymatic and/or hydrolytic breakdown of a strand followed by elimination
Biocompatibility	Degree to which a strand and breakdown products affect surrounding tissue

ideal suture since the type of tissue, the patient condition, and surgeon preference all come into play when selecting an appropriate suture. The availability of several different types of suture materials offered by different manufacturers makes this selection process a difficult one without an understanding of the basic properties of each.

SUTURE MATERIALS

Natural Sutures

Catgut Suture

Catgut is generally derived from bovine intestinal serosa or from the submucosa of sheep or goat intestine. The primary constituent of catgut is collagen, a protein of three polypeptides arranged in a triple helix coil structure. Processing begins with the cleaning and splitting of the gut into longitudinal ribbons followed by additional chemical and mechanical cleaning. The resulting ribbons are then treated with dilute formaldehyde to increase strength and the resistance to enzymolysis by blocking the hydroxy and amino pendant groups on collagen (Chu, 1997b). The treated ribbons are then twisted and dried followed by mechanical grinding and polishing on a centerless grinder to achieve the desired diameter. This grinding process can result in the disruption of fibril integrity at the surface since the strand is composed of twisted ribbons. This leads to weak points that can contribute to inconsistency in strength and, more importantly, to fraying when a knot is run down the length of the suture (Benicewicz and Hopper, 1990; Chu, 1997b). Catgut that is treated in the manner just described is

referred to as plain gut. Tanning of catgut using chromium salts was first developed by Lister in 1840 and is referred to as chromic gut. Chromic gut slows the rate of absorption and results in lower tissue reaction (Chu, 1997b). Since catgut sutures become less pliable on drying, these materials are generally packaged in an alcohol solution.

Catgut has been used for centuries because it is a well known and inexpensive absorbable material. Disadvantages include inconsistent strength, inconsistent tissue absorption, fraying, and tissue reactivity.

Silk Suture

Silk is a fibrous protein derived from the silkworm, normally the *Bombyx mori* silkworm (Chu, 1997b). Processing involves the removal of natural waxes and gums followed by twisting or braiding of the fine filaments into a multifilament construction. To improve the smoothness, beeswax or a siloxane-based coating is applied to the braid. The level and the type of coating can have a significant effect on the knot rundown and the knot security. Silk slowly loses strength over a period of roughly 1 year and is absorbed after 2 or more years (Benicewicz and Hopper, 1990; Stashak and Yturraspe, 1978; Van Winkle and Hastings, 1972). Silk is inexpensive and is considered to be the "gold standard" in suture handling characteristics. However, as a natural material, it can incite a tissue reaction.

Collagen Suture

Another type of collagen suture is reconstituted collagen derived from bovine flexor tendons by enzymatic or acidic digestion to a gel followed by extrusion into a coagulation

bath. The resulting fibers are twisted and can be treated with chromium salts. Collagen sutures tend to be more consistent than catgut sutures and are simpler to process. The primary use for this suture is in microsurgery or ophthalmic surgery.

Cotton Suture

Cotton was introduced as a suture material in 1939 and gained wide use during World War II due to the scarcity of silk. It is based on cellulose derived from long-staple cotton fiber and is coated with wax. When implanted, it slowly loses tensile strength over a 2-year period (Van Winkle and Hastings, 1972). It possesses low strength that increases roughly 10% when the suture is wet (Stashak and Yturraspe, 1978; Herrmann, 1971). It elicits tissue reactivity similar to that of silk and possesses a high level of capillarity. Cotton suture material can also become electrostatically charged, causing it to cling to gloves and surgical linen (Bellenger, 1982). As with collagen the general use of cotton is limited.

Linen Suture

Linen is also based on cellulose and is derived from twisted long-staple flax. Like cotton, its tensile strength increases when wet. It possesses a higher tissue reactivity and greater capillarity than cotton and has found limited use (Stashak and Yturraspe, 1978).

Synthetic Nonabsorbable Sutures

Polyester Suture

Polyester-based sutures include those based on poly(ethylene terephthalate) (PET), poly(butylene terephthalate) (PBT), and polybutester, which is a polyether-ester derived from poly(tetramethylene glycol), 1,4-butanediol, and dimethyl terephthalate. All are produced by the condensation of the corresponding diol or glycol with terephthalic acid or an ester of terephthalic acid. PET is a hard, brittle material, while the longer segment in PBT renders it somewhat less brittle. Both PET and PBT are fabricated into multifilaments to obtain the desired handling characteristics. Coating with Teflon, siloxane-based materials, or poly(butylene adipate) is required to increase surface lubricity. PET suture, introduced in the 1950s is the polyester used most frequently, and it has exceptional strength and minimal tissue reactivity. PBT results in a less stiff fiber than PET. The longer soft segment with the ether linkage in the polybutester reduces the tensile modulus enough that it can be fabricated as a monofilament. With minimal tensile strength loss, the polyesters offer excellent long-term support.

Polyamide Suture

Both nylon-6,6 and nylon-6 are fabricated into sutures. Nylon-6,6 is derived from the condensation of hexamethylene diamine and adipic acid while nylon-6 is derived from the ring-opening polymerization of caprolactam. Both nylons can be fabricated into either monofilaments or multifilament braids,

although the monofilaments tend to be stiff, requiring additional throws to secure the knot (Stashak and Yturraspe, 1978; Bellenger, 1982; Guttman and Guttman, 1994). However, the addition of a pliability fluid to the packaged monofilament suture can improve the pliability (Capperault and Bucknall, 1984). The multifilament nylons are generally coated with poly(butylene adipate) or a siloxane-based material. Since the amide bond is susceptible to hydrolysis, nylon sutures lose tensile strength over time (Chu, 1997b).

Polypropylene Sutures

Polypropylene sutures are based on isotactic polypropylene, polymerized from propylene using a Ziegler-Natta catalyst. Introduced in 1970, polypropylene causes one of the lowest tissue reactions and does not lose strength after it is implanted. Because of its smooth surface, careful knot tying is required in order to secure knots (Bellenger, 1982; Guttman and Guttman, 1994; Stashak and Yturraspe, 1978). Differences in processing of polypropylene can lead to differences in suture toughness, surface smoothness, and surface hardness, characteristics that can contribute to the relative level of fraying and breaking when tying knots (Chu, 1997b).

Fluoropolymer Sutures

Polytetrafluoroethylene (PTFE) is derived from the free-radical polymerization of tetrafluoroethylene and is employed as an expanded monofilament. Incorporation of pores results in a microporous structure that has 50% or more air by volume (Chu, 1997b). Although this inclusion of pores leads to relatively lower strength, expanded PTFE fibers possess a needle-to-suture diameter ratio of nearly one with the unique advantage that blood leakage is reduced relative to other types of sutures that do not have the ability to be compressed. In addition, the surface characteristics of ePTFE suture results in very low tissue drag. Pronova, a new monofilament suture based on blends of poly(vinylidene fluoride) and poly(vinylidene fluoride-co-polyhexafluoropropylene), has been introduced for use in cardiovascular surgery. The homopolymer component provides strength while the copolymer provides suppleness. Suture sizes smaller than 4/0 are made from a blend high in the homopolymer, while the larger sizes are made from a 50/50 mixture. This material reportedly exhibits improved pliability and resistance to fraying and breaking when compared to polypropylene sutures (Ethicon, 1999). Monofilament sutures made from homopolymers of poly(vinylidene difluoride) (PVDF) are available in several markets outside the United States. They are used as a replacement for polypropylene, and have been shown to be more resistant to creep (Wada *et al.*, 2001).

Stainless Steel

A number of different types of metal have been used over the past several centuries including gold, silver, bronze, copper, nickel, tantalum, stainless steel, and other alloys. Austenitic stainless steel is the most suitable type for sutures and is composed of iron, chromium, nickel and molybdenum (Bellenger, 1982). While stainless steel possesses very high strength, is inert, and is noncapillary, it is difficult to handle

FIG. 1. Monomers used in synthetic absorbable sutures.

because of kinking and possible puncturing of surgical gloves (Bellenger, 1982; Capperauld and Bucknall, 1984; Guttman and Guttman, 1994). In addition, the ends of stainless steel sutures can cause tissue irritation (Bellenger, 1982). Stainless steel is available either as a monofilament or as a multifilament braid.

Absorbable Synthetic Sutures

The need for an absorbable suture that was more consistent and more inert than catgut suture initiated the development of absorbable synthetic sutures. Today, synthetic absorbable sutures represent almost 42% of total suture usage worldwide.

Monomers

All of the major synthetic absorbable sutures are based on one or more of five different cyclic monomers—glycolide (GA), L-lactide (LLA), trimethylene carbonate (TMC), *p*-dioxanone, and ϵ -caprolactone (CL) (Fig. 1).

Because these monomers each produce polymers with different characteristics, absorbable polymers must be designed very carefully in order to achieve the desired properties (Tables 4 and 5). For example, construction of monofilaments requires the combination of flexible polymer segments such as that obtained with PTMC, PCL, or PDO with high-strength segments such as that obtained with PGA, PLLA, or PDO. When constructing copolymers in which the predominant block is PGA, the PGA block is prepared last since glycolide polymerizes rapidly with a melting point

TABLE 4 Properties of Homopolymers Derived from Common Monomers

Polymer	Abbreviation	Strength	Flexibility	Rate of hydrolysis
Poly(glycolic acid)	PGA	Excellent	Poor	Fast
Poly-(L-lactic acid)	PLLA	Good	Poor	Slow
Polydioxanone	PDO	Fair	Good	Moderate
Poly(trimethylene carbonate)	PTMC	Poor	Excellent	Slow
Polycaprolactone	PCL	Fair	Excellent	Slow

TABLE 5 Block Construction Considerations^a

Monomer	Polymerization rate	Residual monomer (%)	Glass transition (°C)	Peak melting (°C)
Glycolide	Fast	1–3	36	224–226
L-Lactide	Slow	2–7	65	185
<i>p</i> -Dioxanone	Moderate	4–15	–10–0	110–115
ϵ -Caprolactone	Slow	1–3	–60	70
Trimethylene carbonate	Moderate	1–5	–20	Amorphous

^aDoddi *et al.* (1977); Frazza and Schmidt (1971); Roby *et al.* (1985); Shalaby and Johnson (1994).

above the polymerization temperature of the other common monomers.

Polymerization

The ring-opening polymerizations or copolymerizations of these monomers are accomplished using an organometallic catalyst such as stannous chloride or stannous octoate and a mono- or difunctional hydroxy initiator. Numerous catalysts have been investigated, but the acceptable biocompatibility of tin (II) makes this metal catalyst the one of choice in biomedical polymers (Zhang *et al.*, 1992). In addition, stannous octoate is compatible with glycolide/lactide mixtures ensuring adequate mixing of the catalyst (Wasserman and Versfelt, 1974). The mechanism is thought to involve the formation of an activated ester carbonyl/catalyst complex followed by ring-opening by the initiator (Frazza and Schmitt, 1971; Shalaby and Johnson, 1994; Zhang *et al.*, 1992).

There are several competing reactions in the polymerization of these monomers including depolymerization from polymer to monomer and ester interchange, as well as thermal and/or oxidative decomposition. All of these competing reactions are influenced by the type of monomer, the temperature and the catalyst (Nieuwenhuis, 1992; Zhang *et al.*, 1992). The presence of carboxyl end groups can also have a deleterious effect on the thermal stability both at elevated temperature and at ambient temperature (Brode and Koleske, 1972). For this reason the acid number is minimized by using hydroxyl initiators and by the appropriate purification and moisture protection procedures. Since the presence of impurities can have adverse

TABLE 6 Effect of Composition on Crystallinity^a

Glycolide (mol%)	L-Lactide (mol%)	Morphology
0–25	75–100	Crystalline
25–65	35–75	Amorphous
65–100	0–35	Crystalline

^aGilding and Reed (1979).

effects on molecular weight, sophisticated handling, purification, and drying systems have been developed to ensure ultrahigh-quality monomer and to protect the entire monomer to finished suture process from excessive exposure to moisture and heat.

Synthetic Absorbable Multifilament Braids

Dexon suture introduced in 1971 by Davis & Geck (now Syneture) was the first successful commercial synthetic absorbable suture and is based on polyglycolic acid (Benicewicz and Hopper, 1990). Although PGA was first reported in 1893 by Bishoff and investigated by Carothers in 1932, it was not until the 1960s that Schmitt and co-workers were able to prepare PGA in the high molecular weights necessary for fiber applications such as sutures (Frazza and Schmitt, 1971).

One of the requirements for strength in a suture is a certain level of crystallinity to ensure adequate fiber properties. In the case of glycolide/lactide random copolymers, there are three general composition ranges possible as summarized in Table 6. Crystallinity reaches a maximum as the compositions approach 100% of either monomer and reaches a minimum for compositions comprising roughly equivalent concentrations of both.

Vicryl suture, based on a 90/10 PGA/PLLA copolymer, was introduced by Ethicon, in 1974 (Guttman and Guttman, 1994). Similarly, Polysorb suture was introduced by U.S. Surgical Corp. (now Syneture) in 1991, also based on a PGA/PLLA copolymer.

Although the homopolymer and copolymers exhibit similar properties, there are some differences, the most notable being the degradation profiles. Since the copolymers possess lower crystallinity than the PGA homopolymer, the resulting absorption time for the copolymers is somewhat less than that for the homopolymer (Capperauld and Bucknall, 1984; Chu, 1997c; Fredericks *et al.*, 1984; Guttman and Guttman, 1994; Swanson and Tromovitch, 1982). Modifications to Vicryl suture resulted in the 1996 release of a product with a slightly longer strength loss profile from 40% to 50% of the original strength at week 3 (Ethicon, 1996).

Another distinguishing feature between the three synthetic absorbable braids just discussed is the coating applied to the braid for increased lubricity. Typically, a suture coating must meet three requirements. First, it must allow knots to be run down the length of the suture smoothly without wearing off. Second, the coating must enable the knot thus formed to remain secure. Finally, the coatings must absorb in a similar manner to the suture itself and not increase the tissue reactivity. The initial Dexon and Vicryl braids did not possess coatings and

as a consequence were difficult to use. Each of the three braid products has undergone a number of coating variations.

Multicomponent coatings composed of PGA/PLLA copolymers and water-insoluble fatty-acid salts were developed as one way of meeting these needs (Mattei, 1980). The Vicryl coating is a mixture of equal parts of a PGA/PLLA copolymer and calcium stearate while the Polysorb coating is a mixture of a PCL/PGA copolymer and calcium stearoyl lactylate (USS/DG, 1997; Ethicon, 1996). In each of these coatings, the calcium salt facilitates knot rundown and knot security while the copolymer serves as a film-forming matrix for the salt. Unlike Vicryl and Polysorb sutures, Dexon II suture is coated with polycaprolate (Davis and Geck, 1990). The coatings are formulated so as to exhibit similar absorption characteristics to the suture itself.

Vicryl Rapide suture was introduced by Ethicon as a faster-absorbing synthetic absorbable braid relative to Vicryl suture itself. It is obtained by reducing the molecular weight of Vicryl braid and thereby reducing the time frame for tensile-strength loss.

Ethicon developed a long-term absorbable braid called Panacryl suture. This braided suture is designed for orthopedic use and composed of a PGA/PLLA (3/97) copolymer with a PCL/PGA coating. The tensile loss is complete in 1 year, and mass loss is essentially complete in 1.5 to 2.5 years (Ethicon, 1999a).

The synthetic absorbable braids offer a more consistent strength loss profile than catgut with less tissue reactivity, with the result that the use of these materials has grown dramatically and they are now the most commonly used type of suture in surgery (Rodheaver *et al.*, 1996).

Synthetic Absorbable Monofilaments

Much of the recent development in sutures has been in the area of synthetic absorbable monofilaments. As discussed previously, these materials offer the advantages of lower tissue drag, reduced capillarity, and, more recently, lower cost. To this end, five different sutures have been developed over the past 20 years. These include PDS II, Maxon, Monocryl, Biosyn, and Caprosyn sutures.

PDS suture is based on poly(*p*-dioxanone) and was introduced in 1983 by Ethicon, (Chu, 1997c). The appeal of this polymer system is the inherent simplicity (Doddi *et al.*, 1977). It combines the strength and hydrolytic sensitivity of the glycolic ester linkage with the flexibility and hydrolytic stability of the ether linkage in an alternating structure based on only one monomer. Subsequent to the introduction of PDS suture, improvements resulted in PDS II suture with greater flexibility and better handling characteristics (Chu, 1997c). It has been reported that these improvements were a result of fiber processing modifications (Chu, 1997c; Broyer, 1994). This modification is achieved by heat treating the fiber surface for a short period of time at approximately 125°C to melt and thereby modify the surface morphology. With 25% of its original strength at 6 weeks, PDS II suture offers the longest support of any synthetic absorbable suture (Ethicon, 1989). This extended support allows it to be used in slower healing tissues that previously required a nonabsorbable material (Capperauld and Bucknall, 1984).

TABLE 7 Effect of Block structure on PGA/PTMC Copolymer Properties^a

Block type	PGA content (wt %)	Peak melting (°C)	Tensile strength (kpsi)	Tensile modulus (kpsi)	21-day <i>in vivo</i> str. retention (% of original)	<i>In vivo</i> absorption (days)
Homopolymer	100	227	122	2100	20	<90
Random	88	209	65	970	3	<90
Block	65	216	42	610	53	<180
Modified block	65	213	61	260	69	<180

^aRoby *et al.* (1985).

Maxon suture, based on a PGA/PTMC (67.5/32.5) tri-block copolymer, was introduced in 1985 by Davis and Geck (Benicewicz and Hopper, 1991). The middle block is composed of a PTMC/PGA (85/15) random copolymer while the two end blocks are composed of predominantly PGA (Casey and Roby, 1984). The structure of this copolymer was the result of investigating several block structures and composition ratios of glycolide and TMC (Table 7). As can be observed, increasing the TMC content reduces the tensile modulus, extends the tensile strength loss profile, and increases the time required for absorption. Although the simplest to construct, the random copolymers begin to lose the required properties at a low level of PTMC incorporation. On the other hand, the diblock copolymers begin to approach the desirable properties but do not possess the required flexibility. However, incorporation of glycolide into the PTMC middle block achieves the desired characteristics of extended strength and flexibility. Here the PGA segments contribute high strength and hydrolytic sensitivity while the PTMC segments contribute flexibility and extend the tensile strength loss profile by virtue of its relatively lower hydrolytic sensitivity. It is important to note that the addition of small amounts of PGA to the predominantly PTMC middle block is essential to the absorption of the polymer since PTMC absorbs very slowly if at all. Maxon suture also offers longer support than the original synthetic absorbable braids, comparable to PDS II (USS/D&G and Ethicon IFU).

Unlike the first two monofilaments, Monocryl suture was developed as a shorter-term suture. Introduced by Ethicon, it

was more directly positioned against catgut suture (Bezwada *et al.*, 1995). The structure of Monocryl suture is also the result of a two-step polymerization process based on a PGA/PCL (75/25) copolymer. It has been reported that the first block is a PCL/PGA (45/55) random copolymer while the end blocks are predominantly composed of PGA (Bezwada *et al.*, 1995). It was found that the solubility of the random PCL/PGA middle block in the glycolide added in the second step to form the end block was critical to obtaining a one-phase system with the desired properties. This solubility was dependent on the PCL/PGA middle block ratio with PCL contents in the range of 40–50% being preferred (Bezwada and Jamiolkowski, 1993).

Biosyn suture is a recent addition to the family of monofilaments, introduced in 1995 by U.S. Surgical Corp. Unlike other monofilaments that offer strength-loss profiles that are either shorter or longer than those of the absorbable braids, this product was positioned as a monofilament with a strength-loss profile similar to that of the absorbable braids. The most complex structure of all of the synthetic absorbable sutures, it is based on three different monomers—glycolide, TMC, and *p*-dioxanone in a 60/23/17 weight ratio (Roby *et al.*, 1997). Like Maxon and Monocryl copolymers, the Biosyn copolymer is based on a two-step process. The first block is a random PTMC/PDO (65/35 w/w) copolymer while the end blocks are random PGA/PDO (92/8 w/w) copolymers (Roby *et al.*, 1995). As was the case with the Maxon and Monocryl copolymers, the block structure and composition are critical to obtaining the desired properties (Table 8). It should be noted that small

TABLE 8 Effect of Composition and Block Structure on PGA/PTMC/PDO Copolymer Properties^a

Total PGA content (wt %)	First block PDO (wt %)	Second block PDO (wt %)	Peak melting (°C)	Tensile modulus (kpsi)	Initial loop pull (kg) ^b	Week 3 loop pull (kg) ^b
72	36	4	194	920	8.7	0

^b*In vivo*.

FIG. 2. *In vitro* strength loss for several synthetic absorbable monofilaments.

amounts of *p*-dioxanone added to the PGA end blocks is critical to achieving the desired results. Initial experience with this new suture indicates that it is an attractive alternative to braided synthetic absorbable sutures (Rodeheaver *et al.*, 1996).

The newest synthetic absorbable monofilament suture is Caprosyn, introduced by USS/DG in late 2002. This product was designed to meet the surgeon's needs for a supple, fast-absorbing monofilament for use in plastic surgery and to replace catgut. This material is a tetrapolymer, made by copolymerizing glycolide, ϵ -caprolactone, L-lactide, and TMC in a 68/17/7/7 weight ratio (Roby *et al.*, 2001). The single-step polymerization process gives rise to a random copolymer, where controlling ϵ -caprolactone conversion in a narrow window is key to obtaining the desired flexibility of the finished suture. Too much PCL in the final polymer and it will be very supple but weak; too little and it will be strong but stiff. Caprosyn loses all strength by 3 weeks and is absorbed by the body in 56 days, making it the fastest-absorbing synthetic monofilament. Figure 2 compares the *in vitro* tensile loss curves for the newest synthetic absorbable monofilaments.

Table 9 summarizes the chemical structures for all of the synthetic absorbable sutures discussed. As indicated previously, the glycolic ester unit is present in all of these polymers.

TABLE 9 Chemical Structure of Synthetic Absorbable Sutures

Suture	Block structure	Polymer composition (%)
Multifilament Braids		
Dexon	PGA homopolymer	—
Vicryl	PGA/PLLA random copolymer	90/10
Polysorb	PGA/PLLA random copolymer	90/10
Panacryl	PGA/PLLA random copolymer	3/97
Monofilaments		
PDS II	PDO homopolymer	—

PROPERTY COMPARISONS

Few, if any, studies have been completed that compare properties listed in Table 3 for all sutures at one time. As a result, comparisons are generally limited to selected materials and for selected properties. Since conditions and/or testing procedures can vary, care must be taken when comparing the results of one investigation to that of another. A qualitative comparison of the major properties for the various types of sutures is summarized in Table 10.

Physical

Physical properties are fairly quantitative, lending themselves to repeatable test procedures. The United States Pharmacopeia (USP) is a set of standards that specify test procedures and product specifications. For sutures, these specifications includes length, diameter, tensile knot pull strength, and needle attachment force. Sutures that meet all of the USP specifications may be labeled as "USP." For sutures that meet all but the diameter specifications, the label may state "USP except for diameter" and must contain the diameter overage information in the package labeling. Sutures that do not meet the diameter specification require a larger-than-specified diameter in order to meet strength requirements. Diameter is important since a surgeon will employ the smallest diameter possible in order to minimize the amount of material that is drawn through the tissue and/or placed into the body. Meeting these USP specifications and stating the exceptions, if applicable, are required for regulatory approval by the FDA. A similar set of specifications exist in Europe known as the European Pharmacopoeia (EP).

Handling

Handling characteristics are the most difficult to describe, although attempts have been made to quantify these properties (Chu, 1997a). The tensile modulus of a material used as a monofilament and the characteristics of a coating used on a multifilament braid are responsible for a large share of a suture's handling characteristics. In addition, the application, type of tissue, patient condition, and surgeon preference also contribute to the overall assessment of a suture's handling characteristics. A suture that possesses excellent handling in one setting may possess only fair or even unacceptable handling in another. For this reason, the most reliable information regarding a suture's handling characteristics is generally obtained by performing evaluations in the appropriate *in vitro* or *in vivo* environment.

Biological

Assessment of tensile-strength loss and absorption are typically performed in an *in vivo* or *in vitro* setting. With respect to tensile strength loss, confusion can arise if the testing methods are not properly designated. Specifically, there are two important considerations when comparing the tensile-strength loss profiles for absorbable sutures. The first is the

TABLE 10 Suture Properties^a

Suture type	Fiber type	Knot pull strength	Knot security	Handling	Tissue reactivity	<i>In vivo</i> strength loss
Natural materials						
Catgut, plain	T	Poor	Poor	Fair	High	7–10 days
Catgut, chromic	T		Fair	Fair	Mod.	—
Silk	B	Fair	Good	Very good	High	21–28 days 1 year
Synthetic nonabsorbable materials						
Polyester	B	Good	Poor–Good	Good	Moderate	Indefinite
Polyester	M		Poor	Fair	Low	Indefinite
Polyamide	B	Fair	Fair	Good	Low	15–25% / year
Polyamide	M	Fair	Poor	Poor	Low	15–25% / year
Polypropylene	M	Fair	Poor	Poor	Low	Indefinite
PTFE	M	Poor	Very good	Very good	Low	Indefinite
Stainless steel	T,M	High	Good	Poor	Low	Indefinite
Synthetic absorbable materials						
Braids	B	Good	Fair–Good	Good	Low	10 days to 4 weeks, 1 year
Monofilaments	M	Fair	—			
		Good	Poor–Fair	Fair–Good	Low	10 days to 6 weeks

T, twisted monofilament; M, monofilament; B, braided multifilament; all braids are coated sutures.

type of tensile-strength test employed. The USP knot-pull test involves pulling the ears of the knot in opposite directions and measuring the force required to cause failure. The standard loop-pull test involves pulling the loop formed by the knot in opposite directions and measuring the force required to cause failure. The former test essentially measures the maximum force that can be applied by the surgeon, whereas the latter measures the maximum tissue support force (Rodeheaver *et al.*, 1996). Loop-pull forces are therefore higher than knot-pull forces because the loop measurement involves a double strand of the material, whereas the knot measurement involves the two ears or one strand of the material. Both yield valuable information.

The second consideration is whether the tensile strength is reported as an absolute force-to-break or as a percentage of the original tensile strength. Figures 3A and 3B illustrate the effects of this difference when Biosyn suture is compared to Vicryl suture. An *in vivo* tensile-strength loss comparison using the absolute loop-pull strength is summarized in Fig. 4 for synthetic absorbable sutures and indicates that a wide range of tensile-strength loss profiles is available from which to choose.

As mentioned previously, absorption of a suture can take place months after complete strength loss has occurred (Fig. 5). As expected, the order in which the synthetic absorbable sutures absorb is similar to the order in which the tensile strength is lost (Fig. 6). To support the tensile strength loss and absorption information collected from *in vivo* and *in vitro* studies such as those described above, pharmacokinetic studies are generally performed. Pharmacokinetics involve the implantation of ¹⁴C-labeled polymer into animals and following the level of radioactivity for selected ¹⁴C-labeled by-products. In addition, the tissues are analyzed to determine the extent of by-product deposition, if any, in

the various organs. These studies generally support the data summarized above (Table 11).

COLORANTS

Sutures can be provided dyed different colors or in their natural color. As sutures become wet with body fluids, they tend to blend into the surrounding tissue, making them hard to locate in the surgical field. Dyed sutures are preferred by

FIG. 3. Tensile strength retention plotted as load (N) and percentage of original strength. (Rodeheaver *et al.*, 1996.)

FIG. 4. *In vivo* tensile strength loss of synthetic absorbable sutures. (Roby, 1998.)

FIG. 5. *In vivo* tensile strength loss compared to mass loss for vicryl suture. (Fredericks *et al.*, 1984.)

FIG. 6. Time required for essentially complete absorption. (Roby, 1998; USS/DG, 2002.)

most surgeons because they are easily visualized in tissue. Undyed sutures are typically used by plastic surgeons in subcutaneous applications so that they will not be seen through the skin. The colorants used are approved by the FDA for use in specific suture materials through a Color Additive Petition (CAP). The CAP requires extensive biocompatibility, stability,

and toxicology data in order to receive approval, and limits are placed on the maximum amount of colorant allowed in the suture. Additionally, each batch of colorant is tested and certified by the FDA as meeting established purity criteria. A list of commonly used colorants in sutures can be found in Table 12.

NEEDLES

A needle enables the suture strand to be passed through the tissues that are to be approximated. The most important characteristics of a needle include sharpness, strength, profile, corrosion resistance, and durability. The variety of surgery and surgeons has created a demand for a great variety of needles. Different combinations of length, curvature, wire diameter, and point geometry have resulted in hundreds of types of surgical needles being available. Needles are generally classified by point geometry as shown in Table 13, but additional characteristics such as length, curvature, and wire diameter are considered by the surgeon during product selection.

The increase in sophistication of surgical technique over the years has given rise to a need for smaller and smaller wire diameter needles that will provide increased resistance to bending and breaking while penetrating tissue, as exemplified by the needle and suture shown in Fig. 7, which is typical of that used by CV surgeons during the coronary arterial bypass graft (CABG) procedure. This has been accomplished by the development of new stainless steel alloys that can offer the processability needed to drill, grind, and form a needle, combined with the stiffness and strength that the surgeon requires.

TABLE 13 Surgical Needle Types

Type	Description	Uses
Taper point	A circular cross section smoothly increasing in diameter from tip to body	Cardiovascular and general surgery
Cutting	A triangular cross section smoothly increasing in diameter from tip to body	Plastic surgery
Taper-cutting	A taper-point needle with small facets ground at the tip to provide some cutting effect	Cardiovascular and general surgery
Spatula or diamond	A sharp, flat tip tapering back to a triangular body	Ophthalmic

**FIG. 7.** Surgipro needle and suture used in bypass surgery compared to 0.5-mm pencil lead.

The industry has moved the premium cardiovascular, ophthalmic, and plastic-surgery needles away from the 420 and 300 series stainless steel alloys that were prone to bending, to the precipitation-hardened martensitic 455-type alloys (Edlich *et al.*, 1993). The resulting materials are extremely hard, and lasers are typically used to drill the holes for attachment to the suture. These needles are marketed under the trade names of Ethalloy and Surgalloy in the United States.

All needles start with high-quality stainless steel wire. The first step is to drill a hole in the wire that will accommodate the suture to be attached to the needle. The holes are commonly drilled mechanically or with a laser. The grinding and polishing operations that form the proper tip and body geometry are performed, followed by coining or pressing of the sides to improve rigidity and stability in the needle drivers that surgeons use. If the needles are to be curved, that process is performed followed by cleaning and deburring. If a martensitic alloy is being used, aging at the optimal time and temperature under vacuum is performed in order to increase resistance to bending, which results in an increase of up to 50% in bend moment and tensile strength (Rizk *et al.*, 1995). The cleaning and vacuum steps are critical in order to avoid any discoloration during the heat treat process. Electropolishing may be done in order to improve the surface finish and sharpness of

**FIG. 8.** Needle penetration force as a function of the number of passes through a test medium. (USS/DG Sales Literature, 2002.)

cutting needles. Lastly, a polydimethylsiloxane (PDMS) based coating is applied and allowed to cure. The coating improves tissue penetration performance of the needle by up to 60% (Walther and Raddatz, 1999), and proper curing is essential to provide a durable coating that will not wear off after repeated penetrations through tissue. This is critical because when less force is required to pass the needle through tissue, there is less likelihood of bending or breaking the needle. A new coating for surgical needles has been developed by USS/D&G called NuCoat. It is based on a mixture of polydimethylsiloxanes with an improved curing cycle (Roby, 2003). This new coating process results in a needle that does not show increased penetration forces after repeated tissue passes when compared to standard commercial needles as shown in Fig. 8 (USS/D&G, 2002). Because most surgical procedures require surgeons to make multiple passes through tissue with the needles, it is an advantage to have a needle that maintains a consistently low penetration force.

The current generation of high-quality PDMS-coated 455 series stainless steel needles gives the surgeon a selection of extremely strong, durable needles in a wide range of sizes and styles that minimize trauma to tissue.

PACKAGING AND STERILIZATION

A suture package protects the suture from damage and biological contamination, allows for easy removal of the suture in the operating room, withstands the sterilization conditions used, and contains no contaminants that may transfer to the suture. Currently, a paper or plastic retainer is used to hold the suture and needle in place, with the needle being parked in foam or in a plastic slot or slit. The fiber can be straight, can be

wrapped in a Fig. 8, or can follow an oval or spiral track. The materials used here are medical or food grades of paper, cardboard, and plastics (PVC, PETG, and PP) and must withstand the sterilization method without degradation. Biocompatibility testing is done on any component that may come into contact with the suture to ensure that there are no toxic materials present. If the suture is a synthetic absorbable, a foil moisture barrier must be used to protect the suture from degradation during shipping and storage. This is done by drying and sealing the sterile suture in a foil pouch, and if this is done properly the suture will show no degradation in the package for at least 5 years. Sutures based on synthetic absorbables, polypropylene, and sutures containing PTFE pledgets must be sterilized using ethylene oxide gas, because these materials will degrade when exposed to gamma irradiation or e-beam sterilization. Catgut must be sterilized using gamma sterilization, and the remaining sutures can be sterilized by either method.

REGULATORY CONSIDERATIONS

Sutures are regulated by the FDA as medical devices and are categorized into three different classes—Class I (General Controls), Class II (Performance Standards), and Class III (Premarket Approval).

The regulatory requirements, and therefore the development and commercialization time lines, are quite different for these three classes. Class I materials require certain controls such as those addressing possible adulteration and misbranding to ensure safety. Only stainless steel sutures fall into this class.

Class II materials require that the manufacturer apply the controls defined by Class I materials and demonstrate “substantial equivalence” to an existing approved Class II material, often referred to as the predicate device. Characterization of the new material and the predicate device includes physical and mechanical, biocompatibility, efficacy, and stability testing. This testing is submitted to the FDA in a filing that is referred to as a 510(k). Most suture materials were reclassified to Class II from Class III by the FDA in 1989 based on the large body of existing information and usage.

Class III materials require considerable characterization and testing to ensure safety and efficacy. This type of filing is referred to as a PMA (Premarket Approval). Extensive pre-clinical testing is required as well as multicenter clinical trials. Since the extent of characterization required and the approval timelines for a PMA submission are substantially greater than that required for a 510(k) submission, PMA materials require a longer commercialization time at a much higher cost. The use of a new monomer in significant quantities would probably require a PMA regulatory approval route and is therefore an important consideration in the design of new polymer materials for sutures.

MARKET TRENDS

Suture revenues in 2001 are estimated to have been \$632 million (U.S.) and growing at an annual rate of roughly

2–3% (Frost and Sullivan, 2001). Roughly 13% of the usage was natural sutures, 41% synthetic nonabsorbable sutures, and 42% synthetic absorbable sutures. There has been a shift in the usage of the different materials for several reasons. First, there has been a continual decrease in the use of natural materials in favor of synthetic materials because of the inconsistent properties and the inflammatory tissue response that these materials can exhibit. In the case of catgut, the fear of transmission of TSE has resulted in the banning of the product in major international markets. Second, there is an increasing usage of absorbable synthetic materials over nonabsorbable materials in order to avoid a long-term foreign-body effect. Finally, cost containment in the health-care industry combined with the desire for a suture with less tissue drag and less potential to harbor bacteria has resulted in the development of and the increased usage of absorbable synthetic monofilaments over absorbable synthetic multifilament braids (Rodeheaver *et al.*, 1996). In contrast to the suture market in general, these monofilament sutures are increasing in usage at an annual rate of roughly 15% (Roby, 1998).

Until recently the three major suppliers of sutures were Ethicon, Inc., Davis & Geck, and U.S. Surgical Corp. The last two suppliers were recently acquired by Tyco International and are now called Syneture, reducing the number of major suppliers to two. The required capital equipment, technology, and development time, combined with the near commodity nature of these products, makes a major entry into the suture business relatively unattractive. However, there are a number of smaller suture manufacturers successfully serving various niche markets within the business.

FUTURE DEVELOPMENT

Because of the nature of this mature cost-constrained market, future development will be limited to products that can demonstrate a performance benefit. In addition, it is unlikely that the use of new materials that require a PMA regulatory approval route will be developed unless this benefit is significant.

Suture-Related

Numerous synthetic absorbable suture products have been developed by the major suture manufacturers over the past 25 years (Table 14). These products cover a wide range of tensile strength loss profiles both in multifilament braid and

TABLE 14 Summary of Synthetic Absorbable Sutures

	Short term	Medium term	Long term
Suture	(<3 weeks)	(3–4 weeks)	(>4 weeks)
Multifilament	Vicryl Rapide	Vicryl Polysorb Dexon	Panacryl
Monofilament	Monocryl Caprosyn	Biosyn Monosyn	PDS II Maxon

in monofilament form. Competition will most likely result in additional products, and the development of additional multifilament braid coatings will continue in order to provide the best suture products possible.

As previously mentioned, absorbable sutures lose strength well before absorption is complete. New block structures and/or the incorporation of low levels of different monomers may be developed to decrease this lag time. Ideally, a suture should absorb rapidly following the loss of tensile strength.

Research is also focused on sutures that can do more than just provide mechanical support to the wound. Since the incidence of wound infection is roughly 8%, antibiotic and silver-based coatings or additives are being investigated as antimicrobial agents (Chu, 1997c). Ethicon has introduced a new absorbable braided suture, Vicryl Plus, containing the bacteriostat triclosan (Ethicon, 2002), which has been shown to inhibit colonization of the suture by *Staph a.* and *e.* in *in vitro* studies. The addition of various agents to accelerate the wound-healing process are also being investigated.

Non-Suture-Related

Alternative methods of wound closure include staples, tapes, tissue sealants, and tissue adhesives. The first two methods provide rapid closure with lower infection rates. However, staples do not provide the same level of cosmetic closure as sutures, whereas tapes are generally limited to nonload-bearing topical areas (Quinn, 1998).

Most tissue sealants are based on fibrin glue and possess low strength, require long and sometimes complex preparation times, and require viral deactivation to eliminate the risk of blood-borne viral transmission. BioGlue (CryoLife) is a more recently approved material based on albumin and glutaraldehyde for use as an internal sealant in aortic dissections. Newer tissue sealants based on synthetic absorbable materials, such as CoSeal, FloSeal, and FocalSeal, circumvent some of the inherent weaknesses of fibrin-based sealants (Macchiarini *et al.*, 1999). Although these materials will probably not replace sutures, their hemostatic properties make this closure method a useful adjunct to sutures to reduce bleeding in vessel anastomosis or as an alternative closure method in friable tissues such as the lung.

Topical tissue adhesives based on cyanoacrylates such as Histoacryl, Indermil, and Dermabond adhesives react rapidly with moisture to form a strong bond to tissues. Although acute and inflammatory reactions were reported with the early short-chain derivatives in the 1950s, the development of longer-chain derivatives appears to have reduced the level of toxicity when adhesives are used in topical applications (Maw *et al.*, 1997; Quinn, 1998). Perhaps the largest threat to sutures is a tissue adhesive that is strong, nontoxic, bioabsorbable, and easy to use. This is currently an area of active research that could provide a quantum leap in wound-closure technology.

7.14 DRUG DELIVERY SYSTEMS

Jorge Heller and Allan S. Hoffman

A wide variety of polymeric biomaterials are components of the various formulations and devices that are routinely used for delivering drugs to the body. This chapter reviews the current state-of-the-art of drug delivery systems (DDS) that release drugs in a controlled manner. The major advantage of developing systems that release drugs in a controlled manner can be appreciated by examining Fig. 1, which illustrates changes in blood plasma levels following a single dose administration of a therapeutic agent. As shown, the blood plasma level rapidly rises and then exponentially decays as the drug is metabolized and/or eliminated from the body. The figure also shows drug concentrations above which the drug produces undesirable (e.g., toxic) side effects and below which it is not therapeutically effective. The difference between these two levels is known as the therapeutic index, which is usually based on a dose-response of the median 50% of a population.

Using only a single dose administration, the time during which the concentration of the drug is above the minimum effective level can be extended by increasing the size of the dose. However, when this done, blood plasma concentrations extend into the toxic response region, an undesirable situation. One can also administer safe doses at periodic intervals in order to maintain a desired drug concentration level; however, this is inconvenient, and patient compliance is often poor. For these reasons, there has been great interest in developing controlled-release formulations and devices that can maintain a desired blood plasma level for long periods of time without reaching a toxic level or dropping below the minimum effective level. These DDS are called "zero order" systems since they release drug at a constant rate.

Aside from the clear therapeutic advantage of controlled release products, there are also compelling business reasons for the development of such devices. Because of increasingly stringent FDA regulations, the cost for introducing new drug entities has escalated to more than \$200 million U.S. dollars for each drug, and it is not uncommon for this development to require more than 10 years of research and development work. Thus, it is reasonable for pharmaceutical companies to attempt to

FIG. 1. Drug concentration following absorption of therapeutic agent as a function of time. (—) safe dose, (---) unsafe dose, (-·-) controlled release. [Reprinted from Roseman, T. J., and Yalkowsky, S. H. in *Controlled Release Polymeric Formulations*, D. R. Paul and F. W. Harris (eds.). ACS Symposium Series 33, American Chemical Society, Washington DC, pp. 33–52.]

maximize their financial return for each drug by research aimed at extending the patented lifetime of the drug, and one means of doing this is to patent a new controlled-release formulation with the same drug. However, the commercial feasibility of such a strategy is predicated on a demonstration that the controlled-release formulation is indeed superior in safety and efficacy to the single dose formulation, and most importantly that the cost of the controlled-release formulation is low enough to ensure a reasonable market penetration.

Successful efforts to produce pharmaceutical formulations that would prolong the action of therapeutic agents for any particular dose, thus minimizing the frequency between dosing, go back to the late 1940s and early 1950s with the introduction of the first commercial product, known as Spansules®. This product was designed to increase the duration of orally administered drugs and consisted of small drug spheres coated with a soluble coating. By using coatings with varying thickness, capsule dissolution times could be varied, thus prolonging the action of one dose of the therapeutic agent. Such formulations are now known as "sustained release" or "prolonged release products," and more recently they have been called "controlled-delivery" products.

However, the functionality of such products depends greatly on the local *in vivo* environment, and as such varies from patient to patient. For this reason, a major effort has been underway since the late 1960s focused on the development of products that are capable of releasing drugs by reproducible and predictable kinetics. Ideally, such products are not significantly affected by the local *in vivo* environment so that patient-to-patient variability is greatly reduced. Such devices are known as "controlled-release" products.

Controlled-release polymeric systems can be classified according to the mechanism that controls the release of the therapeutic agent as described in Table 1.

DIFFUSION-CONTROLLED DELIVERY SYSTEMS

There are two fundamentally different devices where the rate of drug release is controlled by drug diffusion. These are membrane-controlled devices and monolithic devices.

Membrane-Controlled Reservoir Devices

In this particular delivery system the active agent is contained in a core or "reservoir" which is surrounded by a thin polymer membrane, and release to the surrounding environment occurs by diffusion through the rate-controlling membrane. This system is called a "reservoir device."

When the membrane is nonporous, diffusion can be described by Fick's first law:

$$J = -D \frac{dC_m}{dx} \quad (1)$$

where J is the flux per unit area, in $\text{g}/\text{cm}^2\text{-sec}$, C_m is the concentration of the agent in the membrane in g/cm^3 , dC_m/dx is the concentration gradient, and D is the diffusion coefficient of the agent in the membrane in cm^2/sec .

Because the concentration of the agent in the membrane cannot be readily determined, Eq. 1 can be rewritten using partition coefficients which describe the ratio of the concentration of the agent in the membrane in equilibrium with that in the surrounding medium.

$$J = \frac{DK\Delta C}{l} \quad (2)$$

where ΔC is the difference in concentration between the solutions on either side of the membrane, K is the partition coefficient, and l is the thickness of the membrane.

Reservoir devices can also be constructed with membranes that have well-defined pores connecting the two sides of the membrane. Diffusion in such microporous membranes occurs principally by diffusion through the liquid-filled pores, where the composition of the liquid will control the overall transport flux across the membrane. In this system, the flux is described by Eq. 3.

$$J = \frac{\varepsilon DK\Delta C}{\tau l} \quad (3)$$

where ε is the volume fraction porosity, which is normalized as fractional area (area of pores per unit area) of the membrane and τ is the tortuosity (average length of pore channel traversing the membrane).

One of the most important consequences of Eqs. 2 and 3 is that the flux J will remain constant provided that the membrane material does not change with time, i.e., provided that D , K , ε , and τ remain constant. However, another very important requirement for zero-order delivery is that ΔC also remain constant. The practical consequences of this requirement is that the concentration of the agent in the core cannot change with time and that the agent released from the device must be rapidly removed ("sink" conditions). Constant agent concentration in the core can be readily achieved by dispersing the agent in a medium in which it has a very low solubility, leading to a saturated drug concentration in the reservoir. However, ensuring that the concentration of an agent at the external surface of the device is essentially zero (i.e., does not build up around the device) is not always possible, particularly with agents having very low water solubility, and deviations from zero-order kinetics can be caused by such "boundary-layer effects."

Another factor that contributes to deviation from constant or zero-order drug release is migration of the agent from the core into the membrane on storage. Then, when the device is

placed in a release medium, the initial drug release is rapid because the agent diffuses from the saturated membrane until the steady-state (zero-order) release rate is achieved. This initial nonlinear portion of the release is known as the "burst effect."

Monolithic Devices

In a monolithic device the therapeutic agent is uniformly dispersed or dissolved in a polymer matrix and its release is controlled by diffusion from the matrix. The matrix is assumed to be inert, i.e., non-swelling or fully swollen, and non-degrading. Mathematical treatment of diffusion depends on the solubility of the agent in the polymer, and two cases must be considered. In one case, the agent is present below its solubility limit and is dissolved in the polymer. In the other case, the agent is present well above its solubility limit and is dispersed in the polymer.

For an agent that is dissolved in the polymer, release can be calculated by two equations, known as early time approximation (Eq. 4) and late time approximation (Eq. 5) (Baker and Lonsdale, 1974).

$$\frac{dM_t}{dt} = 2M_x \left[\frac{D}{\pi l^2 t} \right]^{1/2} \quad (4)$$

$$\frac{dM_t}{dt} = \frac{8DM_x}{l^2} \exp \frac{\pi^2 Dt}{l^2} \quad (5)$$

These equations predict rate of release from a slab of thickness l , where D is the diffusion coefficient, M_x is the total amount of agent dissolved in the polymer, and M_t is the amount released at time t . According to Eq. 4, which is valid over about the first 60% of the release time, the rate decreases linearly with the square root of time. During the latter 40% of the release time the rate decays exponentially with time, as shown by Eq. 5. Plots of these two approximations are shown in Fig. 2.

When the agent is dispersed as particulates in the polymer, release kinetics can be calculated by the Higuchi equation

FIG. 2. Release rate of drug initially dissolved in a slab as a function of time. [Reprinted from Baker, R. W., and Lonsdale, H. K. (1974). in *Controlled Release of Biologically Active Agents*, A. C. Tankaray and R. E. Lacey (eds.). Plenum Press, New York, pp. 15-71.] 2: $M =$ total drug released at $t = \bullet$.

(Higuchi, 1961). Equation 6 is for a planar slab model system.

$$\frac{dM_t}{dt} = \frac{A}{2} \left[\frac{2DC_s C_o}{t} \right]^{1/2} \quad (6)$$

where A is the slab area, C_s is the solubility of the agent in the matrix, and C_o is the total concentration of dissolved and dispersed agent in the matrix. Clearly, in this particular case, release rate decreases as the square root of time over the major portion of the delivery time and deviates only after the concentration of the active agent remaining in the matrix falls below the saturation value C_s .

Applications

Determining whether the reservoir or monolithic device is most appropriate for an intended application will depend upon the need for constant drug release rate, the manufacturing cost, and safety. Even though reservoir-type devices can yield zero order kinetics for long periods of time, the safety of this type of device may sometimes be of concern because rupture of the membrane can lead to sudden release of the drug within the core, especially when the core is either in a liquid state or is a fragile matrix. Thus, in such a situation, the amount of drug in the core and its toxicity must be considered.

Although long-term zero-order drug release achievable with reservoir devices is often highly desirable, manufacture of such devices is expensive and in many applications where device cost is an important factor, the less expensive matrix-type devices are used, even though release rate declines with time. The utilization of monolithic or matrix delivery devices is very common in the veterinary or agricultural fields, where low cost is of paramount importance.

Reservoir Devices: When cost is not an overriding consideration, as is the case in human therapeutics, then reservoir-type devices are an excellent choice and a number of such devices have been developed. The original reservoir DDS products were developed by Alza Corp. in the 1970s. One is the Ocusert[®], which is inserted in the lower cul-de-sac and releases pilocarpine for control of glaucoma and is shown in Fig. 3.

Another reservoir device is the intrauterine contraceptive device Progestasert[®], which is a T-shaped device capable of releasing progesterone from the vertical member of the device. A simpler, rod-shaped implant containing a different

FIG. 3. Schematic diagram of Ocusert. [Reprinted from Chandrasekaran, S. K., Benson, H., and Urquhart, J. (1978). in *Sustained and Controlled Release Drug Delivery Systems*, J. R. Robinson (ed.). Marcel Dekker, New York, pp. 571–593.]

contraceptive steroid, is called the Norplant[®], which was originally developed by the Population Council. The original Norplant[®] system consisted of six silicone tubes, 20×2 mm, and contained levonorgestrel in the core of the tubes, which were designed for implantation in the upper arm. They could maintain a therapeutically effective plasma concentration of levonorgestrel for as long as 5 years.

Drug-eluting stents: A recent example of a device coated with a drug-containing polymer is the Cypher[®] drug-eluting stent developed by the Cordis Corp. In this system, a 316L stainless steel stent is first gas-discharge coated with parylene C to prime the metal for the polymer–drug coating. It is then coated with a polymer matrix consisting of a blend of poly(ethylene-vinyl acetate) and poly(butyl methacrylate) plus the dispersed drug Sirolimus, also known as Rapamycin. The drug inhibits mitosis and proliferation of smooth muscle cells; such proliferation can cause restenosis and occlusion of the blood vessel. In some cases the Cypher[®] may be further coated with a pure polymer coating, (i.e., containing no drug) converting it from a monolithic matrix to a reservoir delivery system. The stent is implanted by balloon angioplasty into a partially or totally blocked small blood vessel (such as a coronary artery). The catheter is threaded to the site of the occlusion where a nylon balloon on the catheter is expanded, and this action expands the stent against the luminal wall of the vessel, pushing back the blocking tissue mass. Eighty percent of the drug is released over 30 days. (Information taken from Cordis Corp. web site.)

A different, competitive drug-coated stent is coming into clinical use as this chapter goes to press. This is the TAXUS Express2[®] Paclitaxel-eluting coronary stent system of Boston Scientific Corp. This stent is stainless steel, using the Express2[®] platform, and is coated with a monolithic matrix polymer-drug mixture. The coating is a dispersed mixture of Translute[®] polymer and Paclitaxel. Translute[®] is an exceptionally biostable, vascular compatible, hydrophobic triblock elastomeric copolymer. Paclitaxel is a multifunctional molecule acting on several pathways implicated in the restenotic cascade. Its primary mechanism of action in most cancer cell lines has been through the stabilization of microtubule dynamics (Helmus, 2003). This stent may also be overcoated with a drug-free, rate-controlling polymer membrane, converting it to a reservoir system.

Even though reservoir-type devices can yield zero-order kinetics for long periods of time, the safety of this type of device may sometimes be of concern because rupture of the membrane can lead to sudden release of the drug within the core, especially when the core is either in a liquid state or is a fragile matrix. Thus, in such a situation, the amount of drug in the core and its toxicity must be considered.

Transdermal patches: To date, the most commercially successful use of drug diffusion-controlled systems is in transdermal applications. In these devices, a polymeric delivery system is held on the skin by an adhesive. The device contains the drug either in a reservoir with a rate-controlling membrane, or dispersed in a polymer matrix. A schematic of a membrane-controlled transdermal patch is shown in Fig. 4. The drug diffuses from the device through the skin and is taken up by the systemic circulation. Because the outer layer of the skin, called the stratum corneum, is highly impermeable to most

FIG. 4. Schematic of membrane-controlled transdermal device.

TABLE 2 Currently Marketed Transdermal Systems

Drug	Product name	Manufacturer
Testosterone	Testoderm®	Alza
Testosterone	Androderm®	SmithKline & Beecham
Estradiol	Alora®	P & G Pharm.
Estradiol	Climar®	Berlex Labs Pharma
Estradiol	FemPatch®	ParkeDavis
Estradiol	Menorest®	Ciba
Estradiol	Vivelle®	Ciba
Estradiol	Estraderm®	Ciba
Nicotine	Habitrol®	Ciba
Nicotine	Nicotrol®	McNeil
Nicotine	Prostep®	Elan
Nicotine	Nicoderm®	SmithKline & Beecham
Nitroglycerine	Deponit®	Schwarz

Clonidine	Catapres TTS®	Boehringer Ingelheim
Fentanyl	Duragesic®	Janssen
Scopolamine	Transderm Scop®	Ciba

drugs, either very potent drugs are used or flux of the drug through the skin may be augmented (a) by the use of penetration enhancers (such as alcohol or propylene glycol), (b) by electrical means such as iontophoresis, or (c) by transient physical disruption of the skin structure using ultrasound. Some of the current FDA-approved transdermal systems are shown in Table 2.

WATER PENETRATION-CONTROLLED DELIVERY SYSTEMS

In this type of delivery device, drug release rate is controlled by the rate of diffusion of water into the device. Two general types of DDS are in use, osmotic and swelling-controlled systems.

Osmotically Controlled Delivery Devices

The operation of an osmotic device can be described by referring to the schematic representation in Fig. 5 (Theeuwes and Yum, 1976). In this device, an osmotic agent is contained within a rigid housing and is separated from the agent by a movable partition. One wall of the rigid housing is a semipermeable membrane, and when the device is placed in an aqueous environment, water is osmotically drawn across the semipermeable membrane. The resultant increase in volume within the osmotic compartment exerts pressure on the partition, which forces the agent out of the device through the delivery orifice.

The volume flux of water across the semipermeable membrane is given by:

$$\frac{dV}{dt} = \frac{A}{l} L_p [\sigma \Delta\pi - \Delta P] \quad (7)$$

where dV/dt is the volume flux, $\Delta\pi$ and ΔP are, respectively, the osmotic and hydrostatic pressure differences across the semipermeable membrane, L_p is the membrane mechanical permeability coefficient, σ is the reflection coefficient (usually ~ 1), and A and l are respectively the membrane area and thickness.

The mass rate of delivery dM/dt of the agent is then given simply by

$$\frac{dM}{dt} = \frac{dV}{dt} C \quad (8)$$

where C is the concentration of the agent in the solution that is pumped out of the orifice.

FIG. 5. Schematic representation of an osmotic pump. [Reprinted from Theeuwes, F., and Yum, S. I. (1976). *Ann. Biomed. Eng.* 4: 343-353.]

FIG. 6. Schematic representation of swelling-controlled release system. As penetrant A, water, enters the glassy polymer B, bioactive agent C is released through the gel phase of thickness $\delta(t)$. [Reprinted from Langer, R. S., and Peppas, N. A. (1983). in *Rev. Macromol. Chem. Phys.* C23: 61–126.]

Swelling-Controlled Devices

In this type of delivery system the agent is dispersed in a hydrophilic polymer that is stiff or glassy in the dehydrated state but when placed in an aqueous environment will swell. Because diffusion of molecules in a glassy matrix is extremely slow, no significant release occurs while the polymer is in the glassy state. However, when such a material is placed in an aqueous environment, water will penetrate the matrix and as a consequence of swelling, the glass transition temperature of the polymer is lowered below the ambient temperature, and diffusion of the drug from the polymer takes place.

The process, shown schematically in Fig. 6, is characterized by the movement of two fronts (Langer and Peppas, 1983). One front, the swelling interface, separates the glassy polymer from the swollen rubbery polymer and moves inward into the device at a velocity, v . The other front, the polymer interface, moves outward as it swells, and separates the swollen polymer from the pure dissolution medium. The polymer may go through a gel state as it swells. In systems where the glassy polymer is noncrystalline and linear, dissolution takes place. When the polymer is highly crystalline, or cross-linked, no dissolution takes place and the swollen polymer remains as a hydrogel.

Although many swellable drug formulations are available, the term "swelling-controlled" is only applicable to those formulations where the release is actually controlled by the swelling phenomenon just described.

Applications

Osmotic Devices: Two types of osmotic devices are in use. One device, known as *Osmer*[®], is a capsule approximately 2.5 cm long and 0.6 cm in diameter and is intended as a research

FIG. 7. Schematic representation of osmotic pump and components. [Reprinted from Theeuwes, F., and Yum, S. I. (1976). *Ann. Biomed. Eng.* 4: 343–353.]

device that can be implanted in the tissues of experimental animals, where it delivers a therapeutic agent at a known constant rate. The agent is placed in an impermeable flexible rubber reservoir that is surrounded by an osmotic agent, which in turn is surrounded and sealed within a rigid cellulose acetate membrane (Theeuwes and Yum, 1976).

In an aqueous environment, water is osmotically drawn across the cellulose acetate membrane and the resultant pressure on the rubber reservoir forces the agent out of the orifice. The device is shown in Fig. 7. It is provided empty and can be filled with the desired therapeutic agent by the user. Because the driving force is osmotic transport of water across the cellulose acetate membrane, rate of release of the agent from the device is independent of the surrounding environment.

A second type of device, known as *Oros*[®], is shown in Fig. 8A (Theeuwes, 1975). This device is intended for oral drug delivery applications and is manufactured by compressing an osmotically active agent plus the drug (which may be osmotically active itself) into a tablet, coating the tablet with a semipermeable membrane (usually cellulose acetate) and drilling a small hole through the coating with a laser. When the device is placed in an aqueous environment, water is drawn across the semipermeable membrane and a solution of the drug is pumped out of the orifice. A major advantage of this device is that a constant rate of release is achieved as it traverses the gastrointestinal tract.

However, this device works best only with water-soluble drugs that act as the osmotic agent. To be useful with water insoluble drugs, a different version, known as the push-pull *Oros*[®], has been developed (Theeuwes, 1979). In this device,

FIG. 8. (A) Cross section of Oros. [Reprinted from Theeuwes, F. (1975). *J. Pharm. Sci.* 64: 987–1991]. (B) Push-Pull Osmotic Pump. [Reprinted from Theeuwes, F., (1979). *Novel drug delivery systems*. in *Drug Absorption*, L. F. Prescott and W. S. Nimmo (eds.). ADIS Press, New York, pp. 157–176.]

two compartments are separated by a flexible partition. The top compartment contains drug and has a delivery orifice. The bottom “push” compartment contains a solid osmotic driving agent such as a water swelling or dissolving polymer. A semipermeable membrane surrounds both compartments and regulates water influx into each separately. The device is shown schematically in Fig. 8B. The “push” compartment is designed to deliver all of the drug out of the device.

An over-the-counter osmotic device is available and known as Acutrim[®]. It has been developed for use in appetite suppression.

Swelling-Controlled DDS: A swelling-controlled oral delivery device commercially available as Geomatrix[®] is shown schematically in Fig. 9. In this device, a drug is dispersed in a swellable polymer such as hydroxypropyl methyl cellulose, which is compressed into a tablet, and two sides are coated with a water-impermeable coating such as cellulose acetate propionate. This impermeable coating restricts the swelling of the matrix it to a “sideways” expansion, and as such, modifies diffusional release kinetics so that if the diffusion length increases

FIG. 9. Schematic representation of swelling-controlled oral system.

as the permeability, DK , increases, then reasonably constant release kinetics can be achieved (Colombo, 1993).

CHEMICALLY CONTROLLED DELIVERY SYSTEMS

There is some confusion in the use of the terms bioerodible, and biodegradable, and although there is no universally accepted definition, bioerodible refers to the solubilization of an initially water-insoluble material with or without changes in the chemical structure, while biodegradable refers to solubilization that occurs as a consequence of breakdown of main chain bonds. The prefix “bio” is used because the erosion or biodegradation takes place in a biological environment and carries no implication that erosion is assisted by enzymes or other active species in the biological milieu, although sometimes this is the case. Hydrolytic degradation is most common (Heller, 1984).

Degradable Reservoir Systems

This system contains the drug in the core of a solid implant covered by a biodegradable membrane. This delivery system is identical to the reservoir system already discussed, except that the membrane surrounding the drug core is bioerodible or biodegradable. Such systems combine the advantage of long-term zero-order drug release with bioerodibility or biodegradability.

Because constancy of drug release requires that the diffusion coefficient D of the agent in the membrane remain constant (Eq. 5), the bioerodible membrane must remain essentially unchanged over the duration of drug delivery. Typically, the bioerodible polymer and the drug are both hydrophobic. Further, the membrane must remain intact while there is still drug in the core to prevent its abrupt release. Thus, significant bioerosion cannot take place until drug delivery has been completed.

The only system that has used this approach is a delivery device for contraceptive steroids known as Capronor[®], based on the biodegradable polymer polycaprolactone. The device is designed to release levonorgestrel at constant rates for 1 year and to completely bioerode in 3 years (Pitt *et al.*, 1980). Even though phase II clinical trials have been successfully completed, the device is no longer under development.

Drug Dispersed in a Biodegradable Matrix

This system is a matrix system and encompasses the majority of all work dealing with the development of bioerodible drug delivery systems. Four major classes of polymers dominate this type of DDS (See also Chapter 2.7).

FIG. 10. Structure of polymers based on glycolic acid and lactic acid.

Poly(lactic acid) and Poly(lactic-co-glycolic acid) Copolymers

These polymers were originally developed as biodegradable sutures and were approved because they degrade to the natural metabolites L-lactic acid and glycolic acid. To this day these polymers occupy a dominant place among biodegradable drug delivery systems (Heller, 1984). Their structure is shown in Fig. 10. Because lactic acid has a chiral center, poly(lactic acid) can exist in four stereoisomeric forms, poly(L-lactic acid), poly(D-lactic acid), *meso*-poly(D,L-lactic acid), and the racemic mixture of poly(L-lactic acid) and poly(D-lactic acid). The polymer is obtained by the cationic ring opening polymerization of the cyclic lactide, or a mixture of lactide and glycolide (Kulkarni *et al.*, 1971).

Erosion rate of poly(lactic-co-glycolic acid) copolymers can be controlled by varying the ratio of glycolic to lactic acid in the copolymer, and the higher the glycolic acid content, the faster the erosion rate (see Chapter 2.7). However, as the amount of glycolic acid in the copolymer is increased, crystalline domains of PGA may form, and solubility in toxicologically acceptable solvents decreases; thus the highest amount of PGA normally used is about 50 mol%. Such copolymers have an average lifetime of about 2–4 weeks.

Poly(L-lactic acid) has been shown to undergo an erosion process that begins at the outer perimeter of the device and moves gradually into the interior, followed by catastrophic disintegration (Li *et al.*, 1990a, b, c). The erosion process has been divided into four steps. In step 1, water diffuses into the polymer and ester bond cleavage starts. In step 2, differentiation between the surface and interior begins, with a drastic decrease in molecular weight in the inner part of the matrix, where the acidic environment accelerates the degradation. In step 3, low-molecular-weight oligomers begin to diffuse through the thinning outer layer, and when the molecular weight of these oligomers is low enough to allow solubilization in the medium, weight loss begins. In the final step 4, a polymer shell remains after the oligomers have solubilized and slow erosion of the shell takes place. Clearly, this complex degradation process does not yield a controlled release rate.

Such an erosion process can have a significant impact on the use of such polymers. When the polymer is used in orthopedic applications such as bone plates, screws, or intramedullar rods, the massive release of acidic products can exceed local tissue clearance capabilities, and it has been shown to produce serious inflammatory responses (Laurencin *et al.*, 1990). In addition to accelerating degradation, the low internal pH can also have adverse effects on acid-sensitive incorporated therapeutic agents, such as DNA, antigens, or some proteins.

FIG. 11. Structure of polymers based on bis(*p*-carboxyphenoxy)propane and sebacic acid.

Polyanhydrides

These materials were first prepared in 1909 (Bucher and Slade, 1909) and were subsequently investigated as potential textile fibers, but found unsuitable because of their hydrolytic instability. Although polyanhydrides based on poly[bis(*p*-carboxyphenoxy)alkane anhydrides] have significantly improved hydrolytic stability they retain sufficient hydrolytic instability to prevent commercialization, despite their good fiber-forming properties. However, it is this hydrolytic instability that makes them excellent candidates for the construction of bioerodible drug delivery systems. At this time, two families of polyanhydrides have been described.

Family I (PA I) The first family of polyanhydrides is based on bis(*p*-carboxyphenoxy)propane and sebacic acid, and the use of this polymer as a bioerodible matrix for the controlled release of therapeutic agents was first reported in 1983 (Rosen *et al.*, 1983). Because aliphatic polyanhydrides hydrolyze very rapidly while aromatic polyanhydrides hydrolyze very slowly, good control over hydrolysis rate can be achieved by using copolymers of aliphatic and aromatic polyanhydrides. In this way, erosion rates from days to many months have been demonstrated (Leong *et al.*, 1985, 1986). The structure of a polymer based on bis(*p*-carboxyphenoxy)propane and sebacic acid is shown in Fig. 11.

Family II (PA II) The second family of polyanhydrides is based on nonlinear dimers and trimers of erucic acid and sebacic acid (Domb and Maniar, 1993). These polyanhydrides had significantly improved mechanical properties relative to family I and by varying the ratio of erucic acid dimer to sebacic acid, materials having a wide range of mechanical properties could be prepared (Domb and Maniar, 1993). However, hydrolysis of the polymer produces sebacic acid and the dimer of erucic acid, which, being a 36-carbon material, is highly water insoluble. The structure of the polymer based on erucic acid dimer is shown in Fig. 12.

More recently, a copolymer based on ricinoleic acid and sebacic acid has been described (Teomin *et al.*, 1999). The polymer has been shown to be biocompatible, but no tissue-clearance data have been described. The structure of the copolymer based on ricinoleic acid and sebacic acid is shown in Fig. 13.

A phase II clinical trial of the erucic acid dimer/sebacic acid polyanhydride containing gentamycin for the treatment of osteomyelitis has been described (Li *et al.*, 2002).

FIG. 12. Structure of copolymers based on erucic acid dimer and sebacic acid.

FIG. 13. Structure of copolymers based on ricinoleic acid and sebacic acid.

Poly(ortho esters)

The first poly(ortho ester) was described in the 1970s in a series of patents (Choi and Heller, 1978a, b, c, 1979) and represent the first example of a new synthetic polymer specifically designed for controlled drug delivery. To date, four families of such polymers have been described, and comprehensive reviews have been published (Heller, 1993; Heller *et al.*, 2002).

Family I-(POE I) This family of polymers was developed at the Alza Corporation and was known then as Alzamer[®]. Use of the polymer has been suggested for contraception (Benagiano *et al.*, 1979) and for narcotic addiction treatment (Capozza *et al.*, 1978). These polymers are no longer under development. The structure of POE I is shown in Fig. 14.

Family II-(POE II) This family of polymers was developed at the Stanford Research Institute (Heller, 1980) and has been extensively investigated in a number of applications. POE II represents a significant advance over POE I in both ease of synthesis and ability to manipulate both mechanical and thermal properties, as well as being able to control erosion times from days to many months. The polymer is highly hydrophobic (Nguyen *et al.*, 1985), so that despite the hydrolytic instability of ortho ester linkages, it is very stable because only limited amounts of water are able to penetrate the polymer. To control erosion rates, acidic excipients can be used to accelerate hydrolysis and basic excipients can be used to retard hydrolysis. Using the latter approach, materials that displayed surface

FIG. 14. Structure of poly(ortho ester) I.

FIG. 15. Structure of poly(ortho ester) II.

FIG. 16. Structure of poly(ortho ester) III.

erosion for over 1 year have been prepared (Heller, 1985). The structure of POE II is shown in Fig. 15.

Family III-(POE III) This family was also developed at the Stanford Research Institute (Heller, 1990a). Because this polymer has a highly flexible structure, it is a high viscosity, semisolid material at room temperature, even at fairly high molecular weights. The structure of POE III is shown in Fig. 16.

Family IV-(POE IV) This is the latest and most successful polymer and was developed at Advanced Polymer Systems, now A.P. Pharma (Ng *et al.*, 1997). The structure of this polymer is similar to that of POE II, but incorporates a short segment of lactic or glycolic acid in the polymer backbone. This segment acts as a latent acidic catalyst and eliminates the need to add acidic excipients to the polymer to control erosion. This represents a major improvement because the addition of acidic excipients makes formulation more difficult and leads to complications due to the diffusion of the acidic excipient from the polymer matrix. A detailed study of the hydrolysis mechanism has been published (Schwach-Abdellaoui *et al.*, 1999). The structure of POE IV is shown in Fig. 17.

Poly(phosphoesters) The general chemical structure of poly(phosphoesters) is shown in Fig. 18.

In the past, interest in phosphorus-containing polymers centered on their flame-retardant properties (Coover *et al.*, 1960). In view of their hydrolytic instability and relatively high cost, interest in these materials diminished. However, as with the polyanhydride system already discussed, it was their hydrolytic instability that renewed interest in such polymers for drug delivery applications (Richard *et al.*, 1991). Because the ultimate hydrolysis products are phosphate ions, alcohol, and a diol, the polymer has the potential to be nontoxic.

Poly(phosphoesters) are prepared by a dehydrochlorination reaction between a phosphorodichlorinate and a diol, as shown in Fig. 19.

These polymers exhibit considerable versatility in that mechanical and thermal properties can be controlled by varying the nature of the pendant R' group and the group R in the polymer backbone.

Applications

Poly(lactic acid) and Poly(lactic-co-glycolic acid) Copolymers

Although the literature is full of reports using PLGA particulates for drug delivery, only a small number of drug delivery devices based on these copolymers have reached commercialization. They are shown in Table 3.

Of these, the ones that have realized the highest commercial success are devices that release a luteinizing hormone releasing hormone (LHRH) analog for the treatment of prostate cancer. This therapy is based on early work by Huggins *et al.*

(1941), who recognized the androgen dependency of prostatic adenocarcinomas, and one treatment modality is to suppress androgen levels by the systemic delivery of LHRH analogs. LHRH analogs are chemical modifications of the natural hormone that are many hundreds of times more potent and down-regulate its receptors with suppression of the production of testosterone, progesterone, and estrogen. Thus, repeated administration at 1-, or 3-month intervals is a common palliative treatment for prostate cancer in patients who are a poor surgical risk.

Another very important application is the incorporation of proteins into these polymers with full retention of biological activity. Although proteins are stable in organic solvents such as methylene chloride, conventional microencapsulation methods cannot be used because proteins will denature when exposed to an organic solvent/water interface. To circumvent this problem, Alkermes Corp. has marketed a proprietary process called Prolease[®] where micronized protein is dispersed

TABLE 3 Examples of Commercialized Devices Based on Poly(Lactic-co-Glycolic Acid) Copolymers

Trade name	Device form	Drug
Suprefact [®] Depot	Strand	Buserilin
Zoladex [®]	Strand	Goserilin
Zoladex LA [®]	Strand	Goserilin
Decapeptyl Depot [®]	Microspheres	Triptorelin
Enantone LP [®]	Microspheres	Leuprorelin
Somatulin LP [®]	Microspheres	Lanreotide
Parlodel LAR [®]	Microspheres	Bromocriptine
Sandostatin-LAR [®]	Microspheres	Ocreotide
Eligard 7.5 [®]	Solution of Polymer and Drug in NMP	Leuprolide Acetate
Eligard 22.5 [®]	Solution of Polymer and Drug in NMP	Leuprolide Acetate
Eligard 30.0 [®]	Solution of Polymer and Drug in NMP	Leuprolide Acetate
Nutropin [®]	Microspheres	Recombinant Human Growth Hormone
Lupron [®]	Microspheres	Leuprolide Acetate

NMP is *N*-Methyl Pyrrolidone
 Zoladex[®] - 1 month delivery
 Zoladex LA[®] - 3 months delivery
 Eligard 7.5[®] - 1 month delivery
 Eligard 22.5[®] - 3 months delivery
 Eligard 30.0[®] - 4 months delivery

in a lactide/glycolide solution in methylene chloride and then atomized into liquid nitrogen that contains a frozen layer of ethanol at the bottom of the vessel. The small particles of polymer solution with dispersed protein are instantly frozen and settle on top of the frozen ethanol layer. The liquid nitrogen is then evaporated, the ethanol melts, and the particles settle into the cold ethanol, where they harden as the methylene chloride is extracted, and they are then harvested (Khan *et al.*, 1992).

This cryogenic method was used to encapsulate recombinant human growth hormone (rhGH) using an 8-kDa, 50/50 copolymer of lactic and glycolic acid. A single injection of microspheres using a 23-gauge needle, suspended in 3% w/v low-viscosity carboxymethylcellulose, 1% polysorbate 20, and 0.9% NaCl in monkeys (*Macaca mulatta*) resulted in elevated blood plasma levels for more than 1 month. The protein was stabilized during the encapsulation process and during *in vivo* release by complexing with zinc (Johnson *et al.*, 1996). This product is now commercially available as Nutropin®.

Polyanhydrides

This family of polymers has been extensively investigated for the treatment of brain cancer, and particularly glioblastoma multiforme, in pivotal studies carried out by Brem and Langer (1996). A striking feature of malignant brain tumors is that they do not metastasize, but rather, recur within 2 cm of the original tumor. Thus, if a drug delivery device containing a suitable antineoplastic agent such as BCNU [1,3-bis(2-chloroethyl)-1-nitrosourea] is placed at the site of tumor resection, survival times should be improved because localized drug delivery would destroy malignant cells not removed by the tumor resection procedure.

A multicenter clinical trial has been carried out, and in a Cox regression model, taking into account the effect of age, Karnovsky score, and tumor type, the BCNU polymer treatment was significantly more effective than placebo polymer ($p = 0.01$). A device known as Glyadel® has been approved by the FDA as a secondary treatment for patients that have failed surgical treatment of glioblastoma multiforme. Glyadel® is a wafer approximately 1.45 cm in diameter and 1 mm thick. Each wafer contains 192.3 mg of a 80:20 poly[bis(*p*-carboxyphenoxy)propane and sebacic acid and 7.7 mg BCNU. A maximum of eight wafers per procedure are used. The wafers are quite brittle and unstable and must be stored at -20°C .

Poly(ortho esters)

While as yet there are no commercial applications for poly(ortho esters), a number of delivery devices based on POE IV are in advanced stages of development.

POE III One of the most significant aspects of POE III is its biocompatibility, which makes this system an excellent candidate for ocular applications. To achieve such biocompatibility it is necessary to use a very pure polymer fabricated aseptically to avoid the possible formation of acidic degradation products. In some applications it is also necessary to incorporate into

the polymer basic compounds such as $\text{Mg}(\text{OH})_2$ that will neutralize acidic hydrolysis products. When such precautions are observed, devices containing 5-fluorouracil, (used as an adjunct drug for glaucoma-filtering surgery), or polymers designed for intravitreal injections can be developed. Animal studies are currently in advanced stages with excellent results (Einmahl *et al.*, 2003).

POE IV Because physical properties of this polymer system can be varied within very wide limits, materials having consistencies and physical properties varying from semisolids to polymers having relatively low softening temperatures can be prepared. The versatility of this polymer system can be illustrated with applications in the treatment of periodontal disease, postoperative pain control, ocular applications, and protein delivery.

Treatment of periodontal disease uses low-molecular-weight polymers based on decanediol and decanediol dilactide with incorporated tetracycline. Such materials are semisolids at room temperature and can be injected into the periodontal pocket with a blunt needle. Effectiveness in human clinical trials has been demonstrated (Heller *et al.*, 2002). In the treatment of postoperative pain, a semisolid formulation based on triethylene glycol and triethylene glycol glycolide is injected into the surgical incision. This treatment results in a high local concentration of an anaesthetic agent such as mepivacaine so that pain control can be achieved with low systemic concentration, thus minimizing undesirable side effects (Barr *et al.*, 2002). Phase II clinical trials of this delivery system are about to be initiated.

Recent work (Einmahl *et al.*, 2003) has shown that this family of poly(ortho esters) shows an ocular biocompatibility that is even better than that of POE III.

Materials suitable for protein delivery are constructed from diol and diol monoglycolide pairs chosen to permit the polymer to be extruded at temperatures low enough so that protein activity is not compromised. In this process, an intimate mixture of micronized protein and finely ground polymer is prepared and extruded into 1-mm-diameter strands, which are cut into suitable length and implanted using a trochar. Excellent release kinetics have been achieved (Rothen-Weinhold *et al.*, 2001).

Poly(phosphoesters)

A poly(phospho ester) with the trade-name of Polylactophate® has been investigated for the release of insulin (Kader *et al.*, 2000) and Paclitaxel. The Paclitaxel device has been trademarked as Paclimer® (Dang *et al.*, 1999). Polylactophate is a copolymer of ethyl phosphate and lactide and has the structure shown in Fig. 20.

Paclimer® was investigated for efficacy in a nude-mice human ovarian cancer cell line, OVCAR3. A significant survival time was achieved.

Pendant-Chain Systems

In one type of pendant-chain system a drug is covalently attached to a biodegradable polymer backbone. In early work

FIG. 20. Structure of Poly(lactophate).

in this field, hydrophobic drugs were covalently attached via labile linkages to the water soluble poly(*N*⁵-hydroxypropyl-L-glutamate) backbone. This drug polymer construct is water insoluble and as the drug is gradually released by cleavage of the labile linkages, the polymer again becomes water soluble. (Peterson *et al.*, 1980). Such systems are toxicologically complicated because the FDA requires unambiguous proof that the chemically attached drug is released in its native form and not as a chemical derivative. Pendant-chain systems are not currently under development with the exception of polymer conjugates used in tumor targeting, covered later in this chapter.

RESPONSIVE “SMART” SYSTEMS

Environmentally-Responsive Systems

Temperature-Responsive, Phase-Separating Polymer Systems

A well-known example of a polymer that undergoes a sharp, thermally induced phase separation is poly(*N*-isopropyl acrylamide) (Heskins and Guillet, 1968). Its transition at 32°C can be shifted to higher or lower temperatures by copolymerization with more hydrophilic or hydrophobic comonomers, respectively. Thus, this material could be of interest in drug delivery applications; however, it may not be suitable due to potential cell toxicity of the homopolymer and its copolymers, although this issue has not been thoroughly investigated.

Of more interest are triblock copolymers of poly(ethylene glycol) and poly(propylene glycol), PEO-PPO-PEO, known as Pluronic[®] or Poloxamer[®] polyols, some compositions of which have already been approved for use in the body. (Wang and Johnston, 1991). While many of these block copolymers have transition temperatures well above body temperature, they do exhibit transitions at body temperature in solutions at concentrations above 16 wt%. However, such materials are non-degradable and thus may not be suitable as injectable DDS. They have been used in ophthalmic applications, but discomfort due to vision blurring and crusting has been reported (Joshi *et al.*, 1993).

One of the more recent trends in thermogelling materials is the development of biodegradable systems suitable as injectable gelling systems. Such materials can be constructed from ABA block copolymers based on poly(ethylene glycol) and poly(lactic-*co*-glycolic acid) copolymers. The triblock may be designed as PLGA-PEO-PLGA or as PEO-PLGA-PEO, where the former will have a more pronounced thermal gelation capability. PLA has also been used as the hydrophobic, degradable block segment. When the block lengths and relative amounts are correctly chosen, a material is obtained that

is soluble in water at room temperature and forms a firm gel at body temperature (Jeong *et al.*, 1999a). Such materials can be injected as a solution having a viscosity not much different from a saline solution. In addition, since only water is used with this material, there are no organic solvent/water interface problems and proteins can be incorporated without loss of activity. These materials are available as dry powders that are reconstituted prior to use. Another thermogelling material that is soluble in water at room temperature and forms a firm gel at body temperature has also been recently described (Jeong *et al.*, 2000). While the exact mechanism of thermogelling is not known with absolute certainty, it has been postulated that the hydrophobic blocks (PLGA or PLA) of the amphiphilic block copolymers aggregate together to form micelles that are in equilibrium with monomeric polymer chains (Jeong *et al.*, 1999b). Then, as the temperature is increased, the equilibrium shifts to micelle formation, and above the critical gelation temperature, the micelles pack together to occupy the entire volume, resulting in gel formation. Evidence for such a mechanism is provided by ¹³C NMR studies, dye solubilization studies, and light-scattering studies, which all show an abrupt change in micellar diameter and aggregation at the critical gelation temperature (Jeong *et al.*, 1999b). It has also been postulated that the water content of the gel will determine its degradation rate and release kinetics of the incorporated therapeutic agent (Jeong *et al.*, 1999b).

Applications

A triblock copolymer based on poly(ethylene glycol) and poly(lactic-*co*-glycolic acid) copolymer is under development under the trade-name ReGel[®]. A formulation of paclitaxel in ReGel[®] is known as OncoGel[®] and a phase I clinical trial with a dose-escalating scheme to determine safety and efficacy in patients suffering from breast and neck tumors has been completed (Rohr *et al.*, 2002). All patients tolerated OncoGel[®] very well with no systemic side effects noted. At the highest dose, which was not specified, OncoGel[®] showed efficacy, and in one case, an 80% reduction in tumor volume was noted. The dose range for a phase II clinical trial has been identified.

Solvent-Responsive, Phase-Separating Polymer Systems

Another means of developing in situ-forming drug delivery systems is polymer precipitation in a poor solvent. Such an injectable delivery system is prepared from a water-insoluble biodegradable polymer dissolved in a water-miscible, biocompatible solvent. When this system is mixed with a drug and injected into the physiologic environment, the solvent diffuses

out into the surrounding tissues while water diffuses in, and the polymer precipitates, forming a solid polymeric implant containing entrapped drug. This method has been used in human (Dunn *et al.*, 1990) and in veterinary applications (Dunn *et al.*, 1995).

The polymer most commonly used is a poly(lactic-co-glycolic acid) copolymer dissolved in *N*-methylpyrrolidone (NMP). This system is known as Atrigel[®]. (See below). There are a number of other systems, such as: (1) poly(lactic acid) dissolved in a mixture of benzyl benzoate and benzyl alcohol, known as PLAD (Duenas *et al.*, 2001); (2) poly(lactic-co-glycolic acid) copolymer dissolved in glycofuroil (Eliaz and Kost 2001); (3) poly(lactic-co-glycolic acid) copolymer dissolved in benzyl benzoate known as Alzamer[®] and (4) sucrose acetate isobutyrate dissolved in NMP or Miglyol, known as SABER (Tipton and Holl, 1998).

Applications

Three formulations of PLGA dissolved in *N*-methylpyrrolidone and containing leuprolide acetate, have been used for the treatment of prostate cancer. These formulations are listed in Table 3.

Temperature- and pH-Responsive Hydrogel Systems

In this approach, responsive polymers and lightly crosslinked gels are incorporated into formulations that alter drug release in response to changes in temperature or pH. Usually these systems are hydrogels that contain absorbed drugs, and when a temperature or pH stimulus is applied, the gel shrinks and the drug is released. Such systems are not very effective, since the drug may gradually release by diffusion from the hydrogel before the stimulus causes it to release in a burst.

One example of polymers that can reversibly respond to temperature changes are hydrogels based on *N*-isopropylacrylamide (Hoffman *et al.*, 1986; Dong and Hoffman, 1987; Hoffman, 1987; Okano *et al.*, 1990). When this monomer is copolymerized with methylene bis-acrylamide the resulting crosslinked materials have been shown to shrink abruptly when heated just above 32°C. The collapse of the hydrogel occurs as a result of a phase transition of poly (*N*-isopropylacrylamide) which is soluble in water below its lower critical solution temperature (LCST) of 32°C but becomes insoluble when the temperature is increased above this temperature. Such materials can deliver biological molecules when triggered by temperature changes, but this is not very practical due to the isothermal condition in the body. However, one unique way to utilize such a thermally responsive hydrogel in the body was developed by Dong and Hoffman (1991). They prepared a combined pH- and temperature-sensitive hydrogel, based on a random copolymer of NIPAAm and AAc, and it was shown to release a model drug linearly over a four hour period as the pH went from those found in the gastric to the enteric regions of the GI tract. At 37°C body temperature the NIPAAm component was trying to maintain the gel in the collapsed state, while as the pH went from acidic (e.g., as it would in the gastric region) to neutral conditions (e.g., as it would in the enteric region),

the AAc component was becoming ionized, forcing the gel to swell and slowly release the drug.

Temperature-responsive smart polymer hydrogels can also be useful for topical delivery to open wounds, skin and mucosal surfaces such as the eye or nose. The temperatures of such surfaces may be a few degrees below 37°C but they are still well above ambient temperature, and that difference could be utilized to deliver a drug from a thermally sensitive polymer formulated with the drug.

Mucoadhesive Polymers

There are a number of mucoadhesive polymer carriers that have been investigated, but the most popular one is a lightly crosslinked poly(acrylic acid); two products are known commercially as Carbomer[®] and Polycarbophil[®]. These hydrogels may be loaded with a water-soluble drug at a slightly acidic pH where the polymeric -COOH groups are protonated. If this polymer/drug system is applied to a mucosal surface such as the eye, the neutralization of the -COOH groups to form the sodium salt can draw water into the formulation and cause the system to thicken. This viscosity increase, combined with the mucoadhesive property of the poly(acrylic acid), can lead to an enhanced residence time of the formulation on the mucosal surface, which enhances the efficacy of drug delivery. Poly(acrylic acid) is also an effective mucoadhesive polymer in the GI tract, especially at the low pH of the stomach. Mechanisms of mucoadhesion are largely attributed to a combination of H-bonding and molecular entanglements of the polymer with the glycoprotein, mucin. (Park and Robinson, 1985; Leussen *et al.*, 1997; Singla *et al.*, 2000, Robinson and Peppas, 2002).

Some researchers have used chitosan as a pH-sensitive mucoadhesive carrier (Henriksen, 1996; Leussen *et al.*, 1997) especially for nasal drug delivery. (Aspden *et al.*, 1997) In this case, the chitosan is not soluble at pH 7.4, but could swell and begin to dissolve at the slightly lower pH that exists in the nose. This could cause the chitosan to gel, adhere to the nasal mucosa, and maintain the drug in place within the nasal tissues. (Ilum, 2001)

Intracellular Drug Delivery

Drugs may interact with the body in three sites: (a) within the circulation or interstitial space, (b) at membrane receptors on cell surfaces, or (c) at various sites within the cell. When a drug or drug/carrier is taken up by a cell, the usual process is endocytosis, and the drug is localized within the endosome. The endosome has a proton pump in its membrane, causing the pH to drop from 7.4 to as low as 5.0; within one to a few hours the endosome is "trafficked" to the lysosome, which is also at a lowered pH. The lysosome contains enzymes that are active at the low pH of that vesicle. If the drug is enzyme-susceptible, its efficacy will be determined by how efficiently it can escape the endosome before it ends up in the lysosome, where it may be enzymatically degraded. Enzymatically susceptible drugs, such as DNA, RNA, antisense oligonucleotides, peptides or proteins must escape the endosome to be effective intracellularly.

pH- and Ion-Responsive DDS: Non-viral Intracellular Nucleic Acid Delivery

Gene therapy and antisense oligonucleotide (asODN) and silencing RNA delivery systems have become very actively researched in the past several years (Felgner *et al.*, 1996; Mahato *et al.*, 1997; Rolland, 1999; Hillery *et al.*, 2001). In particular, since DNA, RNA and asODNs are all highly negatively charged molecules, cationic polymers and cationic liposomes have been used to ionically complex and condense in size these nucleic acid drugs in the body. Plasmid DNA complexes with cationic polymers are called polyplexes, and complexes with cationic liposomes are called lipoplexes. Together these two methods are called non-viral delivery systems. They are much less efficient than viral carriers, but the latter may cause undesirable toxic and immunogenic responses in the body (although there is also some toxicity associated with polycations in the body). Some of the more common cationic polymers include poly(ethylene imine) (PEI), poly(L-lysine) (PLL), chitosan, poly(vinyl imidazole), poly(amidoamines) and acrylic copolymers of *N,N* dimethyl aminoethyl methacrylate (DMAEMA). The resultant polyplexes are typically slightly positively charged nanoparticles of ca. 50-200 nm in diameter. Once they are taken up into a cell by endocytosis, some of the amino groups on the polymers that have the appropriate pK have been postulated to buffer the acidic pH within the endosome by binding protons and thereby causing sodium ions to enter to maintain electrical neutrality. This leads to osmotic swelling and bursting of the endosome, releasing the polyplex (or lipoplex) to the cytosol. This is called the "proton sponge" effect (Behr, 1997), and it may be one step in the mechanism by which polyplexes (or lipoplexes) can transfect cells. It is not clear how and when the polycation actually releases the DNA. It is probably not an efficient process, since the polycation and the DNA must each be "reunited" with their counterions in that process. This may be one reason the non-viral systems are so inefficient. Some polyplexes and lipoplexes also tend to be unstable in serum, possibly due to disruption by proteins and lipoproteins in the circulation, and also potentially due to degradation of the DNA by nucleases. Another challenge to the stability of the polyplexes or lipoplexes may be heparan sulfate groups on cell surfaces that can compete with the DNA for the cationic groups on the polymer or liposome.

Viruses have evolved an efficient system for delivering DNA or RNA to the cytosol which utilizes the lowered pH within the endosome. Certain peptide sequences on the surface of the virus become hydrophobic when their acidic amino acids are protonated, causing those sequences to fuse with or cause pore formation in the endosomal membrane, allowing the virus to deliver its genomic contents to the cytosol. Based on this natural action of the virus, the Stayton/Hoffman research group has mimicked this viral action by designing and synthesizing pH-sensitive polymers, such as poly(propylacrylic acid), PPAA, that would similarly become hydrophobic at the endosomal pHs and disrupt the endosomal membrane. (Murthy *et al.*, 1999; Stayton *et al.*, 2000; Cheung *et al.*, 2001; Murthy *et al.*, 2001; Kyriakides *et al.*, 2002). A pendant glutathione-responsive disulfide group has been added to this acid-responsive polymer, such that when the polymer-drug

complex or conjugate escapes the endosome, it releases the drug after reduction by glutathione in the cytosol (Bulmus *et al.*, 2003). Other approaches by these same researchers have been to design and synthesize membrane-disruptive polymers that are PEGylated via acid-degradable acetal bonds; these bonds degrade within the endosome, exposing the backbone which is membrane-disruptive, leading to the release of the drug to the cytosol (Murthy *et al.*, 2003).

pH-Responsive Enteric Coatings

An enteric coating is a polymer that is insoluble at a low pH and soluble at physiologic pH. The most common reasons for the use of enteric coatings is (a) to protect acid-sensitive drugs from gastric juices, (b) to prevent gastric distress due to irritation caused by certain drugs, (c) to prevent the absorption of certain drugs in the stomach, and (d) to deliver drugs to the small intestine if that is their prime absorption site. The USP test for enteric-coated tablets requires that the tablet withstand agitation in artificial gastric juices at 37°C for one hour and be disintegrated within two hours when agitated in artificial intestinal juices at 37°C.

Enteric coatings have been known for over 100 years and a great many materials have been investigated. A comprehensive tabulation of such materials has been made (Martin, 1965). However, modern enteric coatings are based on polycarboxylic acids that are hydrophobic and water-insoluble at a low pH because the carboxyl groups are unionized and become water soluble at a higher pH where the carboxyl groups ionize.

Examples of enteric coating compositions include partially esterified copolymers of methyl vinyl ether and maleic anhydride (Lappas and McKeehan, 1965) or copolymers of methacrylic acid and methacrylic acid esters. By varying the degree of esterification, or the ratio of methacrylic acid to methacrylic acid esters, the dissolution pH can be modified to any desired value. The copolymers of methacrylic acid and methacrylic acid esters are commercially available as Eudragit L and Eudragit S, and are widely used as enteric coatings. They dissolve at pH 6.0 and 7.0, respectively (Lehman, 1968).

Partially esterified copolymers of methyl vinyl ether and maleic anhydride have also been used as a matrix for the controlled-release of incorporated drugs. An erosion-controlled, zero-order drug release has been achieved (Heller *et al.*, 1978).

Another enteric coating composition of cellulose acetate phthalate has also been widely used. It is insoluble below a pH of about 6.0 and will dissolve at a pH higher than 6.0 (Malm *et al.*, 1951). However, cellulose acetate phthalate is hygroscopic so that proper storage conditions are important.

Mechanical- and Physically-Responsive Systems

Among the most advanced externally regulated devices are mechanical pumps which dispense drugs from a reservoir to the body by means of a catheter. Such pumps can be worn externally with a percutaneous delivery tube or needle penetrating the skin, or can be implanted in a suitable body site. A major application is control of diabetes by delivering insulin

in response to blood glucose levels. A number of such pumps such as the CPI Lilly pump have sophisticated control mechanisms and microprocessors that allow a programmed insulin delivery (Brunetti *et al.*, 1991). They are also used for pain control of terminal cancer patients.

Another means of externally regulating drug delivery is by means of magnetism (Hsieh *et al.*, 1989). In this procedure, small magnetic spheres are embedded within a polymer matrix that contains a dispersed therapeutic agent. When an oscillating magnetic field is applied to the polymer, the normal diffusional release is significantly and reversibly increased.

Rate of drug release from some DDS can also be increased by the use of ultrasound (Kost *et al.*, 1989). This method has been applied to biodegradable polymers and it has been shown that rate of bioerosion and drug release can be significantly enhanced. Unlike magnetically enhanced devices, ultrasound can be used with biodegradable implants and represents a means by which enhanced insulin delivery could be realized. Ultrasound has also been found to enhance drug transport across the stratum corneum in transdermal drug delivery devices.

Self-Regulated, Feedback Systems

During the last three decades, controlled-release administration of therapeutic agents from various types of delivery systems has become an important area of research and significant advances in theories and methodologies have been made. However, even though devices that are capable of releasing therapeutic agents by well-defined kinetics are a significant improvement over conventional dosage forms, these devices do not yet represent the ultimate therapy because the agent is released without regard of the need of the recipient. Therefore, another very significant improvement could be realized if systems could be devised that are capable of adjusting drug output in response to a physiological need or signal. (Heller, 1988.) Such "self-regulated" devices should be capable of altering drug release with a "built-in" response to an environmental signal, such as an increase in insulin delivery rate in response to an increase in glucose concentration. This is different from systems described earlier, where an external stimulus, such as an increase in pumping rate delivers insulin from an implanted pump. The latter DDS are referred to as "externally regulated." Self-regulated devices based on enzyme reactions can be classified as "substrate-responsive" devices.

Self-Regulated Systems

Two different types of devices based on enzyme/substrate-responsive or substrate-responsive reactions have been described. In the first type, an enzyme-substrate reaction modulates drug release from the device while in the second type the substrate itself triggers drug release by an affinity recognition process.

Modulated Devices The first published example of a modulated device was based on a coated monolithic matrix system, where the coating was a hydrogel containing an entrapped enzyme, and the matrix was composed of a drug

physically dispersed in a bioerodible polymer. (Heller and Trescony, 1979). When the enzyme reacted with its substrate, (e.g., an endogenous metabolite) the product caused a local pH change in the device that accelerated the erosion of the bioerodible polymer, increasing the rate of release of the drug. This particular system was based on the reaction between urea and the enzyme urease. The polymer used was a partially esterified copolymer of methyl vinyl ether and maleic anhydride containing a marker drug, hydrocortisone. This copolymer in the form of a disc was coated with a hydrogel containing urease. When this system was placed in solutions having differing concentrations of urea, the hydrocortisone release rate was proportional to the urea concentration, and the effect was "reversible" in the sense that when the urea concentration decreased, the drug release rate was similarly reduced. (Heller and Trescony, 1979).

Clearly, a system that releases hydrocortisone in response to external urea concentration is not therapeutically relevant, but it did demonstrate the feasibility of this concept. A more therapeutically relevant system utilizes pH changes resulting from the glucose oxidase conversion of glucose in the presence of oxygen to gluconic acid, and pH-sensitive polymers that can swell or collapse or degrade in response to that change. Such polymers can be in the form of:

- (a) hydrogel membranes that reversibly alter their porosity by a protonation of tertiary amine functions in the polymer, causing swelling and enhanced permeation of insulin (Albin *et al.*, 1985, Ishihara and Matsui, 1986), or
- (b) porous membranes, where polyacrylic acid (PAAc) has been grafted onto the pore walls, and where protonation of the carboxyl groups causes the PAAc coating to collapse against the pore walls, opening the pores to insulin permeation (Ito *et al.*, 1989, Iwata and Matsuda, 1988) or
- (c) bioerodible polymers that alter their erosion rate in response to pH changes (Heller *et al.*, 1990b).

In a completely different, affinity-based system, insulin was glycosylated, and the glucose groups were complexed with the plant-derived carbohydrate-binding protein Concanavalin A (ConA) which has four binding sites for glucose and other sugars. In the presence of free glucose, the glycosylated insulin is displaced from the complex with ConA in amounts proportional to the external glucose concentration. When this system is entrapped within a glucose- and insulin-permeable, but ConA impermeable capsule, it can deliver insulin in direct response to blood glucose levels (Makino *et al.*, 1990). Nakamae, Hoffman and coworkers (Nakamae *et al.*, 1994) extended this concept to an affinity hydrogel based on poly(glucosylethyl methacrylate) which was crosslinked by affinity association with ConA. In the presence of free glucose, the ConA interactions with the pendant polymeric glucose groups were displaced, and the system swelled. Drug molecules such as insulin could then diffuse faster through the swollen hydrogel barrier system. ConA was also covalently linked into the polymer network, eliminating its potential diffusion out of the swollen gel. (Nakamae *et al.*, 1994; Lee and Park, 1996) (See also Chapter 2.6).

FIG. 21. Reversible enzyme inactivation by hapten-antibody interactions. In this particular case, drug is morphine and enzyme is lipase. [Reprinted from Schneider, R. S., Lindquist, P., Wong, E. T., Rubinstein, K. E., and Ullman, E. F. (1973). *Clin. Chem.* 19: 821–825.]

Siegel and coworkers have used the glucose-stimulated swelling and collapse of pH-responsive hydrogels containing entrapped glucose oxidase to drive a hydrogel piston for release of insulin in a glucose-driven, feed-back manner. (Dhanarajan *et al.*, 2002).

Triggered Devices One important application is the development of a device capable of releasing the narcotic antagonist naltrexone in response to external morphine. Such a device would be useful in the treatment of narcotic addiction by blocking the opiate-induced euphoria by the morphine-triggered release of the antagonist. Development of this device utilizes the reversible inactivation of an enzyme by hapten-antibody interaction (Schneider *et al.*, 1973) as shown in Fig. 21.

In a device based on this principle, naltrexone is contained in a core surrounded by an enzymatically degradable coating that prevents naltrexone release. In the absence of external morphine the device is stable, but upon exposure to morphine, the reversibly inactivated enzyme is activated and degrades the protective coating, which results in naltrexone release. The actual device utilizes the enzyme lipase and a triglyceride protective coating (Roskos *et al.*, 1993).

PARTICULATE SYSTEMS

Microcapsules and Microspheres

A microcapsule includes a well-defined core containing the therapeutic agent, and a well-defined polymer membrane surrounding the core. In controlled drug delivery applications, such systems are of interest because drug release takes place by diffusion from the core through the rate-limiting membrane. Such systems fall under the category of membrane-controlled reservoir devices, already discussed. Consequently, microcapsules are capable of extended zero-order drug release provided that the conditions already discussed are met. Microcapsules may be prepared by a complex, three phase colloidal dispersion method. They may also be made by coating microspheres, which is a simpler process. An excellent review is available (Mathiowitz *et al.*, 1999) so only a few general comments will be made here. The reader is referred to the review article for additional details.

The attractiveness of achieving long-term zero-order drug release with microcapsules may be offset by (a) fairly expensive

manufacturing methods that limit the use of microcapsules to human therapeutics that are not price-constrained and (b) the possibility of membrane rupture and abrupt release of the core material with the consequent overdosing potential.

On the other hand, microspheres are most often prepared by a simpler microemulsion polymerization technique. In microspheres, there is no outer membrane and such devices are in effect matrix devices with the drug more or less uniformly distributed in the polymer matrix. Release kinetics are typical of diffusion from a matrix system, as discussed above. Particle size distribution will be an important variable.

Microspheres and microcapsules are special categories of microparticulates. “Coarse” microparticles may be prepared by simple phase separation and lyophilization or solid diminution techniques, such as grinding and micronizing, using polymer/drug solutions, suspensions or solids. In these cases the particles are often not spherical, and size distributions will be broad, sometimes necessitating sieving.

Despite non-zero-order release kinetics, microsphere and microparticle delivery systems find wide application in both human and veterinary therapeutics because they can be inexpensive, are simple to manufacture and there is little danger of abrupt drug release. A number of particulate DDS have reached commercialization and they are included in Table 3.

Applications

There are numerous applications of macrocapsules and microspheres, and the reader is again referred to the review already mentioned (Mathiowitz and Kreitz, 1999). A number of applications are also listed in Table 3.

Polymer Therapeutics

The term “polymer therapeutics” has been coined to encompass polymeric drugs, polymer-protein conjugates, polymer-drug conjugates and complexes, and polymeric micelles with drugs covalently or physically incorporated in the core (Duncan *et al.*, 1996). An excellent review has recently been published (Duncan, 2003). Polymeric drug carriers are also discussed in other sections of this chapter.

The Enhanced Permeability and Retention Effect (EPR)

The principal rationale driving the development of polymer-drug conjugates, as well as micellar drug delivery systems is the enhanced permeability and retention (EPR) effect, first described by Maeda and coworkers (Matsumura and Maeda, 1986). This effect was attributed to the combination of two effects, (a) the disorganized pathology of tumor vasculature with a discontinuous endothelium which makes it hyperpermeable (“leaky”) to circulating macromolecules and to particulates such as liposomes or micelles having an average diameter between 50 and 100 nanometers, plus (b) poor lymphatic drainage, resulting in retention of the delivery vehicle in the interstitial space of the tumor. Such materials, when administered intravenously will passively accumulate in tumors and can result in an intra-tumor concentration as much as 70-fold

TABLE 4 Polymer-Protein Conjugates on the Market or in Clinical Development^a

Compound	Name	Year marketed	Indication
PEG-adenosine deaminase	Adagen [®]	1990	SCID syndrome
SMANCS	Zinostatin [®] , Stimalmer [®]	1993 (Japan)	Hepatocellular carcinoma
PEG-L-asparaginase	Oncaspar [®]	1994	Acute lymphoblastic leukemia
PEG- α -interferon 2b	PEG-INTRON [®]	2000	Hepatitis C
PEG- α -interferon 2b	PEG-INTRON [®]	Various clinical trials	Cancer, multiple sclerosis, HIV/AIDS
PEG- α -interferon 2a	PEGASYS [®]	2002	Hepatitis C
PEG-HGR	Pegvisomant [®]	2002 (approved EU)	Acromegaly
PEG-G-CSF	PEG-filgrastim [®] , Neulasta [®]	2002	Prevention of neutropenia associated with cancer chemotherapy
PEG-anti-TNF Fab	CD870	Phase II	Rheumatoid arthritis

^aFrom Duncan (2003).

over that found systemically. Polymeric micelles and liposomes may similarly accumulate within the interstitial space of a tumor due to EPR (see below). This type of DDS has been called “passive targeting.”

PEG-Protein Conjugates

Proteins are now recognized as an important therapeutic entity, but there are significant problems associated with their use. Dominant among these is antigenicity and proteolytic degradation, and both of these can result in very short plasma half-lives. These problems can, to some extent, be alleviated by conjugation with poly(ethylene glycol) (PEG), a process known as PEGylation, first described by Davis, Aubuchowski and colleagues (Davis, 2002). This concept is also discussed below as the “stealth” liposome DDS.

The exact mechanism by which PEG protects proteins from enzymatic degradation, reduces antigenicity and prolongs circulation time is not entirely understood. However, because the PEG chains bind and retain water (about 2–3 water molecules per ether oxygen group) it is likely that the PEG chains form a protective “cloud” at the protein surface that strongly retains hydration water and thus resists closer approach to the protein itself (e.g., Torchilin *et al.*, 1995). This protective cloud then shields the protein from the action of degrading enzymes and reduces interaction with receptors, thus reducing immunogenicity. Further, it may also block recognition and capture by the reticuloendothelial system (RES) and further enhance circulation times (See also Chapter 2.13).

Since protein drugs have an active site, this protective cloud can also shield the active site and reduce biological activity. However, it has been suggested that the increased circulation time more than compensates for the reduced activity.

Applications

PEGylated protein drugs used clinically or in clinical development are shown in Table 4 (Duncan, 2003). A unique polymer-drug conjugate based on Styrene-Maleic Anhydride copolymer (SMA) and the drug NeoCardioStatin (NCS), called SMANCS, is also included in this table (Matsumura and Maeda, 1986).

Polymer Drug Conjugates

A schematic representation of a polymer-drug conjugate is shown in Fig. 22. This model was first proposed by Ringsdorf (Ringsdorf, 1975). The essential features of this model are a water-soluble backbone polymer with a covalently attached drug via a spacer. Optionally, a targeting residue can also be attached via a spacer. The water-soluble polymer backbone can be degradable, or non-degradable.

An effective polymer-drug conjugate is stable while in blood plasma, but then gradually releases the drug once it is localized by the EPR effect within a tumor, and the drug is then taken up by the tumor cells. One of the most extensively investigated polymers used in polymer-drug conjugates is poly[N-(2-hydroxypropyl) methacrylamide], known as HPMA (Kopecek and Bazilova, 1973; Duncan and Kopecek, 1984). In this particular polymer system, the drug is covalently attached to the water-soluble polymer backbone via a glycine-phenyl alanine-leucine-glycine spacer. This spacer is stable in the circulation, but once it has been internalized by the tumor cells via endocytic uptake, the enzyme cathepsin B cleaves the peptide spacer within the lysosome, and the drug is liberated from the polymer conjugate and diffuses from the lysosome to the

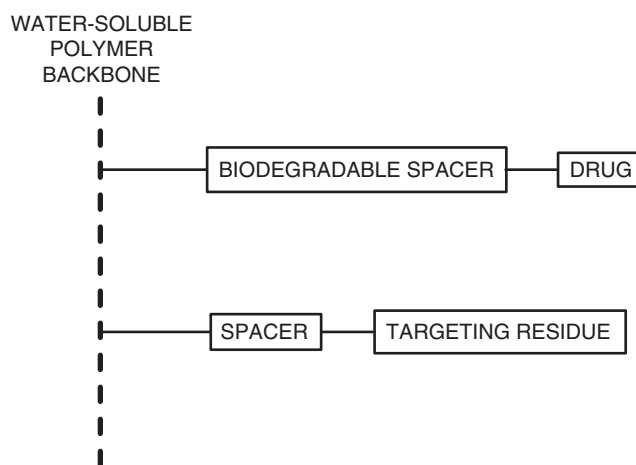

FIG. 22. Ringsdorf polymer conjugate model.

nucleus where it can kill the cell. (Duncan and Kopecek, 1984). This has been called “lysosomotropic” drug delivery.

However, HPMA has a non-degradable backbone so that the molecular weight of the polymer has to be kept below the renal threshold so that the polymer can be excreted. Unfortunately, this also reduces the time the conjugate is in the circulation. Since it has been shown that EPR-mediated passive targeting is directly proportional to the plasma concentration of the circulating conjugate (Seymour *et al.*, 1995) the construction of biodegradable, water-soluble polymer backbones where molecular weights are not limited by renal excretion values is clearly of interest.

Among the first biodegradable polymer-drug conjugates is poly(L-glutamic acid) containing bound paclitaxel, or camptothecin. These conjugates are now in clinical trials (Schulz *et al.*, 2002, Shafter *et al.*, 2002). Recently, a polyacetal-doxorubicin conjugate designed to be relatively stable at pH 7.4 but to rapidly hydrolyze at pH 5.5 has been described (Tomlinson *et al.*, 2003).

Applications

Polymer-drug conjugates in clinical development are shown in Table 5 (Duncan, 2003).

Polymeric Micelles

Amphiphilic, A-B, block copolymers, i.e., block copolymers constructed from a hydrophilic and a hydrophobic segment, are known to assemble in an aqueous environment into polymeric micelles. This self-assembly is due to the large difference in solubility between the two segments. Polymeric micelles have a fairly narrow size distribution and have a unique core-shell structure where the hydrophobic segments form an inner core surrounded by the hydrophilic segments, known as the “corona.” Polymeric micelles only exist above the critical micelle concentration (CMC). Below that concentration the micelles dissociate into the individual polymer molecules, known as unimers. Micelles can also be constructed from graft copolymers with a soluble main chain and insoluble grafts, or side chains. Kataoka, Okano and coworkers have published extensively on polymeric micelles, and have designed many interesting block copolymers for use in polymer micellar DDS. (For example, see Yokoyama *et al.*, 1990). An excellent recent review has also been published (Torchilin, 2001).

Polymeric micelles have excellent potential as DDS. Among these is their ability to solubilize poorly water-soluble drugs

and thus increase drug bioavailability. They can also passively target tumors due to the EPR effect. Like liposomes, micelles can also be targeted by attachment of specific ligands at the ends of the hydrophilic block segment.

Although other hydrophilic polymers can be used to solubilize and stabilize hydrophobic drugs, (Torchilin *et al.*, 1994), poly(ethylene glycol) remains the polymer of choice. (See Chapter 2.13 on Nonfouling Surfaces). However, a variety of polymers have been used to form the hydrophobic block. These include poly(propylene oxide) (Kabanov *et al.*, 1989) poly(L-lysine) (Katayose *et al.*, 1998), poly(aspartic acid) (Yokoyama *et al.*, 1990) γ -benzoyl-L-aspartate (Kwon *et al.*, 1997), γ -benzyl-L-glutamate (Jeong *et al.*, 1998), polycaprolactone (Kim *et al.*, 1998), poly(D,L-lactic acid) (Ramaswamy *et al.*, 1997) and poly(ortho esters) (Toncheva *et al.*, 2003).

Applications

Polymeric micelles have principally been used as drug carriers in tumor targeting applications. Micelles based on Pluronics [tri-block copolymers of poly(ethylene oxide) (PEO) and poly(propylene oxide) (PPO) with the general structure of PEO-PPO-PEO] with incorporated doxorubicin have been shown in a Phase II study to circumvent p-glycoprotein-mediated drug resistance (Batrakova *et al.*, 1996), a phenomenon where anti-neoplastic drugs are pumped out of the cell resulting in failures of chemotherapy regimes. Micelles based on a block copolymer of poly(ethylene glycol)-poly(aspartic acid), with a fraction of doxorubicin covalently bound and a fraction ionically complexed to the aspartic acid units, was investigated in a Phase I clinical trial as a formulation known as NK911 (Nakanishi *et al.*, 2001). While only the non-covalently bound doxorubicin was active, a three-to-four fold improvement in targeting was observed.

Liposomes

The first observation that ordered structures are obtained when water insoluble lipids, such as phospholipids, are mixed with an excess of water was made by Bangham and coworkers in the 1960's (e.g., see historical review by Bangham, 1983). These ordered structures eventually arrange into concentric, closed spherical membranes known as liposomes, or vesicles. Such liposomes can consist of one, or a multiplicity of bilayer membranes. When the diameter of such vesicles is about 25 to 100 nm, they are known as small unilamellar vesicles (SUV) and when the diameter is between about 100 nm to many microns,

TABLE 5 Polymer-Drug Conjugates in Clinical Trials as Anticancer Agents^a

Compound	Name	Company	Linker	Development status
HPMA copolymer-doxorubicin	PK1; FCE28068	CRC/Pharmacia	Amide	Phase II

they are known as multilamellar vesicles (MLV). A good review has recently been published (Gregoriades, 2003).

Liposomes are able to entrap water-soluble solutes in the aqueous inner core. Lipophilic drugs may be entrapped in the lipid bilayers by combining such drugs with the phospholipids used during their preparation.

Vesicles larger than about 200 nm are rapidly cleared from the blood and end up in the macrophages of the reticuloendothelial system (RES). Circulation times of liposomes can be augmented by coating with PEG or sialic acid surfactants. In the former case, PEG is conjugated to a lipid tail, which inserts into the liposome's lipid bilayer, "PEGylating" the liposome. These polymers form a water-retaining coating around the liposome and prevent recognition by the RES system (Gregoriades, 1995a). Such liposomes have been termed "stealth liposomes."

While passive targeting of liposomes to the RES is of some interest, a more interesting approach is one where liposomes with target recognition properties are constructed (Gregoriades, 1995b). Such "active targeting" requires the identification of suitable receptors on the surface of the target cells and appropriate ligands on the surface of the liposome that can recognize this target. When the liposome is PEGylated, the targeting ligand is conjugated to the outer end of the PEG molecules.

Applications

Examples of commercialized liposome-based products are listed in Table 6 (Gregoriades, 2003).

7.15 BIOELECTRODES

Ramakrishna Venugopalan and Ray Ideker

INTRODUCTION

Bioelectrodes are interdomain converters or intradomain modifiers and are used to transmit information into or out of the body. This chapter introduces the reader to the basic reactions that occur at an electrode–electrolyte interface, explains how these processes define the type of electrode, explores some simple equivalent circuit models for the electrode–electrolyte interface, reviews the factors influencing material selection for electrodes, and finally looks at some applications of such electrodes. Although the fundamentals discussed apply to both recording and stimulating electrodes, this chapter focuses on stimulating electrodes in the material selection and application sections because of their recent emergence as very effective treatment options.

Surface or transcutaneous electrodes used to monitor or measure electrical events that occur in the body are considered as monitoring or recording electrodes. Typical applications for recording electrodes include electrocardiography, electroencephalography, and electromyography. Electrodes used

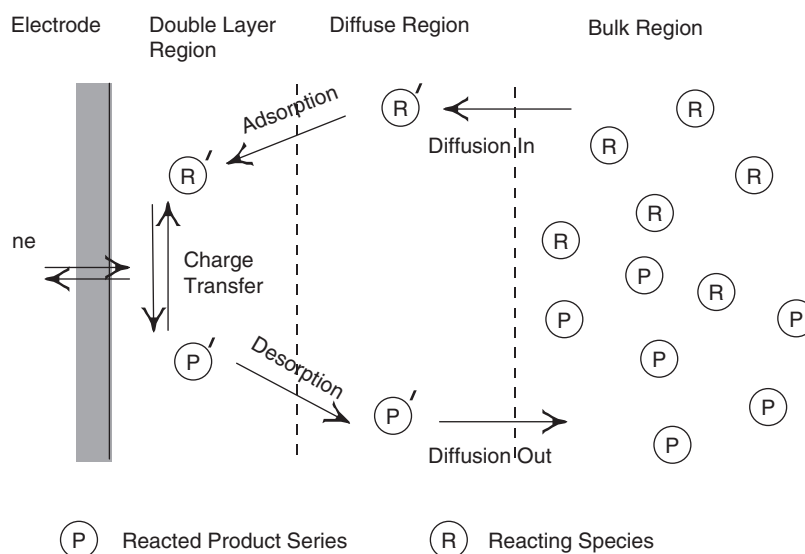

FIG. 1. Faradaic and nonfaradaic pathways of general electrode reactions. The charge transfer reaction at the surface is faradaic. The diffusion and the adsorption/desorption processes are nonfaradaic.

to transmit information into the body influence specific processes that occur in the body and are considered as stimulator electrodes. In all of these applications the electrodes are used to transmit voltage or current waveforms to specific target areas in the body for either direct control of a bioelectric event or indirect influence on the target area through a stimulated chemical change. Such stimulator electrodes are used in cardiac pacemakers and defibrillators to maintain or restore sinus rhythm, in transcutaneous electronic nerve stimulators for pain suppression, in neural stimulation systems for applications ranging from epilepsy control to auditory augmentation, in polarizing devices for intrascutaneous drug delivery, and in stimulators for tissue healing/regeneration.

ELECTRODE-ELECTROLYTE INTERFACE

In 1800 Volta demonstrated that the electrode-electrolyte interface was the source of electrical potential and initiated his research on direct current electricity. The nonlinearity of this interface with current lead to Ohm (1826) using a thermopile as a source of potential and resulted in the law that bears his name. However, the origin of the term “electrode” is attributed to one of the most prolific researchers in electrochemistry, Faraday (1834). In 1879 Helmholtz established the first model for the electrode-electrolyte interface. Several more complex models of this interface were proposed by Gouy (1910) and Stern (1924). This section will explain the basic reactions at the electrode-electrolyte interface, how they define a specific electrode type, and finally the make-up of this interface.

Faradaic and Nonfaradaic Processes

Bioelectrodes can interact with the body fluids (electrolytes) in two primary ways—faradaic and nonfaradaic (summarized in Fig. 1). An electrode may establish ohmic contact with

the surrounding environment thereby transferring electrons across the electrode/electrolyte interface via oxidation and/or reduction reactions. All such charge-transfer processes are governed by Faraday’s law (i.e., the amount of chemical change occurring at an electrode-electrolyte interface is directly proportional to the current that flows through that interface) and hence are called faradaic processes. Electrodes at which faradaic processes occur are also known as charge-transfer electrodes. Under certain thermodynamically or kinetically unfavorable conditions an electrode-electrolyte interface may exhibit an absence of charge-transfer reactions. However, the electrode-electrolyte interface may change because of adsorption or desorption processes that occur at the interface, and transient external currents can flow due to changes in the environment. These processes at the electrode-electrolyte interface are known as nonfaradaic processes.

Polarizable and Nonpolarizable Electrodes

Electrodes in which charge transfer can occur in an unhindered manner represent truly faradaic or perfectly nonpolarizable electrodes. Conversely, electrodes in which no faradaic charge transfer can occur are called perfectly polarizable electrodes. In the latter case the half-cell potential of the electrode results in the formation of an electrical double layer of charge akin to two parallel plates of a capacitor, and charging or discharging of this capacitor monitors or influences a bioelectric event. Although an electrode can behave as either a polarizable or a nonpolarizable electrode under specific conditions at the interface, it will also exhibit a minimal amount of the other process (secondary) during clinical use.

Electrical Double Layer

At a given potential there will exist a charge on the metal electrode (q_M) and a charge in the solution (q_S). The potential

FIG. 2. Simplistic parallel-plate Helmholtz model for electrical double layer.

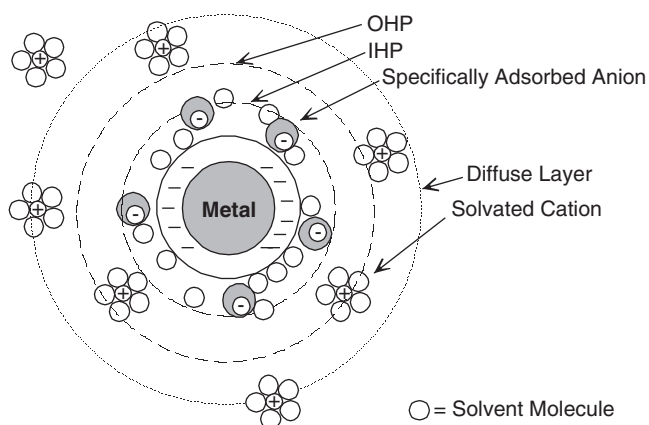

FIG. 3. Multilayer model for the electrode–electrolyte interface. IHP, inner Helmholtz plane, OHP, outer Helmholtz plane.

across the electrode–electrolyte interface and the composition of the electrolyte will determine if the charge on the electrode is positive or negative. The sum total of the charge at the interface will however be equal to zero at all times, i.e., $q_M = -q_S$. The charge on the metal is a result of an excess or a deficiency of electrons, and the charge in the electrolyte is due to an excess of anions or cations in close proximity to the electrode. Helmholtz (1879) established a model for this aligned array of charges referred to as the electrical double layer (EDL). This model is illustrated in Fig. 2.

Under realistic conditions this interface is more complex than the simplified parallel-plate model. The metal electrode still forms one charge array at the electrode–electrolyte interface. On the aqueous solution side of the interface, polar solvent molecules and specifically adsorbed ions or molecules make up the first layer. This layer, referred to as the compact, Stern, or Helmholtz layer, extends to the locus of the electrical centers of the specifically adsorbed ions (inner Helmholtz plane). Charged ions in the electrolyte attract their own sheath of solvent molecules and form what are called micelles or solvated ions. Because these ions are well insulated they interact with the conducting electrode surface primarily through long-range electrostatic forces. The size of these ions and their nonspecific adsorption mechanism results in the formation of a three-dimensional diffuse outer layer. This outer layer extends from the locus of the electrical centers of the solvated ions (outer Helmholtz plane) into the bulk of the solution. The resulting interfacial structure is illustrated in Fig. 3.

FIG. 4. Basic circuit elements. (A) The half-cell potential or battery circuit element. (B) Simplistic double-layer or parallel-plate capacitor circuit element. (C) Hindrance to faradaic transfer or the resistive circuit element.

EQUIVALENT CIRCUIT MODELS

Helmholtz (1879) not only described the nature of the electrode–electrolyte interface, but also proposed the first equivalent circuit model for it, i.e., an idealized parallel-plate capacitor. Warburg (1899), Fricke (1932), Randles (1947), and Sluyters-Rehbach (1970) contributed significantly to continued development of equivalent circuit models for specific conditions at the interface. However, their models did not account for the passage of direct current through this interface. In 1968 Geddes and Baker applied the concept of a shunting (parallel) faradaic leakage resistance across the non-faradaic components that resulted in two equivalent circuit models for the bioelectrode–electrolyte interface. These models accounted for the passage of direct current through this interface. Subsequent experimental investigations by Onaral and Schwan (1982) very strongly corroborated this concept of a shunting faradaic leakage resistance at low frequencies. Detailed analysis of different types of recording and stimulation electrodes and corresponding equivalent circuits are discussed by Geddes and Baker (1989) in their seminal textbook on the principles of biomedical instrumentation. A review article by Geddes (1997) provides a less rigorous historical perspective on the evolution of such circuits, their advantages, and their limitations.

Basic Circuit Elements

A voltage is developed across the electrical double layer and is referred to as the half-cell potential for that electrode under specific environmental factors. It is impossible to measure the potential developed at a single electrode. Hence an arbitrary standard electrode is used to close the circuit, and the total voltage is measured as a difference of the half-cell potentials of the two electrodes. This can be represented in terms of a voltage source element or battery represented in Fig. 4A. The electrical double layer in its most simplistic form is represented by two charged parallel plates with an insulated gap, i.e., a capacitor circuit element (Fig. 4B). The hindrance to the charge transfer that occurs at a faradaic electrode–electrolyte interface is represented by a resistive circuit element illustrated in Fig. 4C.

Simple Equivalent Circuits

The electrolyte/tissue surrounding an electrode will result in a resistive element referred to as the uncompensated or series resistance (R_u) that will be a contributing factor in all cases. An ideally polarizable electrode (nonfaradaic) will be represented

FIG. 5. Simple equivalent circuits. (A) Equivalent circuit for an ideally polarizable electrode. (B) Equivalent circuit element for a practical electrode. (C) A polarizable electrode subject to mass-transport limitations. (D) A polarizable circuit with mass-transport limitations and the half-cell potential of the electrode.

by a series combination of the established double layer capacitance (C_{dl}) and R_u . This is illustrated in Fig. 5A. However, this model predicts infinite impedance for direct current (0 Hz). But, it is known that a direct current can be passed between an electrode–electrolyte interface. This disparity can be explained by placing a charge-transfer resistance (R_{ct}) or a faradaic leakage resistance across the model illustrated in Fig. 5A, as shown in Fig. 5B. Most physiological electrolytes diffuse in and out of the tissue surrounding an electrode. A polarizable electrode with such mass transport limitations (partial diffusion control) will have an impedance term called the Warburg impedance (Z_w) associated with it and will result in the model illustrated in Fig. 5C. Finally, a half-cell potential (E) is associated with every electrode placed in an electrolyte, and it is placed in series with the circuit in Fig. 5C, as shown in Fig. 5D.

Electrodes on a Subject

The equivalent circuit in Fig. 5D is a very good approximation of a single electrode–electrolyte interface. However, it is known that at least a two-electrode system is required either to make measurements of or to initiate a local biological event (E_b). The equivalent circuit models to represent the subject are quite complex because of the varying nature of tissue microstructure. Thus, a simplistic black box model (Z_s) is used to represent the generic subject impedance. The whole equivalent circuit comprising the subject impedance, the biological event, and the two electrodes is illustrated in Fig. 6.

FACTORS INFLUENCING MATERIAL SELECTION

While recording electrodes are not subject to active degradation because of the inherent nature of the application, they are subject to degradation by the environment. Stimulation electrodes, on the other hand, are subject to degradation by the very excitation applications they are used for. All the factors listed in Table 1 are of specific importance to material selection for electrodes (Fontana, 1986; Bard and Faulkner, 1980).

Stimulating electrodes work by producing transient electric fields in their vicinity. The uniformity and precision of

FIG. 6. The equivalent circuit model for a two-electrode scheme on a subject. E_b is the local biological event being monitored or initiated, and Z_s is the simplified black-box model used to represent the generic subject impedance.

Electrical	Potential, current, and quantity of charge
Environmental	Mass-transfer variables and solution variables
Engineering	Availability, cost, strength, and fabricability

such electrical fields are dependent on the charge density distribution created by the stimulation electrode. Although ideally polarizable electrodes can create such fields with no chemical changes at the electrode–tissue interface, they are typically limited to less than $20 \mu\text{C}/\text{cm}^2$ of true surface area for commonly used metallic electrodes (Robblee and Sweeney, 1996). Typical clinical applications require higher charge density distribution, and hence, most stimulation electrodes rely on predominantly faradaic charge transfer mechanisms for direct stimulation of a bioelectric event or a chemical reaction that would stimulate a bioelectric event. Some faradaic processes are reversible while other processes are not (Brummer and Turner, 1977). Irreversible reactions initiate the electrolysis of water (oxygen or hydrogen evolution), oxidation of chloride ions, and corrosion or dissolution of an electrode that produces soluble metal-ion complexes (Geddes and Baker, 1989). This is undesirable, as it can result in multiple local and system biological responses that may change the properties of surrounding tissue or the type of surrounding tissue itself, i.e., fibrous tissue encapsulation to isolate corroding nonbiocompatible object (Grill and Mortimer, 1994; Akers *et al.*, 1977).

This change in property or type of surrounding tissue significantly influences the impedance at electrode–tissue interface (Danilovic and Ohm, 1998; Glikson *et al.*, 1995; Beard *et al.*, 1992). This has necessitated the estimation of a property called the “reversible charge injection limit.” The charge injection limit is the maximum quantity of charge that can

be injected or transferred before irreversible chemical changes occur. The charge injection limit of any bioelectrode will depend on the reversible processes available during stimulation (environmental variables), the shape and surface morphology of the electrode (electrode variables), and finally, the geometry and duration of the stimulation waveform. An excellent review article by Robblee and Rose (1990) discusses the relative importance of the aforementioned factors in achieving reversible charge injection.

Even if careful consideration is given to the reversible charge injection limit, any implanted device (foreign body) will produce local changes in the tissue as discussed before. Consequently, regulated-voltage stimulation (resultant current is dependent on tissue impedance) is susceptible to complex nonreproducible fluctuations in comparison to regulated-current stimulation (direct application of current/charge) for implanted electrode systems. The stimulation waveforms in their simplest configuration may be pulsatile or symmetric sinusoidal. The charge injected (q) by a pulsatile waveform (say a rectangular pulse) is proportional to the pulse current (i) and the time duration (t) for which it is applied, i.e., $q = it$. The charge can thus be controlled very precisely and is independent of the frequency with which it is delivered. In contrast, the charge delivered by a symmetric sinusoidal waveform is dependent on its frequency, i.e., current amplitudes that result in an acceptable charge density at high frequency may deliver an unacceptably high charge density at low frequency. But, symmetric sinusoidal waveforms possess no net dc component and thus have reduced residual effect on the periprosthetic tissue. The basics of simulation waveform geometry, duration, and frequency and how they relate to a specific application can be found in the book chapter on stimulation electrodes by Geddes and Baker (1989) in their textbook on biomedical instrumentation. The design of stimulation waveforms is also one of the strongest emerging research areas in interventional clinical research (Walcott *et al.*, 1998, 1995; Hillsley *et al.*, 1993).

ELECTRODE MATERIALS

5.1 Noble Metals

Platinum is the most popular electrode material because it is stable, inert, and corrosion resistant. However, pure platinum is a very soft metal and is typically alloyed with iridium to improve its mechanical properties, thereby facilitating construction or manufacture of small electrodes. The amount of iridium in a platinum-iridium alloy can vary from ~2% to ~30% without limiting the charge injection ability of the alloy (Robblee and Sweeney, 1996). Small-diameter intracortical stimulation needles that require flexural rigidity to achieve appropriate placement are examples of bioelectrodes that would use platinum-iridium alloys. Although platinum and platinum-iridium alloys exhibit extremely high corrosion resistance even at high injection current densities (50–150 $\mu\text{C}/\text{cm}^2$) without gas evolution or electrolyte oxidation, metal dissolution is not avoidable and occurs at all charge densities (McHardy *et al.*, 1980; Robblee *et al.*, 1980).

Iridium metal can be used instead of platinum in applications that require superior mechanical properties. Although the iridium metal electrodes possess no advantage over the platinum electrodes in terms of charge injection ability, iridium oxide films exhibit significantly reduced interface impedance compared to bare metal (Glarum and Marshall, 1980). This can facilitate greater efficiency of charge flow, thus contributing to prolonged battery life of an implanted stimulation device. Multilayer oxides can be formed on iridium electrodes by cycling the electrochemical iridium potential between predetermined values versus a standard electrode. These multilayer oxides can transfer or inject significant charge densities by reversible transitions between two stable valence levels or oxides (Robblee *et al.*, 1983), but they are very susceptible to limiting charge injection densities due to the shape or type of stimulation waveform. For example, when subjected to a predominantly cathodal pulse of .2 msec the electrode can inject only 1000 $\mu\text{C}/\text{cm}^2$. But, the electrode can inject almost 3500 $\mu\text{C}/\text{cm}^2$ when the cathodal pulses are interspersed with an anodic bias voltage. The anodic bias voltage returns the electrode/oxide to its highest stable valence state between treatments, thereby increasing the charge injection ability of the electrode (Agnew *et al.*, 1986; Kelliher and Rose, 1989). Also, transport and conductivity limitations during the short treatment time frames restrict the utilization of the large charge injection capacity of such electrodes.

Non-noble Metals

Intramuscular electrodes that require high mechanical and fatigue strength may be made from non-noble metals/alloys such as 316LVM stainless steel or nickel-cobalt-based Elgiloy and MP35N. These materials rely on thin passive films for corrosion resistance and inject charge by reduction or oxidation of their passive films. Although large anodic pulses that push these electrodes into their transpassive behavior can lead to significant corrosion, it is important to note that corrosion can result at even relatively low cathodic pulses. These electrodes are capable of injecting ~40 $\mu\text{C}/\text{cm}^2$ and are susceptible to corrosion-related failures even at that level (White and Gross, 1974).

Titanium and tantalum can form insulation oxide films during anodic polarization and can be used for manufacturing capacitive electrodes (electrodes that inject charge without faradaic reactions at the electrode-electrolyte interface). While the titanium oxide possesses a significantly higher dielectric strength compared to tantalum oxide, it is susceptible to significant DC leakage limiting its use in electrode applications. Capacitive electrodes based on tantalum-tantalum pentoxide have limited charge storage capacity (100–150 $\mu\text{C}/\text{cm}^2$) and can be used only in applications above a particular geometric size (0.05 cm^2) for neural prosthesis applications (Rose *et al.*, 1985).

Also, the translation of micro- or nanofabrication technology (Wise and Najafi, 1991) from the semiconductor to the biomedical community is likely to result in multielectrode arrays (Mastrototatro *et al.*, 1992) to either control or monitor different functions of a single event or multiple events.

APPLICATIONS

Cardiology

The pumping of the heart is controlled by regular electrical impulses generated by a group of special cells in the sinus node. The propagation of these impulses in a specific sequence causes the heart to contract, pump blood, and subsequently relax/expand once the signal passes. Any disorganization of this complex generation and propagation of electrical impulses (transmembrane potentials) or abnormal change of heart rate results in a condition called an arrhythmia (Janse, 1994).

When the arrhythmia results in slowing down of the heart, a device called a pacemaker is used to pace or restore the heart to its normal rate (Ellenbogen *et al.*, 1995). When the arrhythmias result in a very rapid heart rate with disorganization of propagation and asynchrony of contraction, a condition called atrial or ventricular fibrillation occurs (Epstein and Ideker, 1995). Ventricular fibrillation is known to be the cause of more than 250,000 deaths in the United States annually. This condition can be rectified using shock therapy, and the corrected rhythm can be maintained using a combination of medication and/or an electronic device called the implantable cardioverter/defibrillator (ICD).

For the first few years after the ICD became commercially available, the electrodes were placed directly on the heart during open-chest surgery (Ideker *et al.*, 1991). These electrodes were approximately 20–60 cm² and constructed out of titanium mesh. More recently, the ICD electrodes have been mounted on catheters that are inserted into the heart by way of the venous system so that major surgery to open the chest is no longer necessary (Singer *et al.*, 1998). These electrodes, typically 5–8 cm long, are frequently made of titanium wire wound around the catheter to form a tight coil with no space between the turns. The sealed, titanium-coated can housing the circuits and battery is used as one of the defibrillation electrodes in the latest ICDs (Fig. 7).

To effectively defibrillate, a certain minimum potential gradient or a certain minimum derivative of the potential gradient must be created by the shock field throughout all or most of the myocardium (Walcott *et al.*, 1997; Ideker *et al.*, 1990). Depending on the type of shock waveform, the minimum potential gradient needed to defibrillate is approximately 4–6 V/cm. The defibrillation electrode material, location, and dimensions affect the potential gradient field created by the shock, and hence, the shock strength needed to defibrillate (Ideker *et al.*, 1991). Other variables, such as orientation of the myocardial fibers, the shape and size of the heart, the presence of cardiac disease, and medications can also affect the shock strength needed for defibrillation (Baynham and Knisley, 1998).

Whereas a minimum shock strength is needed to defibrillate, too strong a shock can have detrimental effects including temporary electrical paralysis of the myocardium, the induction of new arrhythmias by shock itself, and damage or even death to the cardiac cells (Fotuhi *et al.*, 1999). These effects may be caused by electroporation of the cardiac cell membrane, which occurs when the potential difference created by the shock across the cell membrane is so strong that a

FIG. 7. Schematic illustrating the placement configuration of a implantable cardioverter/defibrillator device.

dielectric breakdown forms holes in the membrane that allow indiscriminate passage of ions and other particles.

In contrast, an ablation electrode relies on causing irreversible changes in the target tissue (Iskos *et al.*, 1997). An ablation electrode is used to kill abnormal cells (Jais *et al.*, 1998; Kunze *et al.*, 1998) or normal cells in an abnormal location (Sebag *et al.*, 1997; Atie *et al.*, 1996; Haissaguerre *et al.*, 1994). In the former case, abnormal cells in the atria or the ventricles serve as rapidly firing foci of electrical activity that drive the remainder of the heart or allow the formation of a continuous reentrant loop pathway that excites the heart, initiating tachyarrhythmias. Ablation was originally performed by administering a large DC shock through a catheter electrode placed next to the target tissue and a large plate on the back of the patient. This shock damaged tissue by the direct effects of the large electric field and barotrauma caused by sudden gas bubble formation when arcing occurred between the shocking electrodes. Currently, a radio-frequency pulse applied through a platinum or platinum-iridium catheter electrode is used to kill the tissue by ablating or heating it during the application of the pulse. This technique is more localized and causes less damage to tissue surrounding the area of anomaly (Stancak *et al.*, 1996).

Neurology

Significant advances in imaging modalities, minimally invasive instrumentation, and robotic guidance/placement systems (Hefti *et al.*, 1998; Fenton *et al.*, 1997) are facilitating three-dimensional positioning of stimulation electrodes in the brain. Electrical stimulation of the brain can be used for a variety of applications ranging from pain management to treatment for Parkinson's disease. Stimulation within the brain must be executed without any charge transfer across the electrode-tissue

interface to prevent permanent tissue damage. Capacitor electrodes are ideal for this application. The tissue acts as the dielectric between the capacitive plates and, since the surface of these electrodes are oxide coated, negligible charge transfer occurs (Rose *et al.*, 1985). Several clinical studies provide evidence that deep brain stimulation can be used to control medically refractory essential tremor (Ondo *et al.*, 1998; Lyons *et al.*, 1998) or untreatable Parkinsonian tremor (Ghika *et al.*, 1998; Krack *et al.*, 1998). Motor cortex stimulation has been shown to reduce poststroke pain in patients when muscle contraction was inducible (Katayama *et al.*, 1998).

The spinal cord can also be stimulated to control pain in various clinical conditions (Segal *et al.*, 1998). Percutaneous spinal electrodes are placed in patients who are not suitable candidates for coronary bypass grafting for treatment of ischaemic pain condition such as angina pectoris (Andersen, 1997). They may also be used to control chronic back pain if surgical outcomes are not successful (Rainov *et al.*, 1996). Transcutaneous electrical stimulation (TES) of peripheral nerves has been used to control chronic pain due to spinal cord injury or stroke damage (Taub *et al.*, 1997). Localized stimulation of nerve endings using retinal and cochlear implants has also been attempted to enhance the loss of vision or hearing, respectively (Heetderks and Hambrecht, 1988).

Functional neuromuscular simulation (FNS) refers to the electrical stimulation of skeletal muscle for artificially controlled exercise or restoration of motor function lost due to spinal cord injury or disease (Sweeney, 1992). FNS systems are designed to provide upper-extremity control (Hoshimiya *et al.*, 1989), lower-extremity control (Graupe, 1989), or both. FNS takes advantage of the fact that most motor neurons below the level of injury remain intact. Thus electrical stimulation of the their axons can be used to cause muscle contraction. For example, the phrenic nerve can be stimulated to control respiration, or the sacral nerves can be stimulated to regulate the detrusor muscle in the bladder. Although FNS designers strive to mimic the body's control strategies, it is still extremely difficult to attain the fine gradation of force required to achieve adequate function. A review article by Heetderks and Hambrecht (1988) is an excellent source of information for understanding the potential advances in the clinical application of neural stimulation.

Other

Catheter ablation electrodes can be used via the urethra or perineal cavity to damage/kill benign or malignant hyperplasia in the prostate (Dixon, 1995). Ablation has also been used to reduce the size of metastatic liver tumors and osteoid osteomas by damaging the irregular cells (Salbiati, 1997; Rosenthal *et al.*, 1995). Cryosurgery, i.e., ablation by extreme cooling, has been used to treat refractory hepatic neuroendocrine metastases (Bilchik *et al.*, 1997). Stimulating electrodes may also be used to enhance tooth movement in orthodontics or the growth of teeth. In this case, platinum and noble metals are not useful because they irritate the gingival tissue. Composite electrodes are used with biocompatible gels to keep the electrode separated from the moist gingival tissue (Beard *et al.*, 1992).

Future Trends—Healing and Regeneration

The U.S. Food and Drug Administration has approved a number of electrical bone-growth stimulating devices for treating nonunion fractures and for enhancing spinal fusion (Polk, 1995). These devices generally use one of three approaches to apply low-intensity fields to the tissues—direct current applied to the wound site through surgically implanted wire electrodes; high-frequency (>20 kHz) “capacitatively coupled” sine-wave signals applied through skin electrodes; and low-frequency pulsed electromagnetic fields (PEMFs) applied by Helmholtz-type coils strapped to the limb. The PEMF devices do not conduct current directly to the tissues and, in the strictest sense, may not be considered as electrodes.

The implanted electrodes usually consist of stainless steel or titanium wire, but may include other metals such as silver or platinum. The wires, serving as cathodes, are connected to small batteries supplying a continuous current of 2–20 μA . It is uncertain whether the resulting stimulation of bone growth is due to electrochemical changes in the tissue surrounding the cathodes or to the electric current itself (Black, 1987). Spadaro (1997) used a rabbit femur model to compare the bone growth stimulation by different metallic cathodes at the same current density. The observed differences in the degree of bone formation would seem to argue for an electrochemical, rather than an electrical, basis for the effects. Yet the same results might also be attributed to the mechanical properties of the wires; as the animals moved about, the stiffer wires would transmit more mechanical force to the bone and this micromotion might itself elicit an osteoinductive response.

The capacitatively coupled devices use 2 to 3-cm-diameter electrodes adjoined to the skin through a conductive gel. These are powered by a small battery pack and produce voltage gradients in bone estimated at 1–100 mV/cm at current densities in the $\mu\text{A}/\text{cm}^2$ range. As with the implanted electrodes, the precise basis for their effects are not completely understood but appear to involve the distribution of cations, particularly calcium, at the cell surface (Zhuang *et al.*, 1997).

The range of these applications should expand considerably when the molecular basis for electric field–tissue interactions is better understood. Research in animal models suggests that low-intensity fields may prove to be clinically useful for stimulating wound healing and nerve regeneration. For example, platinum cuff electrodes that surround the nerve or penetrating needle electrodes may be used to stimulate peripheral nerve regeneration (Heiduschka and Thanos, 1998). An electrode array with polymeric guidance tubules or a DC electrical field may also be applied to direct growth of new peripheral nerve axons. The nerves grow toward the cathode of the bioelectrode (Heiduschka and Thanos, 1998). It must be kept in mind, however, that this area of research remains controversial because of frequent difficulties in reproducing experimental results and the absence of a generally accepted model.

SUMMARY STATEMENT

Although significant progress has been made in our understanding of the bioelectrode–tissue interface, it is still not

possible to predict all of its properties with certainty. New materials, micro- or nanofabricating capability, computer processing power, and a better understanding of biological processes over the past two decades have significantly improved our ability to make bioelectrodes that more than adequately monitor or influence a biological event. However, it is becoming apparent at this time that even the most advanced synthetic prosthesis cannot totally restore normal function. Hence, the human impact of interventional and potential regenerative procedures made possible due to current bioelectrodes will form the basis for further advances in this old, but still nascent, field.

QUESTIONS

1. What material would you choose for a deep brain stimulating electrode and why? Develop a simplistic equivalent circuit model for such an electrode–electrolyte interface. You do not have to model the tissue. Model only the interface.
2. Calculate the increase in charge injected by decreasing the frequency of a symmetric sinusoidal waveform by an order of magnitude assuming all other parameters remain constant.
3. Compare and contrast the region of oxide stability (potential range) for titanium alloy and 316L stainless steel electrodes. Assume that the oxides on titanium electrode and stainless steel electrodes are predominantly TiO_2 and Cr_2O_3 , respectively. (Hint: Refer to the Pourbaix diagrams for titanium and chromium.)
4. Would a material used for a radio-frequency ablation electrode also be ideal for a cryoablation electrode (ablation due to freezing)?
5. Develop an equivalent circuit model for a capacitively coupled device used for healing nonunion fractures. You do not have to model the tissue. Model only the interface.

7.16 COCHLEAR PROSTHESES

Francis A. Spelman

INTRODUCTION

Cochlear prostheses help the deaf to contact the auditory environment (NIH, 1995). The problem of sensorineural deafness is immense. The probable number of users of cochlear prostheses has been estimated by some as 900,000 in the United States alone (Levitt and Nye, 1980). Other estimates range as high as 2,000,000 sensorineural deaf in the United States. The treatment for sensorineural deaf patients is the cochlear implant (NIH, 1995). Sensorineural deaf subjects cannot perceive sound without extraordinary aid. That is so because the basic transduction system is lost either as a result of damage or destruction of the cochlea or because the auditory nerve is damaged (Levitt and Nye, 1980).

This chapter introduces cochlear prostheses and some of the materials problems that must be faced by their designers. The concentration of the chapter is on cochlear implants rather than on implants in the brainstem. Approximately 59,000 people use cochlear implants, whereas fewer than 100 have brainstem implants (NIDCD, 2003; Brackmann *et al.*, 1993). At present, cochlear implants are in clinical use, while brainstem implants are still experimental. There is no discussion of tactile prostheses for the deaf (Martin, 1985). This chapter introduces the physiology of the auditory system and describes cochlear prostheses and some of the issues related to biomaterials that bioengineers face in the design of such apparatus.

FIG. 1. Sketch of the auditory periphery, showing the outer, middle, and inner ear. Reproduced with permission from the V.M. Bloedel Hearing Research Center at the University of Washington.

OVERVIEW OF THE AUDITORY SYSTEM

The auditory system can be divided into its peripheral organs and the nuclei in the central nervous system that process the signals produced by the peripheral organs. This is a greatly abbreviated presentation. More details are found in texts like those of Geisler (1998) and Dallos *et al.* (1996). Geisler refers to several Web sites that demonstrate the behavior of the periphery, e.g., <http://www.neurophys.wisc.edu/animations> and the animations of the Association for Research in Otolaryngology, <http://www.aro.org>. The sketch of Fig. 1 shows the auditory periphery.

The Periphery

The auditory periphery consists of the outer ear, middle ear, and inner ear. The outer ear, the *pinna*, collects changes in pressure (condensations and rarefactions) produced by the auditory signals. Those signals are generated by sound sources in the environment of the listener. Acoustic signals are guided to the middle ear along the ear canal, an entry into the head of the subject that is lined by soft tissue. The ear canal is open at its peripheral end and bounded by the eardrum, the *tympanic membrane*, at its inner end. The length of the ear canal is about 3 cm in the human (Geisler, 1998).

The middle ear is bounded distally by the tympanic membrane and proximally by the *cochlea*, where the foot plate of the *stapes* contacts the oval window of the cochlea.¹ In the inner ear are three tiny bones that comprise the *ossicular chain*: the *malleus* (hammer), *incus* (anvil), and *stapes* (stirrup). The bones have flexible connections. They provide a mechanical advantage so that the eardrum can be driven by air and, in turn, can drive the dense fluids that are found in the cochlea. The motion of the foot plate of the stapes is about 75% of

¹The terms *proximal* and *distal* refer to the brain in this case. Proximal is nearer to the brain and distal is further from the brain.

that of the tympanic membrane in the human (Geisler, 1998). Further mechanical advantage is provided by the relative areas of the tympanic membrane and the foot plate of the stapes: the tympanic membrane has about 20 times the area of that of the stapes (Geisler, 1998). Small pressure changes in air are transformed into larger changes in the fluids of the cochlea. Conversely, large displacements of the eardrum produce small displacements of the footplate of the stapes.

The *cochlea* is a snail-shaped organ that is located bilaterally in the temporal bones of the head. The cochlea is oriented such that its wide base faces in a medial and posterior direction, while the axis of its spiral points laterally and anteriorly (Fig. 1).

The cochlea contains three spiraling chambers or *scalae*: the *scala tympani*, *scala vestibuli*, and *scala media*. The *organ of Corti* lies within the *scala media* on the *basilar membrane*. The *hair cells* are located on the basilar membrane (Geisler, 1998; Dallos *et al.*, 1996). The basilar membrane is an elegant structure that acts as a mechanical Fourier analyzer: specific regions of the membrane vibrate maximally in response to the frequency of the sound waves that are imposed on the stapes. The membrane displacements produce maxima for high frequencies at the basal end and for low frequencies at the apical end of the cochlea. The hair cells residing on the membrane have *cilia* that are bent when the membrane vibrates. The hair cells synapse with the peripheral processes of the auditory nerve, the *hearing nerve* in Fig. 1. There are 25–30,000 afferent neurons that synapse with the hair cells (Geisler, 1998). The organization of the auditory nerve is by frequency. Indeed, the entire auditory system is organized by frequency (tonotopically) (Geisler, 1998; Popper and Fay, 1991).

Critical to the design of the cochlear prosthesis is the location of the peripheral processes of the auditory neurons, the cells of the auditory nerve.² The neurons are bipolar cells, and their peripheral processes are found in and under the *bony spiral lamina* (Geisler, 1998; Popper and Fay, 1991; Spelman and Voie, 1996), an osseous or bony structure that extends from the *modiolar* (medial) wall of the *scala tympani* in the cochlea. The cell bodies of the VIII nerve are located in Rosenthal's canal, a hollow structure in the modiolar bone.

The anatomy of the *scala tympani* has led to the design of the cochlear implant. The prosthesis is designed to stimulate the auditory neurons electrically. Placing the sites of electrodes near the neurons without violating the bony wall of the modiulus means that the electrode arrays of the implants are located in the *scala tympani* (see later discussion).

Highlights of the Central Auditory System

The tonotopic structure of the auditory system is found throughout the auditory system. The frequency-dependent structure of the auditory signal forms the responses of single neurons in the auditory nerve (Sachs and Young, 1979). As signals are produced binaurally, those signals travel from each cochlea to the *cochlear nucleus*, where the neurons send data to the *contralateral trapezoid body*, (Sachs and Young, 1979), the *inferior colliculus*, the *medial geniculate nucleus*, and the

auditory cortex (Rubel and Dobie, 1989). The properties of the auditory nerve are well understood and have been for more than a decade. The properties of the cochlear nucleus are under active investigation, as are those of the higher centers of the auditory system.

This chapter focuses on the auditory periphery. It is in the periphery where cochlear prostheses are most effective, although auditory prostheses have been used in the cochlear nucleus, notably for patients who suffer from damage to the VIII nerve (Shannon *et al.*, 1993; McCreery *et al.*, 1997).

Damage to the Periphery

Sensorineural deafness caused peripherally can result from serious damage to the hair cells or to the auditory nerve. Clearly, if the neurons of the hearing nerve are damaged, their peripheral processes cannot be driven and stimulation from sites in the cochlea will not work. In those cases, central prostheses have been used experimentally (Shannon *et al.*, 1993; McCreery *et al.*, 1997).

Damage to the hair cells can result from a number of causes. Pyman *et al.* cite 11 root causes in people over 6 years of age, and seven causes in people under 6 years of age (Pyman *et al.*, 1990). Their population was 65 people in the former case and 29 in the latter. Large numbers of subjects had unknown causes of deafness, but there were cases of meningitis, otosclerosis, and trauma that caused the problems (Pyman *et al.*, 1990). In another study, Hinojosa and Marion analyzed 65 ears and found six causes of congenital deafness in 19 subjects, and nine causes of acquired deafness in 46 subjects. In the latter population, otosclerosis caused the greatest damage, followed closely by bacterial infections (Hinojosa and Marion, 1983).

Damage to the hair cells from loud sounds requires special mention, since the popularity of painful audio systems in automobiles and as portable sources of entertainment appears to be increasing. Hair cells can be damaged by intense sounds (Popper and Fay, 1991); chronic exposure to loud sounds should be avoided despite the relatively small numbers cited by Hinojosa and Pyman (Pyman *et al.*, 1990; Hinojosa and Marion, 1983).

Neural Plasticity

The auditory system responds to stimulation, both anatomically and physiologically. The central nervous system can reorganize itself in response to auditory signals (Brugge, 1991). The plasticity of the system occurs more vigorously in children than in adults. That understanding has changed the application of cochlear prostheses from a focus only on adults to a large distribution of instruments for children as well (Clark, 1996). Deaf children are treated at 2 years of age and in some cases 12 months (Skinner, 2001; Osberger, 1997).

COCHLEAR PROSTHESES

Cochlear prostheses present one of the remarkable success stories of biomedical engineering. The idea of electrical

²The auditory nerve is also known as the VIII cranial nerve.

FIG. 2. Block diagram of a generic cochlear prosthesis. (After Spelman, 1999.)

stimulation of the peripheral auditory system is credited to Volta (1806) and cited in Simmons (1996). More modern approaches to solve the problem of deafness with a neural prosthesis were offered in the latter part of the 20th century (Simmons, 1996; Djourno and Eyries, 1957; House and Berliner, 1991).

Architecture of a Cochlear Prosthesis

The architecture of a cochlear prosthesis is shown in Fig. 2. The architecture shown here follows the textual architecture described on the NIDCD Web site. Here the receiver/stimulator described on that site is divided into a signal processor and controlled current sources (NIDCD, 2003). A microphone is the transducer that converts the auditory signal into an electrical signal. The microphone's signal is sent to an external signal processor. That signal processor decomposes the electrical information into amplitude and frequency data: the signal is filtered and analyzed to produce data about the envelope of the information within a particular frequency band (Loizou, 1999). Other processing techniques have been proposed, but have not been produced commercially (Clopton *et al.*, 2002). Several bands are analyzed simultaneously to develop a vocoder model of the audio signal (Gold and Reder, 1967). The data are transferred across the skin as digital signals. An internal processor takes those data and converts them to current drive signals for the electrodes of the multichannel electrode array. In some implementations, single current sources are used and switched between contacts, while in others multiple sources can be driven simultaneously (Loizou, 1999). The currents that are sent to the electrodes can be either analog or pulsatile signals.

In the past 20 years, cochlear prostheses have become multichannel systems. The first implants employed single electrodes, whereas present devices use up to 22 contacts inside the scala tympani (Spelman, 1999; Loizou, 1999; House and Berliner, 1991). In most processing strategies, one electrode is driven at a time, although analog drives present currents to all electrodes simultaneously (Osberger and Fisher, 1999).

Commercially Available Systems

The following sections are brief descriptions of the strategies that are used by the three manufacturers of cochlear prostheses that are presently available to deaf patients. All of the manufacturers have Web sites that provide additional information.

The Nucleus Implant

Cochlear Pty., Limited, is the largest producer of cochlear prostheses in the world. For further information on the Nucleus prosthesis, visit www.cochlear.com. The Nucleus has an electrode array that uses 22 or 24 electrodes. Twenty-two electrodes are placed in the scala tympani. The 24-electrode array uses two external electrodes that can be used as distant return electrodes. They permit true monopolar excitation of the internal electrodes. The Nucleus Contour electrode array is curved in order to approximate the modiolar wall of the scala tympani, bringing the electrodes of the array into apposition with the cells of the auditory nerve. The external processor extracts frequency information from 20 filters, sampling the auditory signal to determine the frequency bands containing the maximum energy during a given 3.3-msec interval. The envelopes of the signals taken from the filters whose energy is greatest are sampled. The data are distributed to electrodes within the array, driving between five and 10 electrodes within a given sequence. One electrode is driven at a time. The electrodes are driven with biphasic rectangular pulses that repeat rapidly. The auditory signal's data are updated at rates that may be as high as 300 pulses per second (Vandali *et al.*, 2000).

The silicone rubber electrode array, when straightened, approximates a truncated cone whose diameter varies from 0.4 mm at the apical end to 0.6 mm at the basal end. The array is composed of segments of platinum rings, designed to face the peripheral processes of the auditory nerve. Each ring is approximately 0.35 mm in width, and the edge-to-edge separation is about 0.4 mm. The insulated platinum/iridium wires that connect to each electrode are led back through the silicone rubber carrier of the electrodes (Patrick *et al.*, 1990). During insertion, the array is straightened with an internal polymeric stiffener. The array is placed into the scala tympani via a small hole that is drilled through the temporal bone. The stiffener is withdrawn while the array is gently inserted by the surgeon. In the past, the implanted electrode array resided near the lateral wall of the scala tympani when it was implanted in the ear of a human subject (Skinner *et al.*, 1994). The new array more nearly apposes the modiolar wall, although in two of 12 insertions into temporal bones the array pierced the basilar membrane (Tykocinski *et al.*, 2001). Another study in human temporal bones showed that damage appeared to be a function of the technique of the implant surgeon during insertion (Rebscher *et al.*, 2001).

The Clarion

The Clarion cochlear implant is the offering of the Advanced Bionics Corporation (Sylmar, CA). For the

most recent information about the Clarion implant, visit www.cochlearimplant.com.

The Clarion Multi-Strategy device offers several processing strategies to deliver signals to patients (Kessler, 1999). Its processor can operate with several different processing strategies. The strategies include Simultaneous Analog Stimulation (SAS), the Paired Pulsatile Sampler (PPS), and the Continuous Interleaved Sampler (CIS). The microphone and amplifier drive an analog/digital converter signal-compressing software, most often logarithmic compression. The compressed signal is decomposed into a set of digitally filtered signals. The digitized and filtered outputs are transmitted across the skin with an RF link to an internal processor, employing a 49-MHz AM signal (Kessler, 1999). The data are demodulated and demultiplexed internally and delivered to current sources that drive electrodes directly with the compressed and filtered analog signals (Kessler, 1999). The sampling rate is 13,000 samples per second per channel, with an aggregate sampling rate of 104,000 samples per second. The SAS system operates similarly to the Compressed Analog (CA) systems that have been used earlier (Spelman, 1999; Loizou, 1999; Kessler, 1999). The SAS system drives several electrodes simultaneously. It still suffers from the interference that occurs as a result of field interactions among electrodes.

The Clarion processor provides other strategies as well. Continuous Interleaved Stimulation (CIS) was developed by Wilson and his colleagues to overcome the field interactions between channels in the Ineraid implant (Wilson *et al.*, 1991). Biphasic pulses are delivered one pair at a time to the electrodes of the implanted array in the cochlea. The pulses are interleaved (multiplexed) in time to eliminate interactions among the electric fields in the cochlea. The rates of excitation can be varied to optimize the signals delivered to specific patients. The acoustic signal is amplified, compressed, and band-pass filtered. The outputs of the filtered signals are rectified and low-pass filtered to obtain envelope information for each of the band-pass filters. The amplitudes of the pulse pairs are varied in proportion to the magnitudes of the envelopes of the signals in specific frequency bands at the time of analysis. The widths of the pulses delivered are constant. The Clarion processor updates the signals 833 times per second (Loizou, 1999). Eight electrodes are usually driven, although eight pairs of electrodes are provided via the Clarion electrode array.

The processor developed by Advanced Bionics allows the use of paired pulsatile stimulation (PPS) (Kessler, 1999). Paired Pulsatile Simulation (PPS) drives two electrodes simultaneously with paired biphasic pulses while maintaining the maximum physical separation between the driven electrodes. Physical separation limits field interactions between electrodes (Kessler, 1999; Zimmerman-Philips and Murad, 1999).

Osberger and Fisher (1999) reported on 71 patients who used the Clarion Multi-Strategy. The subjects improved their hearing performance when they were used a preferred mode of stimulation. The patients who preferred the SAS mode had been deaf for shorter times than those who preferred CIS (Osberger and Fisher, 1999).

Advanced Bionics has introduced a method to appose the electrodes of their array to the cells of the VIII cranial nerve in Rosenthal's canal, which lies behind the modiolar wall of

the scala tympani. They produced a preshaped electrode that was used jointly with a polymeric Electrode Positioning System (EPS). The EPS applied pressure to the lateral wall of the cochlea, positioning the electrode array against the modiolus. The system was used for 3 years and then recalled in the summer of 2002. For further information, see the Web site of the U.S. FDA. The present offering of Advanced Bionics does not employ the EPS.

The Med-El Implant

The Combi 40 and the Combi 40+ implants are offered by Med-El Corporation (Innsbruck, Austria, www.medel.com). The Med-El electrode array is slim, having 24 contacts. Med-El provides data that indicate that their array can be placed within the entire length of the human scala tympani, 31 mm.

Med-El offers Continuous Interleaved Stimulation, and at this time they offer a high multiplexing rate of 18,000 pulses per second, extracting data with a Hilbert transform approach (Anonymous, 2003). The data can be updated at a rate of 1500 samples per second when 12 contacts are used, as they are in the Combi 40. Med-El employs another approach. They choose the frequencies in the auditory spectrum containing maximum energy, rectify and filter the signals, and then send amplitude-modulated pulses to the electrodes that correspond to the frequencies of maximum energy. The approach has been called an "n of m" strategy (www.cochlearimplants.com; www.medel.com) (Anonymous, 2003).

MATERIALS AND ELECTRODE ARRAYS

Materials issues are salient in the design and construction of electrode arrays. The polymers that are used to insulate the arrays must be compatible with the tissues of the scala tympani; the electrode sites must use metals that can deliver appropriate currents to excite neurons; and the mechanical characteristics of the arrays must allow safe and easy insertion into a volume that is both small and complex in shape. Rebscher and co-workers (1999) describe techniques and tests designed to ensure safe insertion.

Although other parts of the prosthesis are of concern, the concerns are small compared to those that surround the electrode arrays. In this chapter, I address issues of electrode design and choice of materials, the electrical and mechanical properties of insulating materials, and some of the issues that are related to the tissue sheaths that surround electrode arrays in the scala tympani of the cochlea.

Electrode Arrays

Electrode arrays change electrical currents into the ionic currents that can stimulate neurons. The number of electrode sites and the strategy used to drive the contacts determines the electric fields that are generated in the scala tympani, and, ultimately, the number of independent channels that can be driven simultaneously. Several people have suggested ways in

which electrical currents could be combined to focus the neural stimuli. Suesserman and co-workers suggested an approach that was supported by a lumped-element, electrical model of the inner ear (Suesserman and Spelman, 1993). Later, Jolly and co-workers performed experiments to demonstrate that the predicted fields could be produced in the inner ear of the guinea pig (Jolly *et al.*, 1996) and that it might be possible to stimulate independent groups of neurons (Jolly *et al.*, 1997). Later, Middlebrooks and Bierer (2002) and Bierer and Middlebrooks (2002) showed clearly that focused fields produced focused excitation of neurons in the auditory system.

Contacts and Focusing

Simple models of point sources of current can be used to illustrate some of the effects of driving tissue with point sources of electric current. Consider a conductive medium that is semi-infinite in extent and bounded by a perfectly insulating surface. The current source lies on the insulating boundary at location x_0, y_0, z_0 . The dimensions are given in meters. The method of images (Kong, 1986) can be used to show that the potential field produced by the source is:

$$V(x, y, z) = \frac{\rho I}{2\pi} \frac{1}{[(x - x_0)^2 + (y - y_0)^2 + (z - z_0)^2]^{0.5}}$$

where ρ is the resistivity of the medium, given in Ohm-m; I is the magnitude of current, given in amperes; and $V(x, y, z)$ is the electrical potential at location x, y, z , given in volts.

The preceding equation ignores the properties of the electrode, e.g., its polarization impedance, since they are overlooked entirely by the point source approximation (Macdonald, 1987).

Point sources cannot be produced. However, the equation just given describes a hemispherical source of radius r placed on the insulating surface with the source's center at the location of the point source, x_0, y_0, z_0 . As long as the potential is computed for radial distances that are greater than r , the equation is valid and approximates the electrode in the absence of electrochemical effects.

A special case of the potential is illustrative. Let the location of the source be at the origin of a Cartesian coordinate system. Compute the field produced along the z -axis. Let the radius of the hemisphere be $50 \mu\text{m}$. Consider a material, such as perilymph, the fluid that fills the scala tympani, whose resistivity is 0.63 ohm-m . Then,

$$V(z) = 0.1 \frac{I}{z} \text{ volts, } z > 50 \mu\text{m}$$

Let the current be $100 \mu\text{A}$, a reasonable threshold for a $200\text{-}\mu\text{sec}$ pulse in an experimental animal. The potential decreases monotonically from 200 mV at the surface to 50 mV at a distance of $200 \mu\text{m}$.

Problem 3 raises additional issues that can be addressed with this simple model: with a straightforward model of this sort, the engineer can gain a quick understanding of the benefits and limitations of using multiple sources to focus the electric fields in the cochlea. Combinations of positive and negative currents can change the widths of fields, but narrowing the fields will reduce peak potentials.

Thinking about dipole fields leads to that conclusion. A theoretical dipole consists of a pair of positive and negative point sources of current, placed at an infinitesimal distance from each other. The potential field decreases rapidly for distances that are much larger than the separation between the electrodes. The point of the thought experiment is to suggest that the smaller the distance between sources of opposite polarities, the smaller will be their peak potentials at a distance. Hence, sources and sinks of electric current must be used judiciously to focus potential fields.

The point source model of an electrode is suitable for spherical electrodes if their fields are modeled for radial distances greater than the radial dimension of the sphere. The same model works for a hemispherical electrode that is attached to a planar insulator. The electrodes that are used in cochlear prostheses are often more like finite, planar surfaces, and their solutions are not straightforward except in the simplest cases (Rubinstein *et al.*, 1987; Pearson, 1990). The potential field that is generated by a circular electrode has been understood since the time of Weber (Rubinstein *et al.*, 1987) and was described by Wiley and Webster more than 20 years ago (Wiley and Webster, 1982). The critical finding for the latter work is that the current density of such an electrode is nonuniform over its surface and becomes singular at the boundaries of the electrode. Current density is singular at the edges of many kinds of planar electrodes as was shown in an elegant demonstration by Rubinstein (1988). Recessing the electrode can eliminate the singularities of current density at its metallic surface, whereas singularities are found at the aperture of the recessed electrode (Rubinstein *et al.*, 1987). However, shaping the aperture can eliminate those singularities (Suesserman *et al.*, 1991).

Consideration of surface-mounted and recessed electrodes of finite size leads to an understanding of the potential for corrosion of such electrodes. Corrosion will be greater at the edges where the current and charge densities are high. Further, thinking about the boundary condition at the surface of a metallic electrode, that the potential is constant on the surface, suggests that the field produced by an electrode of finite size will differ from that produced by a point source. Figure 3 illustrates some of the points just made. The figure is a simple finite-element model of a strip line on the surface of an insulator. The strip line is 10% of the width of the insulator. The upper surface of the line and its insulating carrier bound a conductive space. The resistivity of the insulator is about 160 times that of the conductive space. The strip is a superconductor, and the bounding surfaces are held at zero potential. The potential across the strip is uniform. The arrows in the figure represent current density; the black contour lines are contours of equipotentials and the colors represent current densities. Note that the current densities are highest at the edges of the strip. Red color corresponds to high current density, while the white color shows current density that is nearly zero.

Finite electrodes produce a second effect, not seen for point sources. As the observer moves closer to the source, the field approaches a constant value over the surface of the source. That is a result of the boundary condition requiring that superconductors have uniform potentials on their surfaces. Of course, the potential decreases as the observer moves laterally away from the source. Figure 4 illustrates the condition. Two curves

FIG. 3. The fields produced by current (0.1 mA) driven through a superconducting strip that is mounted on an insulator that faces a conductive, homogenous, isotropic medium. Done with the student version of QuickField.

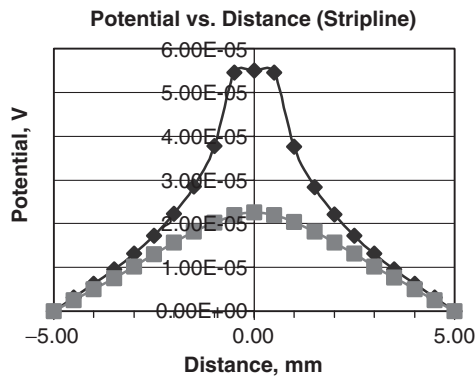

FIG. 4. Potential produced by the stripline of Fig. 3 in a conducting medium. The stripline lies on an insulator whose resistivity is 160 times that of the conducting medium and produces a current of 0.1 mA.

of potential are shown, one calculated for a distance 0.1 mm above the plain containing the source, and the second calculated for a distance 3 mm above the source. The nearer contour shows clearly the uniform potential found when measurements are made near the source.

Another difference between point sources and finite sources is that unused point sources have no effect on the potential fields that are near them, whereas finite sources must sustain constant potentials at their surfaces. Peters did an analysis of that situation that showed clearly the effects that finite sources have on fields (Peters, 2000). The effect is shown in Fig. 5.

FIG. 5. Potential fields measured 0.1 mm and 3 mm above two parallel superconducting striplines, one of which measures current and one of which is passive.

The stripline of Figs. 3 and 4 is driven with 0.1 mA. A second superconducting line lies near the source. When potential is plotted 0.1 mm above the 1-mm-wide line, the effect of the second conductor is obvious as a result of the plateau of potential that is computed over the second line. The effect is less obvious when observations are made 3 mm above the lines. Both curves show that the peak potentials decrease after the introduction of the second, passive line.

Contact Materials

What materials are suitable to make the electrode arrays that are used in cochlear implants? Noble metals, that is, gold,

platinum, iridium, and some of their alloys, have been used extensively (Robblee and Rose, 1990). The arrays that are available clinically employ alloys of platinum and iridium, usually 90% Pt and 10% Ir. Those alloys have been studied and used for decades (Robblee and Rose, 1990; Brummer and Turner, 1977a; McCreery *et al.*, 1992). The platinum provides a material that can carry charge efficiently, while the iridium provides structural strength.

More recently, the oxides of iridium have been investigated and have demonstrated characteristics that are markedly superior to those of platinum (Robblee and Rose, 1990; Meyer *et al.*, 2001; Weiland *et al.*, 2003). Electrode materials are studied with standard electrochemical techniques, notably cyclic voltammetry (Robblee and Rose, 1990) and electrochemical impedance spectroscopy (EIS) (Macdonald, 1987). The former technique provides direct evidence that shows the amount of charge density that a given material can support. EIS gives indirect evidence of the charge-carrying capacity, but provides direct information about the voltage that is required to drive a specific current.

Charge density is a critical variable to consider in the design of a cochlear electrode array. The charge density calculation is usually based on a “geometric” surface area, which assumes that the current density is uniform across the metallic surface. Although that assumption is not valid in most cases, there are few calculations of geometries that result in mixed boundary problems. For the purpose of this chapter, we will assume that geometric areas suffice, but warn the reader to be wary when calculating surface areas. That said, the measurement of the charge capacity of a particular electrode is certainly valid when it is done appropriately (Meyer *et al.*, 2001). The charge density calculation may be in error unless great care is taken to ensure that the electrode’s surface is smooth and that the current density profile is accounted for (Robblee and Rose, 1990; Meyer *et al.*, 2001; Weiland *et al.*, 2003).

Concern for the charge carrying capacity of electrode sites is critical for the design of cochlear electrode arrays, since it bears directly on their safety and longevity. Platinum–iridium arrays have followed the work of Brummer and Turner (1977a, b), usually applying a safety factor of at least 2. The charge densities are held below $150 \mu\text{C}/\text{cm}^2$. Increasing the surface area of a platinum electrode with platinum black can increase the charge density by a factor of 30 (Jolly *et al.*, 1996), but the approach has not been used outside of the laboratory.

Oxides of iridium, both activated and plated, offer real promise for cochlear electrode arrays. The charge densities measured range from $4 \text{ mC}/\text{cm}^2$ to $27 \text{ mC}/\text{cm}^2$ (Meyer *et al.*, 2001; Weiland *et al.*, 2003). Those charge densities are not used consistently, but a safety factor is applied for long-term operation. The charge density can be reduced by as much as a factor of 20 for long-term tests (Meyer *et al.*, 2001). Even so, the promise of IrOx is great: the potential increase in charge density, and thus in maximum stimulus current is nearly a factor of 10. If Pt–Ir can tolerate stimuli whose charges lie below $150 \mu\text{C}/\text{cm}^2$ and IrOx can withstand a long-term stimulus of $1.2 \text{ mC}/\text{cm}^2$. It is easy to compute maximum currents if we assume that we can deal with geometric surface areas. If two electrodes whose areas are 10^{-4} cm^2 are used, and they are driven with square pulses whose durations are 200 μsec , the

maximum safe current is $75 \mu\text{A}$ for the Pt–Ir electrode and $600 \mu\text{A}$ for the IrOx electrode. The IrOx electrode can excite the auditory nerve over its full dynamic range, while the Pt–Ir electrode can barely meet a threshold value (Vollmer *et al.*, 2001).

Another concern for cochlear implant designers is the geometry of their electrode arrays. The developers of thin-film arrays must be concerned with the traces that are used on the thin films. As the arrays get smaller, the traces must decrease in size as well. Although implant designers may think that the currents that they use are small (they are!), the traces are small as well. Temperature increase in the traces may well be a problem as the traces decrease in size (Brooks, 1998). UltraCAD Design, Inc. offers freeware to solve PCB trace problems with a regression relation (www.UltraCAD.com). For example, a copper trace that is 7.5 cm long, $12.5 \mu\text{m}$ wide, and $1 \mu\text{m}$ thick will have a temperature increase of nearly 1°C when it carries $800 \mu\text{A}$. If several traces carry similar currents, temperature in the cochlea could increase artificially, possibly causing thermal damage to the tissue.

Material Properties

The choice of materials for cochlear prostheses extends beyond the selection of materials that will be used on the surfaces of electrode contacts. At issue are the compatibility of arrays with the tissues of the cochlea, and compatibility of the materials that cover the internal processors that are placed in the temporal bones of the recipients of implants. In this chapter, I do not consider the latter, since the ceramic and titanium cases and their silicone cases have not created measurable problems at the time of this writing, at least since some early problems with infection were taken care of in the late 1970s and early 1980s. The materials used as carriers for the electrode arrays have presented issues that will be discussed hereafter.

As was mentioned earlier, Advanced Bionics recalled its HiFocus electrode array. Some attributed that recall to potential concerns with the electrode positioning system (www.leifcabraser.com/cochlear.htm), a polymeric system that placed the array in contact with the modiolar wall.

Placement issues had been raised before about other implants (Skinner *et al.*, 1994; Rebscher *et al.*, 2001). Spiral tomographs of the implanted ear showed that the electrode arrays entered the scala vestibuli by way of the basilar membrane. The composition of the fluids in the scala tympani and the scala vestibuli are dramatically different. The perilymph in the scala tympani is rich in sodium ion, while the endolymph in the scala vestibuli is rich in potassium ion (Dallos *et al.*, 1996). Mixing the two damages and can kill hair cells. Although that is not critical in the case of the sensorineural deaf patient, the electrode arrays are distant from the peripheral processes of the auditory neurons and the leakage of potassium-rich endolymph will damage those neurons as well.

In a study of the electrode arrays produced by Cochlear Corporation and Advanced Bionics corporation, four surgeons implanted both new and old designs of arrays into cadaveric human temporal bones. The investigators assessed the amount of trauma observed, the insertion depth, and proximity to the

modiolar wall. The arrays showed no significant difference in trauma produced by the arrays of the two corporations; the greatest difference was found among the surgeons who did the implants (Rebscher *et al.*, 2001). The Spiral could be inserted further than any of the other designs, and of the new designs, the Contour had the greatest insertion depth. Both the Contour and the HiFocus arrays apposed the modiolar wall (Rebscher *et al.*, 2001).

The preceding paragraph raises the issue of insertion depth. The advantage of a cochlear electrode array that reaches the more apical turns of the cochlea is that it can reach the tonotopic locations that decode frequencies below 1 kHz. For example, insertion of 70% of the cochlear spiral reaches the 300-Hz region of the basilar membrane (Geisler, 1998). Since the range of frequencies necessary to decode speech is 300–3000 Hz (Levitt and Nye, 1980), it is desirable to reach the low-frequency regions of the cochlea with cochlear implants.

That problem and the need to place electrode contacts near to the modiolar wall of the cochlea has led designers to build arrays with mechanical characteristics that make the implants conform to the anatomy of the cochlea. Rebscher and his colleagues (1999) suggested a design that elegantly made use of the mechanical properties of the wires that interconnected the electrode sites and the drive electronics. They built an array that arranged the wires to form a central, vertical beam. The beam bent easily to conform to the spiral shape of the cochlea, and the pitch of the spiraling array could be controlled by the geometry of the beam in a basal–apical direction. Advanced Bionics has employed the design in two of their arrays. *In vitro* measures of the stiffness of Cochlear and Advanced Bionics arrays showed a clear anisotropy for the latter, but not for the former (Rebscher *et al.*, 2001). Another approach suggested the use of shape-memory wire, e.g., Nitinol, within the array to match the cochlear spiral. The wire was shaped to fit the modiolar wall (Spelman *et al.*, 1998), straightened for insertion into the cochlear electrode array, and electrically heated beyond its transition temperature after the array was inserted into the scala tympani. The system has not been commercialized.

The stiffness of a cochlear electrode array is important for ease of insertion, placement near the target neurons, and, possibly, for insertion trauma. The arrays are mechanical beams, and their mechanical properties can be investigated with classical methods in some cases, at least to obtain information about the relative stiffness of arrays that employ different materials (Boyd, 1935; Enderle *et al.*, 2000). For a cantilevered beam of uniform cross section and homogeneous material, the maximum deflection that occurs when the beam is loaded at its free end is

$$y_{\max} = \frac{Pl^3}{3EI}$$

where P is the load in newtons, l is the length in meters, E is the modulus of elasticity in pascals (N/m^2), and I is the cross-sectional area moment of inertia, m^4 .

The preceding equation is a gross oversimplification of a complex problem. The assumptions that underlie the relationship are that the deflection produces small angles, that the cross section is uniform, and that the material is linear

and homogeneous. Cochlear electrode arrays are inhomogeneous: they contain both metallic conductors and polymeric substrates; they may be laminated. Cochlear electrode arrays are tapered. The number of conductors inside of them varies with length. The angles of bending can be large, particularly in the apical turns of the cochlea. The arrays are likely to be anisotropic. Thus, for a complete analysis, more sophisticated mathematics is necessary and may not be amenable to closed-form mathematical solutions. Numerical techniques, e.g., finite-element analysis, are likely to be required for better understanding.

Measurements

Cochlear prostheses are sophisticated instruments that require thorough measurement and analysis. Since they are Class III devices from the point of view of the FDA, they must be carefully tested and the tests documented before they are used.

Each component of a cochlear implant is tested before the assembly can be applied to a human subject. For example, the processing section of the prosthesis must be tested to ensure that it can parse the auditory signal and reassemble the decomposed aggregate into a new auditory signal that can be understood readily by hearing listeners. Although that is not a definitive test for its ultimate users, the deaf, it gives confidence that the processor is not introducing anomalous information. Further, such tests indicate the data rates that must be transmitted across the skin to an internal processor.

The data-transfer link must be tested to ensure that it can sustain the necessary data rates across an appropriate thickness of skin (about 1 cm in the adult human). Animal tests can provide confidence in this case.

The internal processor must be tested to learn whether it can select electrode sites unambiguously and reliably. The current drivers are tested to discover their linearity, repeatability, and voltage range over the full life of the battery. As batteries sag during use, does the transfer function of the current driver remain constant? Is the voltage range sufficient to drive the full dynamic range of every electrode?

The electrode array is tested carefully from the design through the manufacturing process. The tests include long-term soaking, electrochemical tests (Parker *et al.*, 2000), field tests, and neurophysiological tests (Jolly *et al.*, 1996, 1997). As an electrode design is introduced it must be placed in physiological saline solutions for several weeks to discover whether the insulating carriers promote leakage between the conductors of the arrays.

Electrochemical tests include tests of open-circuit potential, whose stability may indicate shorting across traces (Parker *et al.*, 2001), as well as electrochemical impedance spectroscopy, which can also indicate open-circuited and short-circuited electrode sites as well as poorly plated electrode sites (Macdonald, 1987; Parker *et al.*, 2001). (Note that Parker *et al.* is an abstract. A full manuscript can be downloaded from <http://www.eng.monash.edu.au/ieec/ieecbio1999/p41.htm>.) If more complete information about the characteristics of the electrode sites is needed, cyclic voltammetry is in order (Goodisman, 1987; Cogan, 2002).

Measurement of the electric fields produced by electrodes is useful during the initial design phase. It shows the characteristics of the potential fields that are produced by the excitation of single or multiple electrodes (Jolly *et al.*, 1996; Suesserman *et al.*, 1991). It also can show which electrodes have parasitic conductive paths that lie between them (Prochazka and Spelman, unpublished results).

When bench testing and *in vitro* testing are complete, when a cochlear prosthesis is ready for clinical trials, behavioral testing begins. That testing ranges from psychophysical tests (Vandali *et al.*, 2000; Shannon, 1992; Pfungst *et al.*, 1997), to tests of monosyllabic words and simple sentences (Skinner, 2001; Osberger and Fisher, 1999), to investigations of the understanding of contextual information (Vandali *et al.*, 2000). Behavioral testing is the true “gold standard,” since it determines the success or failure of the cochlear prosthesis.

Focusing Fields and the Interaction with Tissue

The cochlear prostheses that are in use today drive electrodes singly, with the exception of the Advanced Bionics SAS system. That is a result of the interference between the fields that are produced by the electrodes of the devices, fields that are defined by the size of the electrodes used, their distances from the target cells, and the magnitudes and phases of the signals that are applied to each contact (Spelman *et al.*, 1995). If fields are focused, it is likely that multiple groups of neurons can be driven simultaneously and independently (Jolly *et al.*, 1997). It is not clear whether such independence will be preferred by patients or that it will provide improved speech perception (Pfungst *et al.*, 1997). It seems logical from the operation of the normal auditory system (Sachs and Young, 1979), but Pfungst’s work argues against it (Pfungst *et al.*, 1997).

Both modeling and experimental studies suggest clear benefits that can result from perimodiolar placement of electrode arrays. The modeling studies show that the fields are clearly more limited in extent when the electrode contacts are near to the target cells (Spelman *et al.*, 1995; Frijns *et al.*, 1996, 2001). Use of the simple model given in the earlier section on “Contacts and Focusing” can demonstrate the narrowing of the field that takes place when a point source is placed near its target.

Recall that finite-sized electrodes do not produce infinitely wide fields as they are approached; the fields approach the width of the electrode (potential curves in Fig. 4 illustrate that fact). However, a point can be made for either point sources or finite sources: the further from the source, the wider the field. That statement is clear for a single electrode, driven as a monopole; less clear for a tripolar configuration, driven as a quadrupole (Spelman *et al.*, 1995). In the latter case, the width of the potential field changes less with distance than for the former case. In both cases, the peak potential in the field is larger the closer the contact or contacts are to the target. Thus, intervening tissue between the electrodes and their target neurons is to be minimized or avoided entirely.

If tissue surrounds the implanted electrode array, then several problems can arise. First, the distance between the electrodes and their target cells will increase. Second, the sheaths

that surround implanted electrodes have higher resistivities than do the solutions of the scala tympani and are anisotropic (Spelman, 2004). Third, tissue sheaths can cause an increase in the impedances of the electrodes and a concomitant increase in the voltage required to achieve excitation, with accompanying increases in power consumption.

The effect of increasing the distance becomes greater the closer is the electrode array to the neurons of the auditory nerve. Considering the simple case of a point source driven as a monopole, the electric field is proportional to the inverse of the distance between the source and the target. For a distance of 100 μm , an increase of 50 μm represents a 50% change in the distance between the cells and the target. If there is a distance of 500 μm initially, the change is 10%. In experimental animals sheaths of 50- μm thickness were found after a few months of implantation (Shepherd *et al.*, 1983; Leake *et al.*, 1990).

The introduction of connective tissue sheaths introduces multiple layers into the analysis of fields in the inner ear. Even a simple three-layered problem produces a complicated result that is not a closed-form solution and will not be addressed here (Spelman, 1989). It is enough to say that the signal produced by the stimulating current will be attenuated and, in the case when the sheath is anisotropic, will likely direct the excitation to undesirable locations (Spelman, 2004).

If cochlear electrode arrays could have their surfaces treated appropriately, they might resist the adhesion of cells and the growth of surrounding tissue sheaths (Dalsin *et al.*, 2003). That approach to combating the growth of cells that are produced by inflammatory responses may prove to be successful for future developments of electrode arrays. The approach can protect the surface of the substrate of the array, but not the metallic surfaces of the electrodes themselves.

Tissue on the surfaces of the electrodes must increase their impedances. Membranous tissues behave like leaky capacitors, introducing materials with specific capacitances of 33.8 $\mu\text{F}/\text{cm}^2$ (Junge, 1977). The introduction of such capacitances can affect the impedance of the electrodes of the array and their abilities to carry currents and stimulate cells. Thus, the materials to prevent cell adhesion to cochlear electrode arrays must be designed to maintain current-carrying capacity and low impedance while they prevent cell adhesion and the growth of undesirable tissue sheaths.

Costs and Benefits

That more than 50,000 people use cochlear prostheses is testimony to their effectiveness. The prostheses have improved monotonically over the past several decades, with substantial improvements in comprehension that occurred when multi-channel prostheses were developed, and more gradual improvements otherwise (Rubinstein and Miller, 1999).

At the same time, cochlear prostheses have been found to be cost effective as well. In careful cost analyses, Cheng and his co-workers investigated cochlear implants and found that they were competitive with other surgical interventions (Cheng and Niparko, 1999). The study accounted for the costs of surgery and rehabilitation, and considered change in the quality of life as an intangible.

DIRECTIONS FOR THE FUTURE

Clearly, multichannel cochlear prostheses will be produced and implanted in large numbers and will be used extensively worldwide. The three major producers of implants are likely to move to more cosmetic devices. All of them presently make behind-the-ear prostheses and are pursuing totally implantable devices. At this time, the greatest two stumbling blocks to the latter are battery and microphone technologies. Implantable microphones will require great attention to the issue of tissue encapsulation around the diaphragm of the microphone.

Another likely improvement will be the number of electrodes that are used in the array. Investigators have pursued a 72-contact array (Spelman *et al.*, 1998), a device that demands a quantum change in processor technology (Clopton *et al.*, 2002). High-density electrode arrays will require great care and attention paid to the issues of tissue growth and compatibility. If a high-density array and its processor are available, they could provide precise phase information that is unavailable now and that will likely make possible successful binaural cochlear prostheses (Clopton and Lineaweaver, 2001).

QUESTIONS

1. Sound at the level of the tympanic membrane demonstrates a pressure peak at a frequency of 2.5 kHz in the human. Consider the boundary conditions of the ear canal and explain why that resonance occurs.
2. Considering the areas of the stapes and the tympanic membrane, as well as the properties of the ossicular chain, compute the approximate ratio of pressures that is found when the tympanic membrane is driven at low frequency. Note that this is an approximate calculation that does not consider the dynamics of the system.
3. Focusing stimuli has been proposed by several people (Suesserman and Spelman, 1993; Jolly *et al.*, 1996) as a solution to the problem of field interference between monopole sources. Consider using dipole and quadrupole sources. Assume that the sources are 50- μm hemispheres located on the surface of an insulating boundary. Let the hemispheres be separated by 200 μm in both cases. Plot the potential fields along two lines: one that is 100 μm above and parallel to the sources, another that is 200 μm above and parallel to the sources. Describe the properties of the fields that are produced. Look particularly at the peak potentials and the half-amplitude widths of the fields. Hints: A dipole consists of two sources, one carrying current I and the other carrying current $-I$. A quadrupole is a special case of a tripole. Three sources are used. The

central source carries current I , while the two flanking sources carry current $-I/2$. For ease of calculation, place one of the sources at the origin, and let the other sources lie on, e.g., the x -axis.

4. Wiley and Webster (1982) give an equation that describes the potential field produced by an electrode of radius a located at the origin of a cylindrical coordinate system. The electrode is placed on the surface of an insulating boundary.

$V(r, z)$

$$= \frac{2V_0}{\pi} \sin^{-1} \left\{ \frac{2a}{\left[(r-a)^2 + z^2 \right]^{0.5} + \left[(r+a)^2 + z^2 \right]^{0.5}} \right\}$$

and

$$J_z(r, 0) = \frac{2V_0}{\rho\pi} \frac{1}{(a^2 - r^2)^{0.5}} = \frac{J_0}{2 \left[1 - (r/a)^2 \right]^{0.5}}$$

where

$$J_0 \equiv \frac{I_0}{\pi a^2}$$

I_0 is the total current flowing into the electrode, J_0 is a current density (defined earlier), ρ is the resistivity of the medium, and r is the radial distance $[x^2 + y^2]^{0.5}$. Place a point source at the origin and compare it to a circular, planar electrode with its center at the origin. Let the radius of the circular electrode be 100 μm . Compute the potential field for $-1 \text{ mm} \leq x \leq 1 \text{ mm}$ at altitudes of 50 and 750 μm . What can you say about the shapes and the peak potentials?

5. A cochlear electrode array employs contacts that are hemispheres 100 μm in diameter. As the designer of the array, you compare Pt-Ir contacts with IrOx contacts. In one stimulus mode, you will use sinusoids of 100 and 1000 Hz. What is the maximum current that you can tolerate for each material at each frequency? Hint: compute charge per phase of the sinusoid.
6. A measurement of the IrOx electrode produces an impedance magnitude of 5 kilohms at 1000 Hz. If you drive a dipole pair with a 1-kHz sinusoid, what voltage range must the current source have if you drive the maximum allowable current that the electrode can tolerate? Assume that the tissue impedance of the cochlea is small compared to the impedance of the electrodes.
7. Two electrode array designs are considered. One uses a silicone substrate and the other a liquid crystal polymer substrate. If a circular cross section is used, with an outside diameter of 200 μm , find the force that would be exerted on a free end whose length is 1 mm and whose deflection is 20 μm . The modulus of elasticity of silicone is 2.76 MPa and that of liquid crystal polymer is 158 MPa. The polar moment of inertia is

$$I_p = \frac{\pi d^4}{32}$$

8. A simple model of electrode impedance is the Warburg model (Macdonald, 1987). This diffusion model can take the form of a parallel resistance/capacitance circuit in which the resistance and capacitance are both inversely proportional to the square root of frequency, i.e.,

$$R(f) = \frac{R_0}{\sqrt{f}}$$

$$C(f) = \frac{C_0}{\sqrt{f}}$$

Compute the magnitude and phase of the electrode's impedance if its impedance is 1 megohm at 10 Hz. Compute for frequencies from 10 Hz to 10 kHz. Assume that the electrode is circular in shape, and that its diameter is 100 μm . If it is covered with a membrane whose specific capacitance is that given in the text, how does the character of the impedance change? Plot the magnitudes and phases for both situations.

9. If the time constant of the membrane that covers the electrode is 125 msec, recompute the impedance for problem 8, accounting for the membrane resistance that parallels the membrane capacitance.
10. Consider the uncoated electrode of problem 8. If a controlled sinusoidal current were applied to the electrode, what would be the peak-to-peak voltage necessary to drive the current, undistorted, over the full frequency range? Assume that the electrode is driven as a monopole and that its counterelectrode has negligible impedance.

7.17 BIOMEDICAL SENSORS AND BIOSENSORS

Paul Yager

SENSORS IN MODERN MEDICINE

A convergence of factors is now resulting in the rapid development of sensors for biomedical use. These factors include:

- Increasing knowledge of the physics, chemistry and biochemistry of physiology
- Pressure for reduction in the cost of delivering medical care through more efficient treatment and shorter hospital stays
- Steadily decreasing costs of microprocessor technology for data acquisition, analysis, and display
- Reduction in the size of sensors due to silicon micro-fabrication and fiber optic technology
- Rapidly advancing sensor technology in nonbiomedical fields and for *in vitro* use for clinical chemistry
- Advances in biomaterials

Advances in computer technology have reached the point that the control of devices and processes is often limited only by the ability to provide reliable information to the computer. Furthermore, the technologies developed by the microprocessor and fiber-optics industries are now spawning a new generation of sensors. Areas benefiting now from these new sensors include the automotive and aerospace industries, chemical and biochemical processing, and environmental monitoring. While there has been ready adoption of new sensor technologies for *ex vivo* measurements, *in vivo* use of such sensors to clinical

practice is lagging far behind. This is due to serious performance deficits of sensor operation *in vivo*, as well as the same regulatory factors that apply to any use of devices and materials *in vivo*. Sensors are as subject to the same problems of biocompatibility as are any other type of *in vivo* device; initial unbridled optimism on the part of analytical chemists for the potential applicability of their sensors to *in vivo* use has given way to a more sober appraisal of the potential of the field.

This chapter provides a brief overview of the current state of application of sensors to clinical medicine, with an emphasis on chemical sensors, biosensors, and the emerging field of micro-fabricated sensors. Several excellent reviews may be found in the literature (Rolfe, 1990; Collison and Meyerhoff, 1990; Turner *et al.*, 1987; Kohli-Seth *et al.*, 2000; West *et al.*, 2003; Nakamura *et al.*, 2003; Jain, 2003; Ziegler, 2003; Vo-Dinh *et al.*, 2000).

PHYSICAL VERSUS CHEMICAL SENSORS

Biomedical sensors fall into two general categories: physical and chemical. Physical parameters of biomedical importance include pressure, volume, flow, electrical potential, and temperature, of which pressure, temperature, and flow are generally the most clinically significant and lend themselves to the use of small *in vivo* sensors. Electrical potential measurement is covered in another chapter in this volume. Chemical sensing generally involves the determination of the concentration of a chemical species in a volume of gas, liquid, or tissue. The species can vary in size from the H⁺ ion to a live pathogen (Table 1), and when the species is complex, an interaction with another biological entity is required to recognize it. When such an entity is employed the sensor is considered a biosensor. It is, in general, necessary to distinguish this chemical from a number of similar interferents, which can be technologically challenging, but this is an area in which biosensors excel. The clinical utility of monitoring compounds in the body has motivated great efforts to develop biosensors. The prime target is improvement upon current methods for determination of glucose concentration for treatment of diabetes. Because of the large numbers of diabetics worldwide and their requirement for frequent measurements of blood glucose, glucose monitoring continues to be the dominant market for enzyme-based biosensors.

INTERACTION OF THE SENSOR WITH ITS ENVIRONMENT

One helpful way to classify sensors is to consider the relationship between the sensor and the analyte, as shown schematically in Fig. 1. The more intimate the contact between the sensor and the analyte, the more complete is the information about the nature of the chemical species being measured. However, obtaining greater chemical information may involve some hazard to the physical condition of the system being studied. This is not a trivial problem when dealing with human subjects.

Noncontacting sensors produce only a minimal perturbation of the sample to be monitored. In general, such measurements are limited to the use of electromagnetic radiation such as light, or sampling the gas or liquid phase near a sample. It may be even necessary to add a probe molecule to the sample to make the determination. Two examples are monitoring the temperature of a sample by its infrared emission intensity, and spectroscopic monitoring of pH-dependence of the

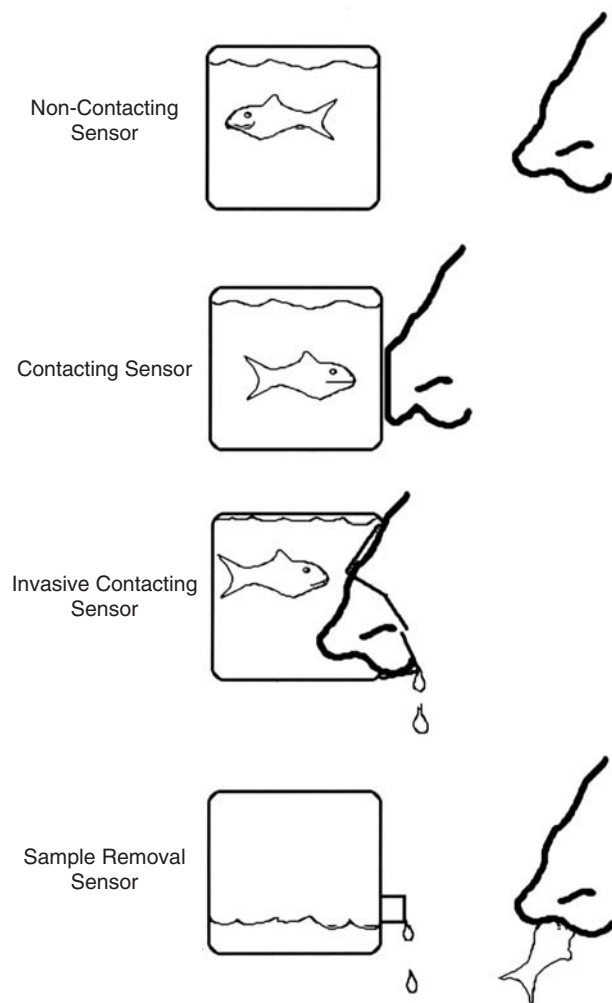

FIG. 1. Different types of relationships may occur between a chemical sensor and the analyte to which it is sensitive.

optical absorption of a pH-sensitive dye. No damage is done to the sample, but limited types of information are available, and chemical selectivity is difficult to achieve *in vivo*.

Contacting sensors may be either noninvasive or invasive. Direct physical contact with a sample allows a rich exchange of chemical information; thus much effort has been expended to develop practical contacting sensors for biomedical purposes. A temperature probe can be in either category, but with the exception of removing or adding small quantities of heat, it does not change the environment of the sample. Few chemical sensors approach the nonperturbing nature of physical sensors. All invasive sensors damage the biological system to a certain extent, and physical damage invariably leads to at least localized chemical change. Tissue response can, in turn, lead to spurious sampling. Furthermore, interfacial phenomena and mass transport govern the function of sensors that require movement of chemical species into and out of the sensor. Restrictions on size of the invasive sensor allowable in the biological system can limit the types of measurements that can be made—even a 1-mm diameter pH electrode is of no use in measuring intracapillary pH values. Clearly, this is the most difficult type of sensor to perfect.

Most contacting sensors are derived from chemical assays first developed as sample removal sensors. Although it is certainly invasive and traumatic to remove blood or tissue from a live animal, removal of some fluids such as urine and saliva can be achieved without trauma. Once removed, a fluid can be pretreated to make it less likely to adversely affect the functioning of a sensor. For example, heparin can easily be added to blood to prevent clotting in an optical measurement cell. Cells that might interfere with optical assays can also be removed prior to measurement. Toxic reagents and probe molecules can be added at will, and samples can be fractionated to remove interfering species. The sensor and associated equipment can be of any size, be at any temperature, and use as much time as necessary to make an accurate measurement. Further, a sensor outside the body is much easier to calibrate. This approach to chemical measurement allows the greatest flexibility in sensor design and avoids many biocompatibility problems.

CONSUMING VERSUS NONCONSUMING SENSORS

There are at least two distinct ways in which a sensor can interact with its environment; these can be called consuming and nonconsuming (Fig. 2). A nonconsuming or equilibrium sensor is one that can give a stable reading with no net transport of matter or energy between the sensor and its environment. For example, while a thermometer is approaching equilibrium it takes up or releases heat, but when it has reached its ultimate temperature it no longer directly affects the temperature of its environment. Some chemical sensors such as ion-selective electrodes and some antibody-based sensors work similarly and have the advantage of being minimally perturbative of their environments. A nonconsuming sensor may become slower to respond after being coated by a biofilm, but may still provide the same ultimate reading.

The consuming or nonequilibrium sensors rely on constant unidirectional flux of energy or matter between the sensor and

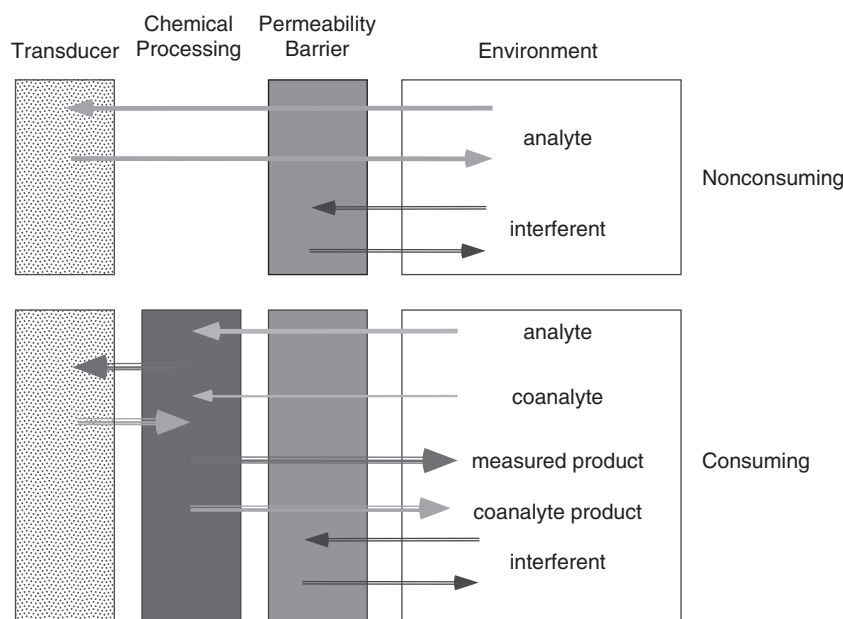

FIG. 2. A schematic diagram comparing consuming and nonconsuming sensors. The transducer is usually isolated from the environment by a permeability barrier to keep out interfering species, and in a consuming sensor, there is usually an intermediate layer in which active chemical processing occurs. In the consuming sensor there is a complex flux of analytes and products that makes it very sensitive to changes in permeability of the sensor–solution interface.

environment. The most common glucose sensor, for example (see later discussion), destroys glucose in the process of measuring it, thereby reducing its concentrations in the tissue in which it is measured, as well as reducing the pH and O_2 concentrations and generating toxic H_2O_2 as a by-product. This chemical measurement cannot be made *in situ* without affecting the system in which the measurement is made, and although it may be tolerable in flowing blood, it may not be acceptable in tissue over the long term. The greater the size of the sensor, the greater its sensitivity, but the more seriously it perturbs its environment. Many of the most fully developed specific *in vitro* analytical techniques for the determination of biochemicals involve irreversible consumption of the analyte, so sensors based on such techniques are difficult to implement *in vivo*.

SITE OF MEASUREMENT

Sample removal sensors are the mainstays of the clinical chemistry laboratory. For example, the first commercially manufactured biosensor—an electrode for measuring glucose—was made by Yellow Springs Instruments for a clinical chemistry analyzer. The major problem with the use of such devices is the time delay inherent in moving a sample to a distant location where the large, expensive instrument resides and waiting for delivery of the information derived from it, as well as the fact that useful instruments are often heavily utilized.

A major activity of modern bioanalytical chemistry is conversion of sample removal sensors into invasive contacting

sensors (Fig. 1). Not only can this approach improve care by reduction of the aforementioned delays, but it can also enable new types of procedures, such as automated feedback control of delivery of drugs to patients. However, development of such an approach often requires inventing new ways of making the measurements themselves. Chemical measurement at bedside or *in vivo* is technologically more challenging than in a prepared chemical laboratory with highly trained technicians. Clinical personnel must attend to the critical needs of the patient and have little time for fiddling with temperamental instrumentation. The instrumentation must therefore be made nearly foolproof, rugged, safe, reliable, and, if possible, self-calibrating.

DURATION OF USE

Two major questions in the design of any sensor are how often and for how long it is expected to be used. There are several factors to be considered:

Length of time for which monitoring is required. Determination of blood glucose levels must be made for the entire lifetime of diagnosed diabetics, whereas intraarterial blood pressure monitoring may only be needed during a few hours of surgery.

Frequency of measurements. Pregnancy testing may have to occur only once a month, whereas monitoring of blood pCO_2 during an operation may have to be made several times a minute.

Reusability of the sensor. Some chemical sensors contain reagents that are consumed in a single measurement. Such sensors are usually called “dip-stick sensors,” such as are now found in pregnancy testing kits. High-affinity antibodies, for example, generally bind their antigens so tightly that they cannot be reused. On the other hand, most physical and chemical sensors are capable of measuring the concentration of their analyte on a continuous basis and are therefore inherently reusable.

Lifetime of the sensor. Chemical sensors all have limited lifetimes because of such unavoidable processes as oxidation, and although these may be extended through low-temperature storage, *in vivo* conditions are a threat to the activity of the most stable biochemical. Most sensors degrade with time, and the requirement for accuracy and precision usually limit their practical lifetime, particularly when recalibration is not possible. Mechanical properties can also limit lifetimes; although a thermocouple may have a shelf life of centuries, it can be broken on its first use by excessive flexing.

Appropriateness of repeated use. The need for sterility is the most important reason to avoid reuse of an otherwise reusable sensor. If it is not logistically possible or economically feasible to completely sterilize a used sensor, it will only be used on a single individual, and probably only once.

Biocompatibility. If the performance of a sensor is degraded by continuous contact with biological tissue (as discussed later), or if the risk to the health of the patient increases with the time in which a sensor is in place, the lifetime of the sensor may be much shorter *in vivo* than *in vitro*.

As a consequence of all of these factors in the design of an integrated sensing system, the probe—that part of the sensor that must be in contact with the tissue or blood—is often made disposable. Probes must therefore be as simple and as inexpensive to manufacture as possible, although it is often true that it is the sale of consumables such as probes that can be more profitable than the sale of the device itself.

BIOCOMPATIBILITY

The function of most chemical sensors is limited by the rate of diffusion through an unstirred layer of liquid at the interface, whether the alteration in rate controls response or merely response time. However, interfacial flux in biological media can be altered further by processes unique to living systems. Biocompatibility is an issue of importance for any material in contact with living systems, but is particularly so for chemical sensors. The properties of the interface are crucial to the ability of the sensor to make accurate, reproducible readings.

In Vitro Use

It is difficult to prevent biofilm formation on surfaces exposed to active media such as bacterial or eukaryotic cell cultures. The growth of a biofilm on a sensor degrades its performance in some way. In fact, in the most extreme case, the sensor can become sensitive only to conditions in the biofilm. Biofilms often consist of bacteria embedded in a secreted matrix of complex polysaccharides. Although the microenvironment of these films may be beneficial to the bacteria, it is detrimental to the function of the sensor for several reasons. First, the chemistry of the film may damage structural or active components of the sensor. Second, if the film completely encloses the sensor, only the film’s microenvironment is sensed, rather than the solution that surrounds it. If the living components of the film metabolize the analyte to be sensed, it may never reach the sensor. Even a “dead” film may exclude certain analytes by charge or size and thereby lower the concentration available for sensing at the surface below the film. If a sensor used *in vitro* is fouled, it can often be removed, cleaned, and restored to its original activity. For example, carbon electrodes containing immobilized enzymes can be restored by simply polishing away the fouled surface (Wang and Varughese, 1990). When sensors are used *in vitro* for monitoring the chemistry of body fluids, preprocessing can be used to reduce the accretion of biofilms that might impede the function of the sensor.

In Vivo Use

Introduction of sensors into the body creates a complex set of problems. The sensor and the body act on each other in detrimental ways that must be minimized if not entirely avoided. Many of the problems (described later) worsen with time and may limit the utility of sensors to very short uses. In some cases, it has been found that the problems are almost immediate, producing spurious results from the outset. Subcutaneous glucose needle electrodes have been found to give accurate results *in vitro* before and after producing erroneous values *in vivo*. The biological environment may simply make it impossible to perform accurate chemical measurements with certain types of sensors.

Effects of Sensors on the Body

The introduction to the body of a sensor is a traumatic event, although the degree of trauma depends on the site of placement. The gastrointestinal tract can clearly be less traumatically accessed than the pulmonary artery. Critically ill patients often must have catheters placed into their circulatory systems for monitoring of blood pressure and administration of drugs, fluids, and food, so that no additional trauma is caused by including a small flexible sensor in that catheter. The size, shape, flexibility, and surface chemistry of the sensor probe are also important factors, although they are covered elsewhere in this volume. The outermost materials of the chemical sensor have at least one requirement not normally placed upon structural biomaterials: they must be permeable to the analyte in question. Thin films of polyurethanes are permeable to at

least some analytes, and Nafion and porous Teflon work in other cases, but this issue is far from resolved. Some metals and graphite can be used directly as electrodes in the body.

When short-term implantation in tissue is possible, there is initial trauma at the site of insertion. Longer-term implantation increases the risk of infection along the surface of the implant. When the site of implantation of the probe is the circulatory system, the thrombogenicity of the probe is of paramount importance. Surface chemistry, shape, and placement within the vessel have all been shown to be of great importance in reducing the risk of embolism. Also, sensors based on chemical reactions often contain or produce toxic substances during the course of their operation, so great care must be taken to ensure that these are either not released or at low enough levels to avoid significant risk to the patient.

Effects of Surface Fouling on Sensor Function

The response of a consuming sensor depends on the rate of flux of the analytes and products across the interface. Indeed, most consuming sensors achieve linearity of response by making the diffusion into the sensor of analyte the rate-limiting step in the chemical reaction on which the sensor relies. Any new surface film over the interface will slow the diffusion and reduce the sensor output signal, producing an apparent reduction in the concentration of the analyte. Only equilibrium sensors avoid this problem, and even they experience a reduction in their response time.

These aforementioned problems of inert biofilms pale in comparison to the problems that arise when the film contains living cells, which is usually the case *in vivo*. As mentioned in other chapters, enzymatic and nonenzymatic degradation of polymers can be greatly accelerated, resulting in mechanical and eventual electrical failure of a sensor. Large changes in local pH, pO₂, and pCO₂ and concentration of other chemically active species such as superoxide can either chemically alter analytes or damage the function of the sensor itself. If, as often happens when a foreign body is implanted in soft tissue, a complete capsule of collagen and macrophages forms, the sensor within it may only be capable of sensing the microenvironment of activated macrophages, which is certainly not a normal sample of tissue.

Thrombus formation in blood is another common problem. Although such schemes as the use of polyurethane coatings and covalent grafting of heparin to that surface that work for vascular grafts are also helpful for sensors, thrombus is a complex, active substance that severely compromises the function of a sensor. In general, sensors in blood are used only for a few days at most and in the critical-care setting, during which time the patient may be undergoing anticoagulant therapy that reduces the problem of thrombus formation. As yet there is no device for permanent implantation in the bloodstream, despite great efforts in this direction.

Because of the trauma involved with insertion and removal of *in vivo* sensors, it is not generally feasible to remove a sensor to calibrate it. Consequently, any calibration must be done *in situ*, and since this would require the delivery of a calibration solution to the sensor, it is not generally done.

Successful *in vivo* sensors to date have been those that do not require recalibration during the lifetime of that sensor.

CLASSES OF SENSORS

New Technologies

As mentioned at the outset, the current rapid pace in development of biomedical sensors is fueled in part by a series of technological advances from other fields.

Fiber Optics

Advances in the field of optical communications have created a new technology for controlling light by using waveguides such as optical fibers. Whereas most of the technology for communication uses near-infrared light and most chemical measurements are made with ultraviolet and visible light, the fiber optic sensor field is bridging the gap by developing fibers that work well in the visible and chemical techniques that employ near-infrared light. Optical fibers have an advantage over wires in that they do not conduct current, so sensors made from such fibers (optrodes) are intrinsically safer than electrochemical sensors or even thermistors in that they reduce the risk of electrical shock to the patient.

Microprocessor-Controlled Devices

The recent availability of powerful, small, and relatively inexpensive computers has permitted designers of sensors to include sophisticated analytical procedures as part of the normal function of the sensors. Many previously manual operations such as calibration can now be completely automated. Rather than building a custom analog circuit to perform a particular function, one can now assemble stock electronic parts and customize only the software for the application. This has also relaxed the once-stringent requirement for linearity of response for the sensor itself—nearly any form of response can be programmed into a lookup table kept in memory. Home treatment of the elderly and chronically ill has been aided by the acquisition of data from sensors in the home. The data can be sent by radio or phone lines to central locations for more sophisticated analysis or routing of emergency services. Improvements in telemetry have led to the development of sensors that have no wires penetrating the body at all, which avoids the route for infection provided by continuous penetration of the body by catheters and electrical leads.

Microsensors and Microfabrication

Because of rapid progress in the semiconductor industry, micromachining of silicon into complex three-dimensional shapes with dimensions of less than 1 μm is now relatively commonplace. Devices can be electrical, such as electrodes, single transistors, and complex circuits; optical, such as photodiodes and optical waveguides; and mechanical, such as sensors, pumps, and microactuators. These diverse devices can be integrated into a single wafer, creating an entire “chemical laboratory on a chip.” Furthermore, silicon microlithography is so successful in producing computers because it allows production of multiple copies of small and precisely manufactured

devices, so the problems and costs inherent in manufacturing hand-made sensors can be avoided.

Physical Sensors

Temperature

The proper maintenance of a particular temperature, such as the 37°C of the human body core, is an indicator of health. Alteration of the temperature of the whole body or of a particular organ may be advantageous during certain medical procedures, such as surgery and preservation of organs, and this requires careful but minimally traumatic monitoring.

Thermometry began with development of devices based on calibrated changes in volume of liquids by Galileo in the 1600s and was perfected in the mid-18th century. Such thermometers are inexpensive and can be quite accurate, but are generally fragile, bulky, slow to respond, and require reading by eye, so they have been largely replaced in the clinical setting. If determination of the surface temperature of the skin is adequate, there are inexpensive techniques available relying on changes in the optical properties of a film of cholesteric liquid crystals, or expensive options such as the use of infrared radiometers. Modern methods of measuring the temperature of a bulk material such as blood or tissue are based on temperature-dependent electrical properties of matter. Devices include thermocouples, resistance temperature detector (RTD) sensors, thermistors, and silicon diodes, microcomputer-based applications of all of these. The sensor must be placed into tissue or blood, so to maintain accuracy there should be little transfer of heat into or out of the body along the leads to the thermometer. A small, self-contained telemetric temperature sensor with no external leads at all was developed by Human Technologies, Inc. It is capable of continuous readings of core temperature for the duration of the device's residence in the gastrointestinal tract.

Thermocouples

The Seebeck effect is responsible for temperature-dependent potentials (or current, in a closed circuit) across the junction between two different metals. Responses (Seebeck coefficients) of 10 to 80 $\mu\text{V}/^\circ\text{C}$ are the range for commonly used thermocouple pairs. In potential measurement circuits, the size of the contact region is immaterial, so very small thermocouples can be made with response times as short as milliseconds. The response is not linear, and either lookup tables or high-order polynomials are needed to linearize the responses. Precision better than 0.1°C is not generally practical. The thermocouple is self-powered and thus introduces no heat to the system being measured, but a reference junction at a known temperature is required, usually within the housing of the digital voltmeter (DVM) sensor electronics (Fig. 3). Thermocouples are cheap and as reproducible as the chemistry of the metals used. Because they can be made extremely small, they continue to be the sensor of choice in some applications. The Cardiovascular Devices Inc. (CDI) Systems 1000 fiber optic sensor for pH, pCO_2 , and pO_2 (see later discussion), ironically, used a thermocouple for its required temperature reference at the tip of the optrode.

FIG. 3. A schematic representation of the manner in which thermocouples are used to measure temperature.

RTDs

The platinum RTD is based on the temperature dependence of the resistance of a metal. If care is taken to eliminate other sources of changes in resistance, chiefly mechanical strain, it is possible to measure temperature quite accurately and reproducibly. When well treated, RTDs are the most stable temperature measurement devices. The best RTDs are still hand-made coils of Pt wire, but these tend to be very expensive and bulky. Recently, deposition of Pt film on ceramics has been developed as a smaller, cheaper alternative with faster response times and nearly the same stability. Nonlinearities require adjustment in software for accurate readings, and because some current must be supplied to make a measurement, there is Joule heating of the device and the sample around it.

Thermistors

These are the most sensitive temperature measurement devices. They are generally made of semiconductive materials with negative temperature coefficients (decreasing R with increasing T). This effect is often quite large (several percent per $^\circ\text{C}$), but also quite nonlinear. Very small devices can be fabricated with response times approaching those of thermocouples. Unfortunately, there are several drawbacks: the response of individual devices is highly dependent on processing conditions, the devices are fragile, and they self-heat. Nevertheless, because of their sensitivity they are the most common transducers for *in vivo* temperatures. For example, they are commonly used as the temperature sensors incorporated in the Swan-Ganz catheter used to determine cardiac output by thermodilution.

Optical Techniques

Optical techniques of temperature measurement have gained favor in recent years, in part because the use of optical fibers for measurements removes the necessity of passing metal wires into body that both allow a path for potentially lethal shock and can perturb electromagnetic fields such as those used in magnetic resonance imaging and other techniques requiring the use of microwaves. The Model 3000 Fluoroptic Thermometer (Luxtron Corp.) is such a device; it is based on the temperature dependence of the lifetime of

phosphorescent emission from an inorganic material (magnesium fluorogermanate) placed at up to four different locations along four 250- μm plastic optical fibers. This allows four nearly independent temperature measurements at spacings as close as 3 mm, which is useful for monitoring microwave-induced hyperthermia. Accuracy to $\pm 0.2^\circ\text{C}$ over a 40°C range is claimed. The expense of this type of device has initially limited its use to situations in which metal wires are not acceptable, but any of several recent temperature measurement schemes may prove substantially cheaper. Particularly when integrated with other sensors in a single multichannel device, optical thermometry may prove more popular than the use of thermistors.

Pressure

The most common sensor placed into the circulatory system of hospitalized patients is a blood pressure monitor. Both static and pulsatile blood pressure are key signs for monitoring the state of patients, particularly those with impaired cardiac function or undergoing trauma such as surgery. Although it is possible to measure the static blood pressure external to the body by using pressure cuffs and some acoustic or optical means of detection, such techniques are subject to a number of artifacts and do not work well in patients with impaired cardiac function. The site of measurement may be either an artery or vein, and the sensor may be implanted for short-term use during an operation, or over a longer term in an intensive-care-unit setting. It is even possible to monitor intraarterial pressure in ambulatory patients over long periods.

The pressure ranges generally seen in the circulatory system range from 0 to 130 mm Hg above the ambient 760 mm Hg. The most commonly available pressure transducers for accurate measurement in this range have been strain gauges, which are temperature-sensitive devices about an inch in diameter. The transducer itself is therefore placed outside the body, and pressure is transmitted to the transducer through a catheter. The transducer must be calibrated at least at turn on, and older models also required a two-point calibration against at least one calibrated pressure different from atmospheric and periodic rezeroing against ambient.

The mechanical properties of the catheter clearly can affect the accuracy of the waveform recorded by the transducer, as can the viscosity of the solution filling the catheter.

Blood would normally clot in the stagnant interior of the catheter, degrading the sensor response and causing a risk of embolism, so it is necessary to flush the catheter periodically with heparinized saline to keep both the lumen of the catheter and the artery patent. This requires the presence of a fairly complex set of sterile tubing and valves attached to a saline reservoir. Because flushing the catheter perturbs the pressure, it is not possible to obtain truly continuous measurements.

Most transducers have been fragile and expensive, and a factor that contributes to the cost of their use is the requirement that all materials in contact with blood must be sterilized. There is generally a diaphragm that separates the blood and saline from the mechanical transducer. This diaphragm and associated dome-shaped housing have in the past been a permanent part of the apparatus that required cleaning and sterilization between uses, but recent advances in manufacturing inexpensive, mechanically reproducible diaphragms have allowed this part also to be made disposable.

Other pressures of clinical importance are intracranial pressure and intrauterine pressure. Although in both these cases no direct invasion of the circulatory system is required, periodic flushing of all catheters is required. If, on the other hand, the sensor can be placed directly in the cavity in which the pressure is to be measured, flushing may not be necessary. Advances in silicon processing have allowed the manufacture of extremely small pressure sensors based on thin diaphragms suspended above evacuated cavities. The position of the diaphragm depends on the instantaneous pressure differential across it, so these devices can be used as both microphones and pressure monitors. The pressure can be monitored electrically, based on changes of capacitance between the diaphragm and the apposing wall of the cavity, or optically by monitoring changes in the reflectivity of the resonant optical cavity between the diaphragm and wall. This latter approach is the basis for fiber optic sensors introduced by FiberOptic Sensor Technologies, Inc., and MetriCor Corporation.

Chemical Sensors

A variety of chemical sensors employing different transduction mechanisms are currently employed for *in vivo* and *in vitro* measurements of biological parameters. These are summarized in Table 2.

TABLE 2 Transducers Used in Chemical Sensors

Transducer	Mode of measurement
Ion-selective electrode, concentration gas-selective electrode, FET Oxygen electrode, electrochemical electrode	Potentiometry—determination of surface of charged species Amperometry—monitoring available concentration of electrochemically active species
Low-impedance electrodes for monitoring conductance, impedance, admittance Optical waveguides with detection of absorption, fluorescence, phosphorescence, chemiluminescence, surface plasmon resonance Thermistors, RTD, calorimeters Piezoelectric crystal SAW, BAW, etc., with chemically selective coating	Monitoring changes in bulk or surface electrical properties caused by altered molecular concentrations Photometry Monitoring temperature change induced by chemical reaction Change in sound absorption or phase induced by binding to device

FIG. 4. Schematic of a pH meter and the potentials generated at various interfaces. Independent potentials generated in a pH measurement system: E1, measuring internal AgCl electrode potential; E2, internal reference solution-glass potential; E3, glass asymmetry potential; E4, analyte-glass potential; E5, reference liquid junction potential; E6, reference internal AgCl electrode potential. Any contamination or fouling at any of those interfaces causes degradation and drift. E4 is the potential that varies with solution pH, but a key source of error is E5, the liquid junction potential generated at the point where the reference electrolyte must leak slowly from the reference electrode body.

pH

The pH values of blood and tissue are normally maintained within narrow ranges; even slight deviations from these values have great diagnostic value in critical care. Measurement of pH is made either by electrically monitoring the potential on the surface of pH-sensitive materials such as certain oxides or glasses (potentiometric sensor), or by optically monitoring the degree of protonation of a chemical indicator. The pH electrode has traditionally incorporated a thin glass membrane that encloses a reference solution (Eisenman, 1967) (Fig. 4), although of late some success in the use of pH-sensitive field effect transistors (pHFETs) has been reported and a solid-state pH electrode based on a pHFET is being marketed. Another device is the light-addressable potentiometric sensor now produced by Molecular Devices Inc., which has shown great promise for *in vitro* measurement for biosensing (Hafeman *et al.*, 1988). Electrical measurements require the use of a reference electrode that is often the source of problems and has a lifetime dependent on the volume of electrolyte that it contains. Consequently, miniaturization of pH electrodes for long-term *in vivo* use has been a difficult problem. Such sensors are non-consuming, but surface fouling can influence the readings, and recalibration must be performed frequently.

Because of these drawbacks, there has been a shift toward optical indicator-based sensors using fiber-optic detection (Saari and Seitz, 1982; Jordan *et al.*, 1987; Jones and Porter,

1988; Benaim *et al.*, 1986), and at least two such sensors are now in advanced clinical trials. In these sensors, a small amount of dye with a pH-dependent fluorescence spectrum is immobilized in a polymer or hydrogel at the end of an optical fiber. Exciting light is sent down the fiber and the fluorescence emitted is returned to a photodetector along the same fiber. The detector can discriminate between the reflected exciting light and the probe's emission because they are at different frequencies. Such a sensor requires no reference and can function until the dye leaches from the probe or is bleached by the exciting light. However, both electrical and optical measurements of pH are dependent on the temperature, so pH measurements are always performed in conjunction with a temperature measurement as close to the site of the pH sensor as possible. Also, no pH sensor is absolutely specific, so in an uncontrolled environment there is always the risk of interferences. For example, the electrical sensors are subject to errors in the presence of biologically important metal ions, and fluorescence-based pH sensors are affected by fluorescence quenchers such as some inhalation general anesthetics.

Ions

Many simple ions such as K^+ , Na^+ , Cl^- , and Ca^{2+} are normally kept within a narrow range of concentrations, and the actual concentration must be monitored during critical care. Potentiometric sensors for ions (ion-selective electrodes or ISEs) operate similarly to pH electrodes; a membrane that is primarily semipermeable to one ionic species can be used to generate a voltage that obeys the Nernst (or more accurately the Nikolski) equation (Ammann, 1986):

$$E = \text{constant} + \frac{2.303 RT}{zF} \log[a_i + k_{ij}(a_j)^{z/y}]$$

where E is the potential in response to an ion, i , of activity a_i , and charge z ; k_{ij} is the selectivity coefficient; and j is any interfering ion of charge y and activity a_j .

Glasses exist that function as selective electrodes for many different monovalent and some divalent cations. Alternatively, a hydrophobic membrane can be made semipermeable if a hydrophobic molecule that selectively binds an ion (an ionophore) is dissolved in it. The selectivity of the membrane is determined by the structure of the ionophore. One can detect K^+ , Mg^{2+} , Ca^{2+} , Cd^{2+} , Cu^{2+} , Ag^+ , and NH_4^+ by using specific ionophores. Some ionophores are natural products, such as gramicidin, which is highly specific for K^+ , whereas others such as crown ethers and cryptands are synthetic. S^{2-} , I^- , Br^- , Cl^- , CN^- , SCN^- , F^- , NO_3^- , ClO_4^- , and BF_4^- can be detected by using quaternary ammonium cationic surfactants as a lipid-soluble counterion. ISEs are generally sensitive in the 10^{-1} to 10^{-5} M range, but none is perfectly selective, so to unambiguously determine ionic concentrations it is necessary to use two or more ISEs with different selectivities. Also, ISEs require a reference electrode like that used in pH measurements. One can immobilize ionophore-containing membranes over planar potential-sensitive devices such as FETs, to create ion-sensitive FETs (ISFETs). As the potential does not depend on the area of the membrane, these work as well as larger bench-scale electrodes. An advantage of this approach is that a dense array of different ISFETs can be manufactured in a small area by using

TABLE 3 Electroactive Chemicals

Inorganic species
Single-electron transfers:

FMN/FMNH

microfabrication techniques. Early problems with adhesion of the membranes to silicon have been largely solved by modifications of the design of the FETs themselves (Blockburn, 1987). The most typical membrane material used in ISEs is poly(vinyl chloride) plasticized with dialkyl sebacate or other hydrophobic chemicals. This membrane must be protected from fouling if an accurate measurement is to be made.

Electrochemically Active Molecules

If a chemical can be oxidized or reduced, there is a good chance that this process can occur at the surface of an electrode. Selectivity can be achieved because each compound has a unique potential below which it is not converted, so under favorable conditions a sweep of potential can allow identification and quantification of different species with a single electrode. This process is the basis for detection of a number of important biochemicals such as catecholamines (Table 3). Some species are determined directly at electrodes and others indirectly by interactions with mediator chemicals that are more easily detected at particular electrode surfaces.

Because detection involves conversion of one species to another, this is a consuming sensor, with all of the attendant problems. At least two electrodes are needed, and current must flow through the sample for a measurement to be made, although a precise reference electrode is not as necessary as in a potentiometric sensor. Near the electrode surface the concentration of either the oxidized or reduced species may differ greatly from the bulk concentration. This is partially because of depletion of the analyte near the surface (the diffusion layer), as well as attraction or repulsion of charged species from the charged electrode surface in the diffuse double layer (Fig. 5).

Since the current flow is the measured quantity and current is proportional to the number of molecules converted per unit time, the signal is controlled by mass transport, the electrostatics in the electric double layer, and specific chemical and

FIG. 5. A representation of the concentration of a charged analyte near the surface of an electrode (at left) at which it is being consumed. Note that there is a linear gradient of concentration in the unstirred diffusion layer and a further depletion or enrichment of the analyte when it is close enough to the electrode to sense the surface potential.

physical interactions at the electrode surface. The great advantages of electrochemical detection are counterbalanced by its great sensitivity to surface fouling and any process that changes the resistance between the measuring electrodes. Also, there are interfering compounds present at high concentrations *in vivo* such as ascorbate that can swamp signals from more interesting but less concentrated analytes such as catecholamines. Tricks such as using selective membranes over the electrodes can solve some of these problems. For example, negatively charged Nafion allows passage of catecholamines but blocks access to the electrode by negatively charged ascorbate.

Blood Gases

Perhaps the most important physiological parameters after heart rate and blood pressure are the partial pressures of blood gases O_2 and CO_2 ($p\text{O}_2$ and $p\text{CO}_2$). It is also often useful to compare pressures of these gases in the arterial and venous circulation. The pulse oximeter, now manufactured by a number of vendors, allows noninvasive determination of the degree of saturation of hemoglobin in the arterial circulation, but does not give any information about the actual $p\text{O}_2$. It only works on the arterial circulation near the periphery and gives no information about $p\text{CO}_2$. An invasive fiber optic probe developed by Abbott Critical Care Systems (the Oximatrix 3 Sv O_2) allows measurement of oxygen saturation directly in veins by measuring the reflected light at three wavelengths (Schweiss, 1983). Since the affinity of hemoglobin for O_2 depends on the pH, which in turn depends on $p\text{CO}_2$, it is necessary in many cases to measure the actual $p\text{O}_2$, $p\text{CO}_2$, and pH simultaneously. As all these sensors depend on temperature, a temperature probe is also required. The first successful fiber-optic measurement of *in vivo* $p\text{O}_2$ was reported by Peterson in 1984, and the principle employed has been used for most successful subsequent $p\text{O}_2$ sensors (Peterson *et al.*, 1984). The CDI System 1000 was a fiber optic sensor for pH, $p\text{CO}_2$, and $p\text{O}_2$, as shown in Fig. 6. It was the first complete blood gas sensor, and it combines the use of fiber optics with a smooth shape and size to avoid creating turbulence in the blood flow, and a covalent heparin coating to reduce thrombogenicity.

Two methods dominate for the measurement of pO_2 . The first and most popular employs the amperometric Clark electrode, which consumes O_2 and generates H_2O_2 and OH^- as by-products. The internal electrolyte in the sensor is separated from the external medium by a Teflon or silicone-rubber membrane that readily passes O_2 but prevents both water and other electrochemically active species from passing. Severe fouling of the membrane can reduce the rate of O_2 diffusion and hence the response. The alternative optical approach relies on the efficient collisional quenching of most fluorophores by O_2 . As the fluorescence intensity is inversely proportional to pO_2 , the reduction in intensity can be used as the basis of a fiber-optic sensor. Because this method relies entirely on the intensity of the fluorescent signal, it is subject to drift and degradation from photobleaching and thus is not appropriate for long-term use.

The same hydrophobic membranes that are permeable to O_2 are also permeable to CO_2 , so they may be placed over pH electrodes or pH-sensitive optical probes containing bicarbonate buffer for selective determination of pCO_2 (Zhujun and Seitz, 1984; Gehrich *et al.*, 1986).

BIOSENSORS

Definition and Classification

The repertoire of chemicals that can be determined by the sensors mentioned previously is relatively limited. To determine the presence or concentration of more complex biomolecules, viruses, bacteria, and parasites *in vivo*, it is necessary to borrow from nature (Fig. 7). Biosensors are sensors that use biological molecules, tissues, organisms, or principles. This definition is broad and by no means universally accepted, although it is more restrictive than the other common interpretation that would include all the sensors described in this chapter. The leading biological components of biosensors are summarized in Table 4. Enormous progress has been made in the development of biosensors in recent years, and this work has been recently and exhaustively reviewed (Turner *et al.*, 1987; Kohli-Seth *et al.*, 2000; West *et al.*, 2003; Nakamura *et al.*, 2003; Jain, 2003; Ziegler, 2003; Vo-Dinh *et al.*, 2000).

FIG. 6. A schematic drawing of the probe of the Cardiovascular Devices System 1000 fiber-optic blood gas sensor, based on three different combinations of selective membranes and fluorescent probes. Light enters and leaves from the left.

Most of the applications have been in the realm of analytical chemistry for use in chemical processing and fermentation, with the exception of development of enzyme-based glucose sensors, on which we will focus.

Currently, commercially available are biosensors for glucose (used first in an automated clinical chemistry analyzer and based on glucose oxidase), lactate, alcohol, sucrose, galactose, uric acid, alpha amylase, choline, and L-lysine. All are amperometric sensors based on O_2 consumption or H_2O_2 production in conjunction with the turnover of an enzyme in the presence of substrate. A urea sensor is based on urease immobilized on a pH glass electrode (Turner, 1989). Most of these sensors are macroscopic and are employed in the controlled environment of a clinical chemistry analyzer, but the ExacTech device, manufactured by Baxter since 1987, is a complete glucose sensor containing disposable glucose oxidase-based electrodes, power supply, electronics, and readout in a housing the size of a ball point pen. One places a drop of blood on the disposable electrode and a few seconds later a fairly accurate reading of blood glucose is obtained. It is widely believed that much more frequent measurement of blood glucose with correspondingly frequent adjustments of the dose of insulin delivered could significantly improve the long-term prognosis for insulin-dependent diabetics. Increasing the frequency of the current sampling method (i.e., puncturing the finger for drops of blood) is not acceptable. Much progress has been made toward the goal of producing a glucose sensor that could be implanted for a period of time in the tissue or blood (Thome-Duret *et al.*, 1996; Hu and Wilson, 1997; Reach and Wilson, 1992; Ishikawa *et al.*, 1998; Gerritsen *et al.*, 1998; Shichiri

FIG. 7. The development of biosensors is driven by increased need for biochemical information in the medical community, and the knowledge that nature senses these chemicals best, combined through emerging technologies to interface the biochemicals with physical transducers.

TABLE 4 Biological Components of Biosensors

Binding	Catalysis
Antibodies	Enzymes
Nucleic acids	Organelles
Receptor proteins	Tissue slices
Small molecules	Whole organisms
Ionophores	

The two categories are not mutually exclusive, for example, some enzymes may be employed for binding alone.

TABLE 5 Advantages and Disadvantages of Biochemicals for Chemical Detection

Advantages for binding:
“Uniquely” high selectivity
Possibility of raising antibodies to nearly all antigens
Antibodies and biotin–avidin system allow selective attachment of markers and reporters of binding
High binding constants possible
Several possible detection modalities
Ion flux through gated channels can provide gain
Advantages for catalysis:
For every biochemical there is an enzyme that can be used to detect its presence
High selectivity possible with some enzymes
Several possible detection modalities
Enzymatic cascades can provide gain
Universality of redox coupling and pH effects permit common transduction schemes
Disadvantages of biosensors:
Biomolecules generally have poor thermal and chemical stability compared to inorganic materials
The function of the biological component usually dictates that they must have narrow operating ranges in temperature, pH, ionic strength
Susceptibility to enzymatic degradation is universal
Need for bacteriostatic techniques in their fabrication
Time-dependent degradation of performance is guaranteed with the use of proteins
Production and purification can be difficult and costly
Immobilization can reduce apparent activity of enzymes or kill them outright
Most live organisms need care and feeding

et al., 1998). However, the problem is a formidable one that epitomizes the attempts to develop biosensors for *in vivo* use.

Background

The Utility of Biochemical Approaches to Sensing

Some of the many advantages of using biochemicals for sensing are summarized in Table 5. The most important is that, despite the disadvantage of using chemically labile components in a sensor, they allow measurement of chemical species that cannot otherwise be sensed. Sensors have been fabricated that incorporate small biochemicals such as antibodies, enzymes and other proteins, ion channels, liposomes, whole bacteria and eukaryotic cells (both alive and dead), and even plant and animal tissue.

Immobilization

One of the key engineering problems in biosensors is the immobilization of the biochemistry used to the transducing device. Approaches range from simply trapping an enzyme solution between a semipermeable membrane and a metal electrode, to covalently cross-linking several enzymes to a porous hydrogel coated on a pH electrode, to covalently cross-linking a complete monolayer of antibody to the surface of an optical fiber. The immobilization of a layer of material

over the transducing device increases the response time, so for altered sensitivity and greatly enhanced selectivity, speed is often sacrificed. Monolayers do not contain much material, so to detect binding of so few molecules, it is generally necessary to employ some amplification scheme, such as attachment of an enzyme to an antibody that announces its presence by converting a subsequently added substrate to a large quantity of readily detected product. Such schemes add complexity and time to the detection. Immobilization also has unpredictable effects on the activity and stability of biochemicals.

Sensing Modalities

Potential-Based Sensors (pH and ISE)

Some of the first biosensors employed enzyme-catalyzed reactions (such as those of penicillinase, urease, and even glucose oxidase) that affect pH. By putting a pH electrode into the solution containing the enzyme it is possible to monitor the rate of enzymatic turnover. It is also possible to use pH to monitor the change in production of CO₂ by bacteria in the presence of substrates that they are capable of metabolizing (Simpson and Kobos, 1982). However, there is always a problem for *in vivo* use of pH-based sensors related to the fact that the external environment is capable of strong buffering of pH changes, and any change in pH in the immediate environment of the sensing surface is reduced toward the bulk pH by a degree that depends on the strength of that buffering.

Electrochemical Sensors

Many enzymes perform oxidation and reduction reactions and can be coupled, if indirectly, to electrodes. The electrochemically active species in enzymes is generally a cofactor (Table 3) that, when bound, is not accessible to the electrode surface at which the electron transfer must take place for detection. In the case of the glucose oxidase reaction, the normal biological reaction is:

The enzyme uses an FAD coenzyme to mediate the oxidation, and the resultant FADH₂ is directly oxidized by O₂ to return to FAD to prepare for the next catalytic reaction. Unlike NAD and NADP, FAD is tightly bound to the enzyme, so normally only a small diffusible molecule such as O₂ can gain access to it to alter its oxidation state. This means that under many circumstances, such as those present in tissue, the concentration of O₂ is rate limiting, so the sensor often measures not glucose but the rate at which O₂ can arrive at the enzyme to reoxidize its cofactor. There are two electrochemical ways to couple the reaction to electrodes: monitoring depletion of O₂ by reducing what is left at an electrode, or monitoring buildup of H₂O₂ by oxidizing it to O₂ and protons. The latter approach is generally used to avoid direct effects of O₂ variation on the electrode, but this does not completely solve the problem. The electrode reaction for peroxide oxidation is as follows:

The best solution to date to cast off the tyranny of the rate-limiting step of O₂ diffusion has been the use of electrochemical

FIG. 8. The structure of the ferrocene–ferrocinium ion couple that allows one to overcome the dependence of the glucose oxidase reaction on pO_2 . The two five-membered rings are cyclopentadienyl anions and the iron may be in either the Fe^{2+} or Fe^{3+} states, giving a total charge of 0 or +1.

mediators that are at a higher concentration than O_2 and can therefore shuttle back and forth between the protein and the electrode faster than the enzyme is reduced, so that the arrival of the substrate such as glucose is always rate limiting. A typical chemical that works in this way is ferrocene, a sandwich of an iron cation between two cyclopentadienyl anions (Fig. 8). It exists in neutral and +1 oxidation states that are readily interconvertible at metal or carbon electrodes. A proprietary modified ferrocene is used in the aforementioned ExacTech carbon electrode–based glucose sensor. Other glucose oxidase–based electrodes have been employed on catheters for *in vivo* determination of blood glucose, with varying degrees of success (Gough *et al.*, 1986). Thrombus formation is generally a problem, as is the possible alteration in localized glucose levels in tissue traumatized by insertion of probes, no matter how small. It may well be that use of the techniques employed in keeping pressure catheters clear will also work with biosensors such as this.

An elegant and oft-tried approach that avoids many of the problems inherent in implantable sensors is to extract fluid from the body and to measure the glucose concentration of that fluid. In the past few years, the Cygnus Corporation has developed the use of iontophoretic extraction of glucose through the skin for its GlucoWatch—a wristwatch-sized device that requires no puncturing of the skin. By passing a small current between two electrodes on the skin, ions and neutral species are made to flow from the extracellular fluid space to a gel pad under one electrode. Glucose oxidase in the gel pad reacts with the glucose, producing a measurable analyte (H_2O_2), which is subsequently detected electrochemically. The electrodes with their overlayer of gel-immobilized enzyme last 12 hours, and every few days the wearer has to move the watch to prevent skin irritation.

Optical Waveguide Sensors

Fiber optics can be used either as thin flexible pipes to transport light to and from a sensor at a remote site, or in a way that takes advantages of the unique properties of optical waveguides. The former mode still dominates, and the CDI blood gas sensor uses three fibers just to move photons to and from the small volumes of immobilized chemistry at the probe end. The Schultz fiber-optic glucose sensors involve a more

sophisticated use of the light path exiting the optical fiber combined with clever use of lectin biochemistry. In principle, these sensors allow continuous measurement of blood glucose. There are at least two features specific to waveguides that have been used for sensors for *in vitro* measurement that may soon find themselves ready for *in vivo* use as well. In one, the ability of light sent down two fibers to interfere with itself on return to the source allows sensitive measurement of changes in the length or phase velocity of the fibers. This, in turn can be altered by enzymatically induced changes in the temperature of the fiber or its cladding in the volume surrounding the fiber. Another approach is to use the light in the evanescent wave that exists in the region just outside the waveguide to probe a small volume adjacent to the surface. If binding species such as antibodies are immobilized on the surface, it is possible to selectively excite and collect fluorescence from the surface layer even in the presence of high concentrations of fluorophore or other absorbers in the bulk solution. This technique has allowed the use of antibody-based detection of analytes such as theophylline in whole blood in a sensor designed by the ORD Corporation. These sensors are primarily for single use, and one fiber is used for each measurement. Nonspecific adsorption to the fiber surface, which is a serious interference in such sensors, can be reduced by using surface passivating films of proteins such as bovine serum albumin.

Complex fiber-optic sensors have been developed (Michael *et al.*, 1998). These use imaging fiber optic bundles (with as many as thousands of individual fibers) to create an array of multiple chemical sensors. By selectively illuminating the proximal end of single fibers one at a time (or in patterns), it is possible to photopolymerize selective chemistries onto the end of the illuminated fibers. This allows the creation of arrays of probes at the end of the bundle with as many different chemistries as there are polymerization steps. This approach has been applied to a variety of different chemical detection scenarios (While *et al.*, 1998; Healey *et al.*, 1997a, b).

Today the most rapidly growing type of waveguide sensor actually does not use a waveguide at all. In surface plasmon resonance (SPR), light is totally internally reflected from an interface that is coated with a very thin film metal such as gold. At a specific phase matching angle, light from the incoming beam is coupled strongly into plasmons in the metal surface film, where it propagates for a short distance. The advantage of this technique over conventional waveguide approaches is that a very large fraction of the input beam is coupled into a very thin layer near the surface. Since the phase matching condition is strongly dependent on the refractive index of medium adjacent to the metal film, but in the low-index layer, small changes in the protein content in that layer can be easily detected. Because the analyte can be measured with no requirement that it be modified by an optical or chemical label, this approach is inherently less expensive and faster than other techniques with comparable sensitivity. Commercial instruments in planar and fiber-optic configurations have become available, and SPR monitoring of proteins and other molecules is rapidly becoming a standard research laboratory technique. As yet there are no commercial instruments for *in vivo* use based on SPR.

Acoustic/Mechanical Sensors

Binding of material to surfaces changes its mass, which can change either the object's resonant frequency or the velocity of vibrations propagated through it. This has allowed development of sensors called surface acoustic wave (SAW) or bulk acoustic wave (BAW) detectors that are based on oscillating crystals. Sensitive detection of analytes is relatively easy in the gas phase, and while there have been reports of selective detection of analytes using immobilized antibodies, there is still controversy as to how or if the technique works when the oscillating detector is in contact with liquid. It is, however, unlikely that this technique will prove applicable to *in vivo* use, where some nonspecific adsorption of protein is almost unavoidable.

Thermal and Phase Transition Sensors

Chemical reactions can give up heat because they involve breaking and formation of chemical bonds, each of which has a characteristic enthalpy. There is also a strong effect of the heats of solution of the substrates and products, particularly charged species. Many enzymatic reactions release 25 to 100 kJ/mol, or 5 to 25 kcal/mol (Table 6). A 1-mM solution of substrate completely enzymatically converted to product with a 5-kcal/mol heat of reaction would increase in temperature by 0.005°C, which is readily measurable in laboratory conditions. Sensors based on this principle are in use as detectors in chromatography and in principle could be applied to almost any enzymatic reaction. Some reactions have little or no heat production (e.g., ester hydrolysis, such as the acetylcholinesterase reaction) but can be observed using "tricks" such as coupling the reaction to the heat of protonation of a buffer such as Tris:

Alternatively, a sequence of enzymes such as glucose oxidase followed by catalase can be used, which converts the hydrogen peroxide produced by the oxidase to O₂ and water in another exothermic reaction (Danielsson and Mosbachs 1987). However, the technical difficulties in making such measurements in the thermally noisy environment of the human body have so far prevented application of this principle to development of *in vivo* sensors.

An alternative thermal approach is to use the depression in phase transition temperatures of pure compounds by dissolving in them dissimilar small molecules that prefer the fluid

TABLE 6 Enthalpies of Some Enzymatic Reactions

Enzyme	Substrate	$-\Delta H$ (kJ/mol)
Catalase	H ₂ O ₂	100
Cholesterol oxidase	Cholesterol	53
Glucose oxidase	Glucose	80
Hexokinase	Glucose	28
Lactate dehydrogenase	Sodium pyruvate	62
NADH dehydrogenase	NADH	225
Penicillinase	Penicillin-G	67
Urease	Urea	61

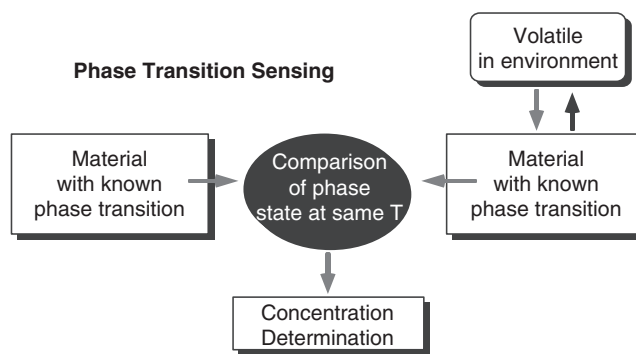

FIG. 9. A schematic diagram of the process of phase transition sensing, which is an application of the well-known purity dependence of phase transition temperatures. Some diagnostic technique must be applied to allow a quantitative comparison of the phase states of two samples of the material, one of which is in equilibrium with small molecules in the environment, and another of which is at the same temperature, but chemically isolated.

phase over the crystalline phase. If the temperature is known, the concentration of the small molecule can be determined by the extent of the freezing-point depression (Fig. 9). This principle has been successfully applied to the detection of general anesthetics and is now being applied to the development of a fluorescence-based fiber-optic probe for *in vivo* use (Merlos, 1989; Merlo *et al.*, 1990).

Biomembrane-Based Sensors

A complex biological system that has been applied to the development of sensors is the biological membrane and the lipids and proteins that make it up. Numerous approaches have been made to apply lipid bilayers to chemical detection, including at least two sensors for general anesthetics (Merlo, 1989; Merlo *et al.*, 1990; Wolbeis and Posch, 1985). Membrane receptor proteins are responsible for transducing many important biological binding events and could be used to great advantage for monitoring such chemicals as hormones, neurotransmitters, and neuroactive drugs. Several schemes have been tried to this end, including immobilizing ligand-gated ion channel receptor proteins in fiber-optic devices and measuring the binding of fluorescently labeled ligands, and reconstituting them into defined lipid monolayers on solid electrodes (Eldefrawi, *et al.*, 1988) and across holes as bilayers (Ligler *et al.*, 1988). These electrical techniques promise the most sensitive detection, as a single channel opening can be monitored electrically, but also involve some of the most difficult technical challenges, including stabilizing of the normally fragile lipid bilayer. An ancillary benefit of the use of biomembranes is that phospholipids have been reported to enhance the biocompatibility of biomaterials, so they may have a dual role in bilayer-based sensors.

Microfabrication-Based Sensors

The use of microfabrication has become a central tool in the development of many types of sensors. The first attempt to meld semiconductors with chemical and biosensors was use of the chemical field-effect transistor, which has now become

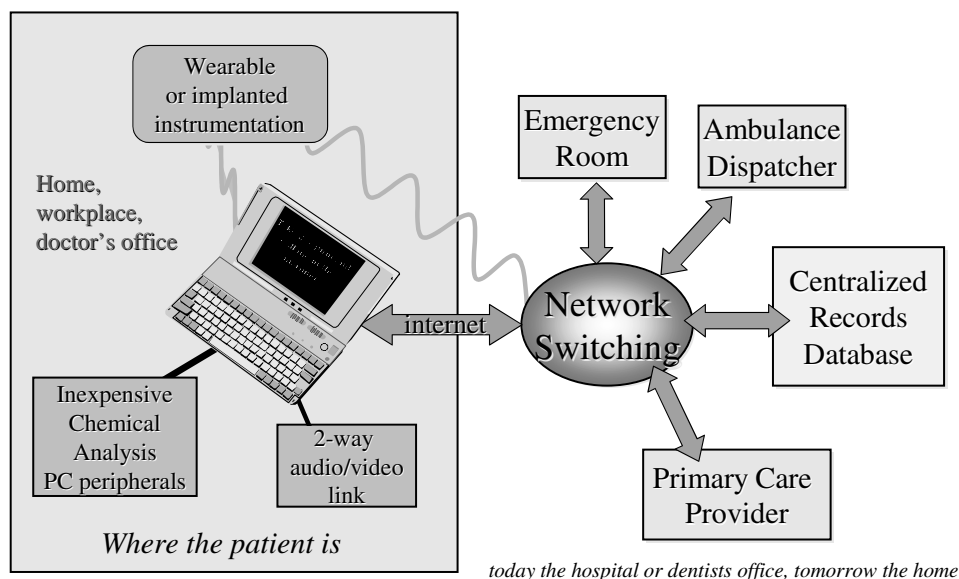

FIG. 10. A concept for a new type of doctor-patient interface as part of vision of distributed diagnosis and home healthcare (D2H2). By utilizing the existing infrastructure for wired and wireless data communication, as well as existing capabilities for storing large amounts of patient data, it will be possible in the near future to allow patients to maintain an up-to-date record of many different health parameters without frequent visits to hospitals and physicians. For biomaterials purposes, the most important data will concern the status of implanted devices and systems.

a commercial product, as least for the measurement of pH. Subsequent use of microfabrication has focused on fluidic channels, optical windows, and electrodes with dimensions ranging from millimeters to micrometers. Foremost among the applications of microfabrication has been the forming of small channels in insulating materials (such as glass or plastic) for capillary electrophoresis. Although strictly speaking a chromatographic technique and not a sensor technique, integrated systems that incorporate both microcapillary electrophoresis and optical or electrical detection have so many of the functions of a sensor that the differentiation is perhaps no longer meaningful. The strong interest in making highly parallel arrays of capillaries for high-throughput screening and DNA diagnostics has prompted intense development activity in microcapillary arrays both in academe and in industry.

The small dimensions of microchannels allow new types of devices to be designed that have no parallel in the macroscopic world. Several laboratories have lately exploited the properties unique to the low-Reynolds-number flows usually found in microdevices to create novel sensors and sensor systems. The primary use for such components has, so far, been in tabletop instruments. However, there is every reason to believe that such devices will soon work their way into *in vivo* systems as well.

MICROTOTAL ANALYTICAL SYSTEMS AND THE FUTURE

In the near future, several factors can be expected to influence the development of sensors. Once it has been demonstrated that a given type of sensor has practical value, the process of making it cheaply and reproducibly becomes

supremely important in determining whether it sees the marketplace. Automation of the fabrication of small *in vivo* probes will be a high priority in the next few years. There will probably be a great increase in chemical sensors that are manufactured from the start with silicon microfabrication in mind, rather than the current practice, which is generally scaling beaker chemistry down to the size of microchips. The problem of ensuring that a sensor is as biocompatible as possible, while maintaining its function, will continue to be the most pressing problem for *in vivo* use for some time. Advances must continue to be made in materials, probe shape and size, site of use, and manufacturing. There will continue to be a strong emphasis on development of noninvasive techniques that will avoid the difficulties of biocompatibility. It may well be that near-infrared spectroscopy and magnetic resonance imaging techniques will be able to provide sufficient chemical information to diagnose some disease states. The biomolecules employed in biosensors have so far been restricted to natural enzymes and antibodies, but there is every reason to expect that as it becomes more common to tailor molecules for particular jobs, we will be able to improve on nature for transduction of chemical events.

One of the most exciting areas in chemical sensors research is microfabricated total analytical systems, or μ TAS. Its great appeal is the potential to place complete miniaturized chemical sensing instruments in many more locations than is now possible. Current capabilities for both wired and wireless communication have advanced to the point that we can envision dense and extensive networks of sensors connected to central processing facilities for applications ranging from environmental monitoring to process control, agriculture, and biomedical diagnostics. It is also clear that medical care can be greatly improved by moving more biomedical diagnostics out of the

centralized medical laboratory and into the operating room, the ambulance, by the patient's bedside (both in and out of the hospital), and into the medicine cabinet at home (see Fig. 10). With increasing reliance on complex courses of medication to improve and extend the lives of an aging population, there is a large potential market for medical chemical monitoring. Microfluidics will play a central role in enabling instruments capable of complex chemical measurements in instruments that will be small enough to be practical. Microfluidics can be viewed as an enabling technology in the decentralization of medicine.

Several near-term developments could be very advantageous for the development of chemical and biochemical sensors. These include the following:

- Development of microfluidic automation of most common sample preconditioning steps to eliminate the need for restricting chemical testing to use only by trained personnel
- Availability of a wide range of both semi-permanent and single-use disposable microfluidic chemical analytical systems for complex chemical analysis in packages the size of a cellular telephone
- Elimination of the need for large centralized laboratories and the associated long lag between sample collection and receipt by the user of interpreted chemical information
- Ready availability of inexpensive small sensors connected via wire and wireless links to networked two-way data transmission systems—"distributed chemical sensing networks"

The distribution of biomedical analysis of fluids to remote sites could not only improve medical care, but also empower the individual to be more active in the maintenance of his or her own health.

Clearly, this technology must be inexpensive, chemically versatile, and relatively accurate to be successful as a commercial product. The size of samples of blood will have to be on the order of a few drops. This immediately brings us into the realm of microfluidics. Practical implementations of microfluidics require dealing with samples far more complex than those regularly introduced into instrumentation with such narrow channels. Microfluidics systems are very vulnerable to problems inherent in unrefined samples to be encountered in the scenarios for which these instruments are being proposed. For example, many of the best sensing technologies in the analytical chemist's arsenal are not suited to complex mixtures of analytes with overlapping interfering signals. This is true for both optical and electrochemical detection methods. Surface fouling is a many-faceted problem in small channels, in that it can lead to converting every fluid transport channel into a chromatography column or, in the worst cases, can lead to loss of the entire sample to an irreversibly adsorbed layer upstream of the detector (see Chapter 2.13, "Nonfouling Surfaces"). Electrochemical sensors have always been vulnerable to fouling, but in microfluidic systems, the electrodes will usually not be removable for refurbishment by the user. Some types of ancillary techniques, such as electro-osmotic pumping, dependent as they are on the nature of the chemistry of the

channel walls, are particularly susceptible to disruption by sample-to-sample variability.

Finally, colloidal suspensions, whether biological, organic, or inorganic in nature, are a threat to continuous operation. Depending on individual size, charge, and state of aggregation, they can clog small channels, remove coatings on channel surfaces, and interfere with optical measurements. The severity of the problems caused by fouling and clogging depends on whether the analytical instrument is planned for continuous multisample analysis or is designed around disposable single-use sample-contacting components. However, the presence of particles is a serious problem in both cases and has not been adequately dealt with in all but a few instrument designs. These instruments will be moving to nonlaboratory situations and environments in which users will have little or no training, so the instrument itself must perform nearly all sample preconditioning steps. The user will not perform anything more complicated than putting samples in the machine, and perhaps not even that!

To make point-of-care medical diagnostics work outside the hospital or doctor's office, the patient has to self-sample the blood. Current methods for removing a drop or two from the finger are too painful to be used frequently or casually. As a role model, blood-sucking insects have developed ways to remove small volumes of blood from the human body with little notice by the human. MEMS-based devices that could emulate the mosquito would enable the development of user-friendly monitors of blood chemistry.

Regardless of the nature of the sensor, it is clear that the continuing reduction in the size and cost of computers will be reflected in increasing use of sensors to provide crucial input in "smart" devices, be they for the control of drug delivery or of prosthetic limbs. Automated health-care delivery systems will reduce the need for reliance on the constant vigilance of overloaded hospital personnel and allow the chronically ill to be monitored and treated outside of a hospital setting.

SUMMARY

Physical and chemical sensors are already important in the diagnosis and treatment of the critically and chronically ill. New physical, chemical, biochemical, and biological sensing technologies are currently under development that could greatly augment our current *in vivo* capabilities. Biocompatibility remains the most important problem for all such sensors, particularly for biosensors and other chemical sensors in which transport of material is vital to function. The economic and human impact of improving the lot of diabetics is such that success of such a sensor will open the way for many other *in vivo* biosensors.

Acknowledgments

I thank the faculty and students of the Biomaterials group of the Center for Bioengineering for acquainting me with the state of the art in solutions to the biocompatibility problem, and my own students and postdocs for helping me continue to learn about sensing.

7.18 DIAGNOSTICS AND BIOMATERIALS

Peter J. Tarcha and Thomas E. Rohr

INTRODUCTION

The ability to make quantitative measurements is critical to progress in any technical discipline. In medical diagnostics, very small quantities of analytes often need to be quickly and accurately measured in complex biological mixtures.

TABLE 1 Typical Analytes in Solid Phase Immunoassay

Category	Example
1. Clinical	
a. Therapeutic drugs	a. Digoxin
b. Hormones	b. Thyroid stimulating hormone
c. Pregnancy/fertility	c. Human chorionic gonadotrophin/estradiol
d. Cardiac markers	d. Troponin I
e. Infectious disease	e. Hepatitis B surface antigen
f. Hemotological analytes	f. Ferritin
g. Cell surface markers	g. CD4/CD8 ratio
h. Cancer	h. Prostrate specific antigen
i. Allergy	i. Immunoglobulin E
j. Genetic testing	j. DNA sequences for paternity/forensics/heredity
k. DNA probes	k. Hepatitis C
2. Other	
a. Agricultural	a. Aflatoxin
b. Environmental, e.g., pesticides	b. Diazinon
c. Veterinary	c. Canine heartworm

This is accomplished by using the ability of certain pairs of biomolecules to bind to one another at high affinities. Individual members of such a pair of molecules are generally referred to as ligands, and as members of a ligand binding pair. High-affinity binding confers high specificity, and the use of binding molecule pairs has allowed the design of assays which have revolutionized the field of medical diagnostics. Examples of some current diagnostic assays utilizing binding molecules are shown in Table 1.

The most important use of a biomaterial in a binding molecule-based clinical diagnostic assay is to serve as a compatible solid phase or as a support to which specific binding molecules, such as antibodies and antigens, will be attached. These immobilized binding molecules specifically capture analytes or other ancillary reagents from a test mixture. In the most common assay formats, the test mixture is then removed and the solid phase washed by addition and removal of a wash solution. Subsequent assay steps involve the addition and removal of required reagents, again followed by wash steps. In earlier formats, the inside of a polystyrene test tube or microtiter plate well often served as the solid phase. More recently, microparticles and nanoparticles have replaced coated vessels as the solid phase of choice. Particles provide a larger total surface area upon which to immobilize binding molecules and can be manufactured as liquid suspensions. A dispersed configuration also greatly reduces the diffusion distances of soluble reagents to the solid phase, shortening the incubation times required for recognition and binding. Furthermore, since the reaction vessels are not coated with binding molecules, they need no special handling, are much less expensive to produce, and are suitable for use with any of the assays of a product line. The use of microparticles can, however, complicate the separation of the solid-phase reagent from other components of the test mixture. Much of the current activity in the development of new ligand binding assay formats involves either

automation of the steps of traditional assay schemes or design of homogeneous assay formats that do not require separation or wash steps. Four examples of traditional ligand binding immunoassay formats are illustrated in Fig. 1.

This chapter will not review the chemical properties, methods of characterization, or surface modifications of the many solid-phase biomaterials currently used in medical diagnostics. This subject has been reviewed previously (Tarcha, 1991) in a treatise on the theory and practice of solid-phase immunoassay (Butler, 1991). The current chapter is intended to present trends and new concepts in the use of biomaterials for medical diagnostics, many of which have not yet been commercialized.

NEW SOLID-PHASE MATERIALS FOR LIGAND BINDING ASSAYS

Particles

Some of the very attributes that make micro- and nanoparticulate solid-phase reagents attractive for use in ligand binding assays can also be detrimental. Unlike the case with coated reaction vessels, the separation of a microparticle solid phase reagent from other reaction components can be difficult. Particles can usually be separated from a reaction mixture by centrifugation; however, when there is no significant difference in density between the particle and the continuous phase, high *g* forces may be necessary. Centrifugal sedimentation of protein-coated microparticles can cause them to become aggregated, necessitating the use of energetic means (e.g., sonication) to redisperse them. In addition, assay formats using centrifugal force are not easily automated.

Microparticles can be separated from other reagents by capture upon appropriate filters or membranes, but subsequent recovery for further reaction steps can be difficult. Examples of commercially successful semiautomated clinical analysis systems using filter recovery of microparticles include the IMx and AxSym instruments marketed by Abbott Laboratories (North Chicago, IL). These instruments utilize microparticle capture enzyme immunoassay (MEIA) technology, which efficiently separates bound and unbound immunoreactants by the capture and washing of the microparticle solid-phase reagent on a glass fiber matrix. Further assay steps and signal development are performed on this matrix (Fiore *et al.*, 1988).

A unique reagent system has been described that used solution kinetics for the ligand binding reactions, followed by the formation of a microprecipitate solid-phase *in situ* (Monji and Hoffman, 1987). The system took advantage of a water-soluble, thermally precipitating polymer, poly(*N*-isopropylacrylamide), that was conjugated to a monoclonal antibody. This polymer precipitated reversibly from water above a critical temperature of 31°C, enabling bound immune complexes to be precipitated, centrifuged, and washed repeatedly. Nonspecific binding, which normally produces backgrounds in conventional solid-phase systems, was low because of the hydrophilic nature of the polymer and resulting precipitate.

FIG. 1. Schematic outlines (a–d) for noncompetitive solid-phase enzyme immunoassay formats. The solid phase comprises antigen (formats a, b) or antibody (formats c, d) immobilized on a solid support. In the first incubation, these immobilized binding molecules capture the soluble analyte (antibody in formats a and b, antigen in formats c and d) from the sample. Different methods can be used to detect the captured analyte, indirectly with labeled antibody (formats a and c) by a bridge (format b), or by more elaborate indirect procedures (format d). (Reprinted with permission from Tijssen, 1985, copyright 1985, Elsevier Science.)

Intrinsically Colored Particles

In the past 7 or 8 years there has been an increasing use of rapid, “self-performing” assays utilizing chromatography strips (Pope *et al.*, 1996, 1997a, b; Tarcha *et al.*, 1991). In such a format, a binding molecule such as an antibody or antigen is immobilized in a “capture zone” midway along a porous strip. Colored colloidal particles coated with binding molecules are deposited between the capture zone and the site of test sample application. The particles become hydrated and are carried along with the test sample as it moves along the strip by capillary action from its site of application. Test samples can be applied by pipette or dropper, or by dipping one end of the strip in the test sample. In a direct “sandwich” assay, binding molecules on the colored particles capture analyte from the test sample as they travel along the strip. The particles become captured and produce a colored region when the immobilized binding molecules of the capture zone bind to analyte that has bound to the particles. The analyte becomes “sandwiched” between the binding molecules immobilized on the strip and

those on the particles. In a “competitive” format, either the binding molecules on the particles or of the capture zone are analogs of the analyte. In the absence of free analyte, the binding molecules on the particles will bind directly to the binding molecules of the capture zone of the strip. The presence of analyte in the test sample inhibits binding of the colored particles at the capture zone as analyte molecules occupy the binding sites of one set of binding molecules. For qualitative assays these events can be observed visually without the aid of an instrument. Quantitative results can be obtained with the use of surface densitometers, colorimeters, or fluorometers.

Latex particles that have been imbibed with dyes are available commercially and have been used for tests of this sort. Higher apparent extinction coefficients can be gained through the use of particles that are intrinsically colored because of their chemical structure. For example, colloids made of selenium have been used as red labels in visual strip-based immunoassays (Yost *et al.*, 1990). Methods of producing selenium colloids for

use in immunoassays and their surface properties have been described (Mees *et al.*, 1995).

Nanoparticles made of polypyrrole have also been used as intrinsically colored labels in immunoassays. The intense black color of polypyrrole (apparent molar absorption coefficient $\epsilon_{\max} \sim 10^5 \text{ L mol}^{-1} \text{ cm}^{-1}$) is presumably due to electronic transitions within the conjugated chain structure. These particles can be functionalized to permit covalent attachment of binding molecules (Tarcha *et al.*, 1991). More recent work (Bieniarz *et al.*, 1999) has indicated that intentional surface modification for covalent antibody immobilization may not be necessary because of the propensity of nucleophiles such as thiols and amines to add to the electrophilic sites of the polypyrrole. Composite nanoparticles of colloidal silica combined with polypyrrole were developed at the University of Sussex (Maeda and Armes, 1993, 1994; Maeda *et al.*, 1995) and have also been shown to function well in immunoassays (Pope *et al.*, 1996).

Magnetically Responsive Particles

Current Strategies The desire to automate microparticle-based ligand binding assays has led to a search for alternatives to centrifugation or filtration as a means of separating microparticles during reagent changes and wash steps. One approach is to use microparticles that will respond to a magnetic field. Application of an external magnetic field to a reaction vessel can cause magnetically responsive microparticles in the test mixture to migrate to the vessel wall, where they can be held by the field while reagent changes and wash steps are performed. Removal of the field releases the microparticles for reaction with the next assay reagent. For this assay format to be practical, the coated microparticles must have surface properties that make them resist irreversible aggregation during magnetic capture. Furthermore, although the particles must exhibit a strong degree of magnetization while in a magnetic field, their magnetization must be lost when the field is removed; otherwise they will continue to attract one another in the absence of the magnetic field and be difficult to disperse.

Materials displaying these magnetic properties are referred to as being *superparamagnetic*.

For a material to be superparamagnetic, the individual particles of magnetic material must be so small, typically 2–20 nm, that they constitute only a single magnetic domain, and they must be kept dispersed so no permanent long-range magnetic order can form in an applied magnetic field. Superparamagnetic microparticles can be produced by dispersing nanoparticles of magnetically responsive material within colloidal particles or by distributing them within the voids of porous microparticles. Superparamagnetism is also displayed by liquid dispersions of monodomain magnetic nanoparticles. Such dispersions are referred to as *ferrofluids*.

Superparamagnetic microparticles suitable for use in diagnostic ligand binding assays are available commercially from several suppliers (Table 2). For example, Bang's Labs distributes a superparamagnetic microparticle preparation produced by dispersing monodomain Fe_3O_4 nanoparticles in colloidal polystyrene. The result is polydisperse with an average particle diameter of 1 μm . This type of particle will have some of the Fe_3O_4 nanoparticles exposed on the microparticle surface, which can cause inactivation of some sensitive biological reagents, especially enzymes. For these cases, particles having a polystyrene coat applied over the Fe_3O_4 -bearing particle are also offered. Polysciences, Inc., produces superparamagnetic "Biomag" microparticles by applying an aminosilane coating to magnetite nanoparticles. The resulting nanoparticle aggregates are somewhat polydisperse with diameters centered around 1.5 μm . Monodisperse superparamagnetic microparticles are produced by Spherotech, Inc., and Interfacial Dynamics Corp. A monodisperse polystyrene core particle is coated with a shell containing Fe_2O_3 nanoparticles, then with an outer shell of polystyrene. Because the magnetite is contained only in a shell region, these particles usually cannot display as strong a magnetic response as those having a uniform dispersion of magnetite throughout the particle. Superparamagnetic microparticles available from Dynal begin with a porous polyurethane latex core. Nanocrystals of Fe_2O_3 and Fe_3O_4 are precipitated within the pores of the core particle, then a

TABLE 2 Suppliers of Magnetically Responsive Particles Useful in Ligand Binding Assays

Supplier	Particle size	Composition	Comments
Bang's Labs, Indianapolis, IN	1 μm	Fe_3O_4 nanoparticles dispersed in colloidal polystyrene	Polydisperse
Interfacial Dynamics Corp., Portland, OR	2.8 μm	Colloidal polystyrene core coated with Fe_2O_3 shell, then polystyrene outer shell	Monodisperse
Polysciences, Inc., Warrington, PA	1.5 μm	Aggregates of aminosilane-coated magnetite nanoparticles	Polydisperse
Spherotech, Inc., Libertyville, IL	1.0, 2.5, 4.0, 7.0 μm	Colloidal polystyrene core coated with Fe_2O_3 shell, then polystyrene outer shell	Monodisperse
Dynal, Inc., Lake Success, NY	2.8, 4.5, 5.0 μm	Fe_2O_3 and Fe_3O_4 precipitated inside porous microparticle	Monodisperse
CPG Corp., Lincoln Park, NJ	5 μm	Magnetite precipitated inside controlled-pore glass particles	Porous particles
Miltenyi Biotec Inc., Auburn, CA	30–70 nm	Magnetite core particle with dextran coat	Nanoparticles
Immunicorp., Huntindon Valley, PA	130–170 nm	Magnetite particles with protein overcoat	Nanoparticles

polystyrene coat is applied, resulting in a nonporous particle. CPG Corp. offers large, magnetically responsive porous glass particles in two size ranges of 37–74 and 74–125 μm diameter, with pore sizes ranging from 500 to 1000 Å.

Many of these microparticles are available with their surfaces modified with carboxyl, amino, or other chemical groups, which alter surface characteristics and allow the covalent attachment of binding molecules. Commercial suppliers also offer microparticles with various binding molecules already attached.

Another use of magnetically responsive reagents is in the sorting of particular types of living cells. Particles coated with binding molecules specific for unique surface ligands of certain types of cells will bind only to that cell type in a complex mixture of other cell types, such as whole blood. The cell–particle aggregate can then be separated from the mixture by the application of a magnetic field. For this application, aqueous-compatible ferrofluids are advantageous. Ferrofluids that can be dispersed in aqueous solutions are produced by dispersing nanocrystals of magnetite in very small (5–50 nm diameter) colloidal particles. Because of their small size, dispersed ferrofluids do not readily move in an applied magnetic field. The binding of multiple ferrofluid particles to a cell, however, can create an aggregate magnetic force on the cell–ferrofluid complex that is strong enough to achieve its separation. Use of ferrofluids has the advantage that unbound ferrofluid particles will not be captured. Immunicon and Miltenyi offer aqueous suspensions of somewhat larger nanoparticles with attached binding molecules for this purpose (Table 2).

The advantage of magnetically responsive reagents for automated immunodiagnosics is reflected in the fact that several of the commercial leaders in the field are using this technology in their current high-throughput immunoassay analyzers. Examples include Abbott Laboratories' Architect, Bayer's ACS 180 and Immuno 1, Beckman-Colter's ACCESS, Tosoh's AIA-1200 DX, and Johnson and Johnson's VITROS systems.

New Strategies Measurement of Magnetic Force An alternative method to simplify medical diagnostic immunoassay formats is to use the solid phase itself as the signal generator, eliminating the need for additional reagents and steps. Measurement of the magnetic force exerted upon magnetically responsive reagents by a magnetic field can serve as the assay readout signal. In a "sandwich" format, superparamagnetic microparticles coated with ligand binding molecules specific for a particular analyte are mixed with the test mixture and a solid phase that has also been coated with ligand binding molecules specific for the analyte. Presence of the analyte in the test mixture will cause some of the microparticles to become bound to the solid phase. Unbound or weakly bound particles can be removed by application of a magnetic field. The reaction vessel can then be moved near a magnet attached to a force-sensing device and the force exerted upon the magnet by the bound particles measured. The force exerted upon a typical superparamagnetic microparticle is more than nine orders of magnitude greater than that exerted by gravity upon a binding molecule the size of an antibody. This amplification allows assay sensitivities comparable to those of enzyme immunoassays to be achieved using conventional force measuring devices

such as electronic balances (Rohr, 1995). The resultant assay system contains only binding molecules and microparticles, greatly simplifying reagent production and stability. The binding of magnetically responsive microparticles to solid phases has also been measured using atomic force microscopes and micromachined cantilever devices (Baselt *et al.*, 1998).

Single-step assay formats are also possible using magnetically responsive microparticles. In Fig. 2A, a reaction vessel (RV) has a binding molecule (Ab1) specific for the analyte immobilized upon its bottom. A second binding molecule (Ab2) specific for a different site on the analyte is attached to a magnetically responsive microparticle to form the magnetic reagent (MR). The test sample containing the analyte of interest (A) and the magnetic reagent are introduced into the reaction vessel, which is fitted with a lid (L). The binding molecules on the microparticles bind whatever analyte is present, resulting in some fraction of the microparticles becoming bound to the vessel bottom through the analyte. The reaction vessel is placed on an elevator (E) below a magnet (M) attached to a microbalance (B). The microbalance is zeroed; then the elevator (E) moves the reaction vessel close to the magnet (Fig. 2B). The increased intensity of the magnetic field causes the unbound microparticles to be pulled to the underside of the vessel lid. Because of their close proximity, the unbound

FIG. 2. (A) One-step sealed vessel magnetic force immunoassay. Antibodies (Ab1) specific for an epitope of the analyte of interest (A) are immobilized on the bottom of a reaction vessel (RV). The analyte and a magnetically responsive reagent (MR) are introduced into the reaction vessel, which is fitted with a lid (L). The magnetically responsive reagent consists of a superparamagnetic microparticle coated with a second antibody (Ab2) specific for a second epitope of the analyte. The result of incubation is the binding of the magnetically responsive reagent to the vessel bottom through the captured analyte. (B) An elevator (E) moves the reaction vessel close to a magnet (M), causing unbound magnetically responsive reagent to be pulled to the underside of the lid, where it exerts an increased force upon the magnet, increasing its apparent weight as measured by the attached balance (B) (Rohr, 1995).

FIG. 3. Magnetic force immunoassay for alpha-fetoprotein (AFP). A test sample containing no analyte was mixed with the magnetically responsive reagent in the reaction vessel and incubated for 30 min at room temperature. The reaction vessel was then placed on the elevator in the remote position (Fig. 2A); the balance was zeroed and data collection began. After 30 seconds, the elevator was raised to position the vessel lid close to the magnet (Fig. 2B). The apparent weight of the magnet rapidly increased as unbound magnetically responsive reagent was pulled to the underside of the vessel lid (response A), where a 6-mg weight change was observed after 90 sec. For measurements of test analyte solutions, the elevator was lowered and the reaction vessel replaced with one containing the magnetically responsive reagent and AFP at a concentration of 15 μg per ml. After 150 sec incubation, the elevator was again raised to bring the vessel close to the magnet (response B). The responses C, D, E, and F were obtained with test solutions containing concentrations of AFP of 50, 100, 200, and 350 $\mu\text{g}/\text{ml}$ (Rohr, 1995).

microparticles collected under the lid exert a much stronger force upon the magnet than do those that remain bound to the well bottom. This force is displayed by the balance as an apparent change in the magnet's weight. By changing the distance between the reaction vessel and the magnet, the strength of the applied field can be adjusted to be just sufficient to pull nonspecifically bound particles off of the well bottom.

Results from an assay of this type developed for human alpha-fetal protein (AFP) are shown in Fig. 3. Assay of a solution containing no AFP resulted in virtually all of the magnetic reagent being pulled to the underside of the vessel lid, with an observed 6-mg force change (Fig. 3, trace A), or more than 10,000 times the rated sensitivity of the balance. Assay of samples containing 15, 50, 100, 200, and 350 ng of AFP resulted in decreasing force changes as more particles became bound to the well bottom through the captured AFP analyte (Fig. 3, traces B, C, D, E, and F, respectively). The sensitivity of this homogeneous immunoassay is comparable to that of current commercial immunoassays (Rohr, 1995).

Self-Assembled Monolayers

Unique possibilities for the micropatterning of metal surfaces containing specific biorecognition molecules have been shown by Whitesides and his group (Roberts *et al.*, 1998). They have engineered surfaces using self-assembled monolayers (SAMs) by designing a series of assembly molecules to

promote specific binding while simultaneously inhibiting non-specific binding. The basic structure of the assembly molecule is an alkane with a thiolate end group on one end and a poly(ethylene oxide) (PEO) spacer attached to the other. The free end of the poly(ethylene oxide) can be functionalized with a carboxylic acid group for activation and coupling with specific binding ligands. Thiols form bonds with metals such as gold and silver. When a surface of either of these metals is exposed to a thiolated SAM reagent, rapid *chemisorption* orients the carboxylated PEO outward from the surface for subsequent coupling to the specific binding molecule of interest.

Such reagents are ideally suited to analysis using a surface plasmon resonance (SPR)-based biosensor commercially available from BIAcore AB (Uppsala, Sweden). The sensor of this device can detect molecules binding to its surface and has the advantage of being able to monitor binding events in real time. SPR analysis is done by reflecting visible-to-near-infrared radiation off a textured surface that has been coated with a thin film of a coinage metal, typically silver or gold. The mobile electrons of the metal, combined with the topography of the textured surface define "surface plasmons," which are groups of electrons with inherent resonance energies. At a certain angle of incidence for a fixed wavelength of light, the oscillation frequency of the electric dipole of the incident photons will match the resonance frequency of the surface plasmons, resulting in absorption. The angle of incidence at which maximum energy absorption occurs is called the "plasmon notch" angle and can be precisely determined. Subsequent binding or absorption of anything to the surface of the sensor will cause the "plasmon notch" angle to shift (Johnsson *et al.*, 1991). The instrument is thus able to measure the extent of capture of an analyte by an immobilized antibody by measuring the resultant shift in the "plasmon notch" angle. Nonspecific binding of proteins or other substances at the interface will also give rise to a signal, which has limited the utility of the technique to some extent.

Using a BIAcore 1000 instrument, it was shown that applying mixed SAMs composed of thiol-alkane-PEO and thiol-alkane PEO-COOH significantly inhibited the nonspecific binding of the proteins lysozyme, ovalbumin, carbonic anhydrases, and fibrinogen. In contrast, nonspecific binding of the protein cytochrome *c*, which is known to interact with surface carboxylic groups, was more difficult to inhibit. The Whitesides group also described the immobilization of various other proteins to SAMs and demonstrated the measurement of biospecific binding for several analytes (Lahiri *et al.*, 1999; Rao *et al.*, 1999).

Molecularly Imprinted Surfaces

Molecular imprinting of polymeric surfaces is a process in which an analyte or other binding molecule serves as a template, around which a polymer is "molded." The template molecule is combined with one or more monomers that can be polymerized and cross-linked. Alternatively, the molecule of interest can be covalently modified through labile linkages with polymerizable groups. After polymerization, the template molecule is removed by extraction and/or chemical cleavage,

leaving behind a void that has the size and shape of, and possibly electronic complementarity to, the target analyte binding molecule (Mosbach and Ramstrom, 1996; Ramstrom *et al.*, 1996, and references contained within). Monomers are chosen such that the cross-linked imprint matrix is highly resistant to physical and chemical factors and can be reused repeatedly. Since some of the resultant binding constants for the target molecule approach those found in antibody–antigen interactions, these structures may find applicability in reusable biosensors and other diagnostic devices.

The concept of imprinting has been extended beyond the use of conventional synthetic monomers and polymers to natural polymers such as enzymes. In one example, an enzyme–inhibitor complex was precipitated in an organic solvent, locking in the secondary structure of the enzyme (Staahl *et al.*, 1991). After removal of the inhibitor, the enzyme was shown to be catalytically active in organic media.

Further extension of the concept of imprinting by taking advantage of the tremendous diversity of natural polymers as the matrix is an intriguing possibility. Work in this direction was done at the University of Washington using a radio-frequency glow discharge (RFGD) plasma deposition technique to form a polysaccharide-like surface with protein-imprinted “nanopits” (Shi *et al.*, 1999). Exposure to the templates of binary protein mixtures of bovine serum albumin and immunoglobulin G in a competitive manner revealed a significant preferential adsorption of these proteins to their respective imprints.

Surface-Enhanced Spectroscopies

Surface-Enhanced Raman Scattering

Another aspect of the surface plasmon resonance phenomenon (see “Self-Assembled Monolayers,” above) is the dramatic increase in the intensity of Raman light scattering, fluorescence, and infrared absorption observed when some molecules are brought into close proximity to (but not necessarily in contact with) metal surfaces displaying surface plasmon activity. The surfaces need to be textured or coated with minute metal particles or have periodic structure such as that of an optical grating. Colloidal dispersions of certain metals, especially gold and silver, can also show these dramatic signal enhancements. In 1974 Dr. Richard P. Van Duyne first recognized this effect as a unique physical phenomenon for Raman scattering and coined the term “surface-enhanced Raman scattering” (SERS) (Jeanmarie and Van Duyne, 1974). The intensity of Raman scatter as the result of surface enhancement can be several million times greater than that observed with unenhanced solution-state spectroscopy.

In all solid-phase immunoassays up through the late 1980s, the solid phase was used to separate bound from unbound species. Tarcha and co-workers (Rohr *et al.*, 1989) realized that the surface enhancement effect could be used to design homogeneous, no-wash immunoassays. This generally involved the use of antibodies conjugated to Raman-active dyes. When these dye conjugates formed an immune complex with a binding molecule attached to a plasmon-active surface, the Raman scattering signal from the captured dye label

was enhanced because of the SERS effect. Uncaptured label was not enhanced, and hence not detected, thereby eliminating the need for separation steps. Other assay configurations that employed metal colloids to which dyes had been adsorbed were also demonstrated (Tarcha *et al.*, 1996). Using this approach, no-wash immunoassays for several large- and small-molecule analytes were performed [e.g., human chorionic gonadotropin (HCG) and theophylline, respectively].

Surface-Enhanced Sensors

Sensors based on the SERS effect have been described for the detection of gene probes (Isola *et al.*, 1998). Raman-active dye-labeled probes were shown to hybridize to amplified oligonucleotides, SERS signals being detected after deposition of a silver layer over the hybridized samples.

Sensors based on surface-enhanced infrared absorption have also been demonstrated using model systems consisting of *Salmonella* bacteria and the enzyme glucose oxidase and antibodies directed against them (Brown *et al.*, 1998). Characteristic infrared absorption bands were detected as binding molecules immobilized on a plasmon-active metal surface captured their complementary binding molecules. It was suggested that the fingerprints of the spectrum could be used for identification as well.

Reusable solid phases with potential for use in surface-enhanced fluorescence sensors have been described (Tarcha *et al.*, 1999). They were made by depositing well-defined layers of SiO₂ or SiO onto silver island films. The surface-enhancement factors observed for the fluorescence of dyes were only 10- or 20-fold, as is usually the case, but the study data were consistent with theory in that fluorescence from dyes having low quantum yields was more greatly enhanced than that from dyes with high quantum yields. In addition, the study showed that the SiO₂ coating allowed washing and reuse of the device without degradation of the metal surface’s activity. The coating also helped reduce photodecomposition of adsorbates on the silver surface without substantial loss in the observed enhancement factor.

Issues related to the protein stability, biocompatibility, and reproducibility of SERS-active surfaces have been addressed by Natan and co-workers (Keating *et al.*, 1998). They made reproducible colloidal gold–protein conjugates and enhanced their SERS activity by forming aggregates of these conjugates with silver colloids. The stability of the model protein used in the conjugate, cytochrome *c*, was reported to be good.

As continued advances are made in the physical and chemical stability of the plasmon-active surfaces, in control of colloidal aggregate size, and in the biocompatibility of the surfaces with protein, the use of these surface-enhanced techniques will move beyond the research stage and into commercial instruments.

Other Biosensor Strategies

Many of the principles discussed in this chapter can be applied to the design of biosensors. A major goal of biosensor development is the production of a device that can be permanently implanted *in vivo*. Such a device could provide long-term feedback to an indwelling therapeutic pump as a

closed-loop system. Insulin delivery to a diabetic patient is the most obvious application. Such sensor systems have not yet been successful commercially because of limited functional stability resulting from a loss of activity of the binding molecules. A second problem is fouling or encapsulation of the sensor, leading to decreased rates of analyte transport to the sensor surface. Implantation and reimplantation can be traumatic for the patient and always pose a risk of infection or other complications, so the device must be easily sterilized and able to function for an extended period of time before needing replacement.

Many reviews giving in-depth coverage to the current and future art of biosensor design are available (Wilkins and Atanasov, 1996; Pfeiffer, 1997; Bergveld, 1996; Wang, 1999). In addition, see chapters in this book on "Bioelectrodes" and "Biomedical Sensors and Biosensors." Here we will only mention two unique approaches to solving some classical biosensor problems. Researchers at the University of New Mexico made it possible to extend the life of an indwelling glucose sensor by recharging it with fresh immobilized enzyme (Xie and Wilkins, 1991). In the device enzyme immobilized on dispersed carbon powder was contained within a membrane that isolated it from the biological milieu. The enzyme-coated particles were replaced through recharge and discharge tubes attached to the device. Naturally, this is an invasive procedure and its commercial acceptance would be questionable if it had to be done frequently.

A second approach avoids the use of enzymes, providing for *in vivo* residence with no access port by using a noninvasive fluorescence readout through the skin, while addressing the problem of biocompatibility and fouling (Russell *et al.*, 1999). This device uses biocompatible photopolymerized poly(ethylene glycol) hydrogel particles that contain fluorescein isothiocyanate-dextran (FITC-dextran) and tetramethylrhodamine isothiocyanate-labeled concanavalin A (TRITC-ConA). Concanavalin A has a natural binding affinity for glucose and dextran, which is a polymer of glucose. In the absence of free glucose, the FITC-dextran binds to the TRITC-labeled concanavalin A, quenching the fluorescence of the fluorescein label through fluorescence energy transfer. Free glucose competes with the FITC-dextran for binding to the TRITC-labeled concanavalin A, thereby decreasing fluorescence quenching. As a result, observed fluorescence increases linearly over a glucose concentration range of 0 to 600 mg/dl. The authors demonstrate that it is possible to create a microparticle-based fluorescent glucose sensor suitable for subcutaneous implantation in a fashion similar to that of a tattoo.

LIGAND IMMOBILIZATION ON SOLID PHASES

Linker Arms

The sensitivity of a solid-phase-based immunoassay depends primarily on the quality of the antibody (high binding constant), quality of the immobilization procedure (minimal loss of binding activity after immobilization), and a low level of background signal, generally referred to as nonspecific binding.

In a sandwich-type immunoassay, the capture antibody is immobilized to the surface by adsorption or by random or specific chemical coupling. Loss of binding activity by the immobilized species can be minimized by reducing unproductive events such as denaturation or attachment in an unfavorable orientation. As shown in Fig. 1 for a sandwich immunoassay, the analyte of interest binds to the immobilized capture antibody, then a labeled second antibody binds to the bound analyte. The label on the second antibody allows detection of the binding event. Nonspecific binding of the labeled antibody to the solid phase must be minimized to avoid undesired background signal. In order to reduce nonspecific binding the solid phase is usually overcoated with one or more benign proteins or surface-active agents such as casein, bovine serum albumin, or a member of the Tween series of nonionic surfactants. As with biomaterials for *in vivo* implantation, the surface properties of biomaterials for medical diagnostics largely determine their performance, bulk properties being much less important. This subject is also covered in the chapters on "Surface Properties of Materials" and "Nonfouling Surfaces" found in this book.

Antibodies can be covalently linked to surfaces to improve their stability toward displacement and to orientate them optimally for binding to their complementary ligand (Bieniarz, *et al.*, 1993; Husain and Bieniarz, 1994; Pope *et al.*, 1996). Further improvement may be obtained by using linking molecules that provide spacing from the surface. Linking molecules may be homo- or heterobifunctional with respect to their chemically reactive groups, heterobifunctionality providing for more versatile sequential conjugations. A representative review article (Wong and Wong, 1992) and a comprehensive monograph (Hermanson *et al.*, 1992) describe the general chemical characteristics and methods for the use of linker molecules in the immobilization of proteins. Linker molecules are commercially available from companies such as Pierce Chemical Company of Rockford, IL.

Linking molecules are also widely used to link, or *conjugate*, one molecule to another, rather than to a surface. For example, antibodies are often linked to an enzyme such as alkaline phosphatase to form conjugates, the enzyme serving as a reporter molecule or label. The performance of a linker molecule is influenced by its length, reactivity, and solution properties. An example of one linking strategy started with the commercially available heterobifunctional linker 1-[[4-[(2,5-dioxo-1-pyrrolidinyl)oxyl-carbonyl]cyclohexyl]methyl]-*H*-pyrrole 2,5-dione (SMCC). This linker results in a spacing of nine atoms between linked molecules. The SMCC linker was extended further by coupling a series of 6-aminocaproic acid units, forming linkers that provide spacings of 16, 23, and 30 atoms after conjugation (Fig. 4 and Bieniarz *et al.*, 1996). It was found that the activity of soluble antibody-enzyme conjugates improved with the length of the linker. The same series of extended linker arms were used to couple antibodies to nanoparticles for use in an immunoassay. Again, the apparent activity of the immobilized antibody increased with the length of the spacer.

In the immobilization of a biomolecule, the solubilization of the linker in contact with the aqueous medium may also play an important role in the resultant activity, perhaps because of the microenvironment it provides for the protein.

FIG. 4. Synthesis of extended heterobifunctional linkers. (Reprinted with permission from Bieniarz *et al.*, 1996, copyright 1996, American Chemical Society.)

For example, it was shown that two model enzymes, trypsin and alpha-chymotrypsin, could be made more stable toward thermal inactivation by modification of their accessible lysine groups with anhydrides or chloranhydrides of aromatic carboxylic acids (Mozhaev *et al.*, 1988). The authors attributed this result to a hydrophilization of the surface area of the protein globule. In earlier related work (Mozhaev *et al.*, 1983), the same enzymes were modified with acryloyl groups and copolymerized with acrylamide to form a hydrogel. In this structured, hydrophilic environment, the enzymes were found to be over 100 times more stable against irreversible thermal inactivation.

It should be anticipated that further improvements in binding activity and in reduction of nonspecific binding will occur through the use of specifically designed, soluble linker arms that provide a local environment benign to the immobilized or conjugated binding molecule. An additional benefit can be obtained if the linker is "protein-resistant" and repels adsorptive binding of the labeled second antibody (Lee *et al.*, 1989; Jeon *et al.*, 1991; Litauszki *et al.*, 1998). Linker molecules that are uncharged water-soluble oligomers or polymers can passivate a surface against the nonspecific binding of proteins through a combination of low interfacial free energy of the hydrated surface and high chain mobility.

The use of solubilizable linkers is taught in a patent describing the development of a waveguide-based apparatus for homogeneous fluorescence-based immunoassays (Herron

et al., 1997). In order to avoid wash steps, nonspecific binding must be minimized in this assay format. The authors describe the use of water-soluble poly(ethylene glycol) (PEG) spacers, both to covalently attach whole antibodies and Fab' fragments to waveguides and to simultaneously passivate the waveguide surface. In one technique a linker is formed by modifying both ends of PEG molecules of various lengths with ethylenediamine. The solid phase is pretreated with glutaraldehyde to generate an aldehyde surface. Excess linker is then added to the modified solid phase to generate a "PEGylated" surface that has amine end groups remaining for coupling of an antibody or antibody fragment.

A second technique, which appears to be more effective, is the use of a triblock copolymer composed of a hydrophobic block poly(propylene oxide) (PPO) flanked on either end by hydrophilic blocks of poly(ethylene oxide) (PEO). This class of copolymer surfactant, known in the literature under the tradename of Pluronic, is commercially available from BASF Corporation (Parsippany, NJ). In the method described, the surface was first coated with Pluronic PF108 or PF105. Next the free PEO chain ends of the copolymer were derivatized in a photoactivated coupling reaction with a bifunctional photoaffinity cross-linker. A logical option described is the use of a benzophenone having a maleimido group at one of the para positions. Upon irradiation, the photoactivatable group of the cross-linker covalently binds to the free PEO chains, leaving the reactive maleimido group of the linker available for coupling

to a desired Fab' fragment. Using this procedure, the best data yielded ratios of nonspecific-to-specific binding approaching 0.003 on polystyrene supports.

Photolinking

In recent years there has been an increase in the use of controlled patterning in the immobilization of ligand binding molecules to accommodate various assay formats, such as immunoassays performed along membranes and microporous strips, and multiligand 2D matrices used for screening of various analytes. The same techniques are also applied to the patterning of molecules that promote the adhesion of cells to surfaces having potential as scaffolds for tissue engineering.

SurModics, Inc., of Eden Prairie, MN, has developed PhotoLink, a commercial process for the covalent immobilization of biomolecules onto the surface of any hydrocarbon-containing material. This process involves the application of photoactivatable reagents to the surface followed by exposure to light, to achieve covalent coupling to the surface through activation of the photogroups. The photoreagents are typically polymers that can serve as linkers or surface modifiers, or biologically active molecules to which photoactivatable groups have been attached. They can also be heterobifunctional coupling reagents having both photoactivatable and chemically reactive groups. In contrast to graft polymerization for surface modification, this approach does not involve photoinitiation of polymerization.

Biomolecules can be immobilized by either a one-step or a two-step method. In the one-step method, the biomolecule is prederivatized with a photoreactive moiety. This photoreagent is then applied to the surface and irradiated with light of suitable wavelength to effect the coupling. In the two-step method, the surface is prederivatized with a photoreactive coupling reagent. The coupling agent, either a photopolymer or a heterobifunctional photoreagent, has appropriate functional groups available to subsequently immobilize the molecule of interest by conventional coupling techniques. The building blocks of typical heterobifunctional photolinking reagents are shown in Fig. 5.

Aryl ketones, such as benzophenone derivatives, have most commonly been used as the photoactivatable species for such photoreagents, although aryl azides, such as azidonitrophenyl groups, have also been used. Benzophenone derivatives are typically attached to the polymers or other molecules to be immobilized onto the surface. For example, the technology can be applied to hydrophilic polymers, such as polyvinylpyrrolidone, polyacrylamide, and PEO, which are used in certain applications because of their unique protein-resistance properties. Though all of the mentioned polymers are effective, the last has been the most completely studied for protein resistance applications (Lee *et al.*, 1989; Jeon *et al.*, 1991; Litauszki *et al.*, 1998).

Upon photoactivation, aryl ketones abstract a hydrogen atom from the surface and form a new carbon-carbon bond. The ability of the activated intermediate to return to the ground state if no coupling occurs and the tendency of the benzophenone derivatives to associate with hydrophobic surfaces

FIG. 5. Building blocks for typical heterobifunctional photo-crosslinking reagents, where R is a photoreactive linker and X is a chemical linker. (Reprinted from Amos *et al.*, 1995, pp. 895-926, by courtesy of Marcel Dekker, Inc.)

both contribute to the efficiency of the photocoupling. The mechanism of aryl ketone photocoupling is shown in Fig. 6.

This basic photoimmobilization technology can be used in diagnostic applications to both prevent unwanted protein adsorption by immobilization of hydrophilic polymers and to covalently immobilize proteins of interest to the surface (Amos *et al.*, 1995). Figure 7 depicts an experiment where a variety of radiolabeled proteins with varying molecular weights were incubated in polyacrylamide-coated wells of polystyrene microtiter plates at a concentration of between 7 and 25 $\mu\text{g/ml}$. The plates had been previously photomodified with the hydrophilic polyacrylamide polymer to reduce nonspecific protein binding. After incubation with the protein, the surfaces were washed extensively using a buffer containing Tween-20 and the individual wells then separated and the quantity of bound protein determined by liquid scintillation. The proteins and their molecular weights included human gamma globulin, 150 kDa; thrombin, 36 kDa; chymotrypsinogen, 25 kDa; ribonuclease, 14 kDa; insulin B chain, 6 kDa; neurotensin, 1673 Da; and angiotensin, 1046 Da. This modification resulted in a 40-90% decrease in protein adsorption.

FIG. 6. Aryl ketone photocoupling mechanism to surfaces where S_1 = singlet excited state, T_1 = longer lived triplet state, and ISC = intersystem crossing. (Reprinted from Amos *et al.*, 1995, pp. 895-926, by courtesy of Marcel Dekker, Inc.)

FIG. 7. Adsorption of various proteins onto modified polystyrene. Corning Costar Ultra Low Binding Lab Coat strip plates, modified with hydrophilic photopolymers, were compared with unmodified Costar strip plates. (Reprinted from Amos *et al.*, 1995, pp. 895–926, by courtesy of Marcel Dekker, Inc.)

Utilizing the same technology, biomolecules such as nucleic acids, antibodies, antigens, and enzymes can be covalently attached to surfaces for use in diagnostic kits. Covalent immobilization can be helpful for binding molecules that do not adsorb or adsorb very poorly. Covalent attachment can include site-specific immobilization of antibodies. For example, linkage of antibodies through the carbohydrate side chains usually found in the Fc region can increase sensitivity because of favorable surface orientation.

Enzyme immunoassays have been reported using visual detection on membranes having photoimmobilized antibodies (Gorovits *et al.*, 1991). These authors photochemically modified the surface of porous membranes using azido compounds having a second chemically reactive moiety for protein coupling. In the case of photolinking 4,4'-diazidostilbene-2,2'-disulfonate, proteins were subsequently immobilized by the activation of one or two of the reagent's sulfo groups with carbodiimide. When the diethylacetate *p*-azidobenzaldehyde linker was used, the protein was subsequently coupled to the immobilized aldehyde by reductive amination, involving Schiff base formation followed by reduction to the stable secondary amine with sodium borohydride. Regenerated cellulose proved to be the best support material in this work. Tests reported were for the analytes thyroxine, human immunoglobulin, human chorionic gonadotropin, and cells of the bacteria *Shigella sonnei*.

The surfaces of commercial polysulfone and polyethersulfone ultrafiltration membranes have been successfully modified using benzophenone or benzoylbenzoic acid to surface polymerize acrylic acid (Ulbricht *et al.*, 1996). The resulting acid groups were used for the covalent immobilization of various proteins. Because of the tendency for homolytic chain scissions at several locations with polymers of this structure, careful control of ultraviolet excitation energy was necessary.

These examples illustrate the growing use of photolinking rather than present an extensive review of the literature. Its use, combined with lithographic techniques, is bound to grow as the need for multiple analyte tests on smaller and smaller devices increases because of cost sensitivity and the need to reduce the volume of medical waste.

Steric Inhibition

Although immobilizing water-soluble polymers on the solid phase can suppress nonspecific binding of labeled proteins in many immunoassays, the presence of these polymers can have a detrimental effect in a chromatography-based assay format. This format requires the interaction of two solid-phases, both possessing attached binding molecules (see the section describing intrinsically colored particles earlier in this chapter). The detrimental effect of attached, water-soluble polymer acting as a steric stabilizer was illustrated in a competitive assay for the analyte estrone-3-glucuronide (E1G) (Pope *et al.*, 1997a, b). The assay used intrinsically black polypyrrole nanoparticles, made using poly(vinyl alcohol) as a colloidal stabilizer. As shown by X-ray photoelectron spectroscopy, even after extensive cleaning, the particles possessed a significant surface concentration of poly(vinyl alcohol). The presence of the polymer does not inhibit the immobilization of the antibodies to the particle surface, nor the ability of the immobilized antibody to bind soluble analyte; however, the ability of the particle-bound antibody to bind to an analyte immobilized on the capture zone of a chromatography strip was inhibited. This inhibition is likely due to steric stabilization of the particle against interaction with another hydrated surface. As a result, the binding molecules cannot approach close enough to one another to interact. Steric stabilization is distinguished from electrostatic stabilization in that in the former the stabilizing molecules are usually uncharged. In aqueous systems, these surface molecules are almost always water-soluble polymers. As such surfaces approach one another, the concentration of water-soluble polymer will increase in the region between the two surfaces. Coalescence is not favored in this case because of osmotic and entropic effects. The principles of steric stabilization are described in a seminal paper by Napper (1977).

Data confirming these proposed principles as they apply to chromatography-based assays was obtained (Pope *et al.*, 1997a, b). As shown in Fig. 8, selective degradation of the poly(vinyl alcohol) by cleavage of the polymer chain at vicinal diol sites [originating from infrequent head-to-head polymerization in the precursor poly(vinyl acetate)] increased the binding response of the immunoreagent 140-fold for the E1G immunoassay.

SPECIFIC ACTIVITY OF SOLID PHASE IMMUNOREAGENTS

In the development of biomaterials for implantation, *in vivo* biocompatibility is always of paramount concern. Biocompatibility can be somewhat predicted using *in vitro* cell-based assays, which monitor cell growth and spreading or the release

FIG. 8. Standard assay curves for a model competitive immunoassay for the hormone estrone-3-glucuronide (E1G) in a chromatography-based format. Polypyrrole latex immunoreagent reacted with periodic acid (●) and unreacted control latex immunoreagent (▲). (Reprinted with permission from Pope *et al.*, 1997a, copyright 1997, American Chemical Society.)

of cytokines. The most common methods of assessment are the retrieval of implanted material, the sectioning and histological analysis of encapsulation, and the measurement of cellular markers of inflammation. Similarly, in a solid-phase ligand binding assay, the biocompatibility of the surface of the materials with the binding molecules (e.g., antibodies, antibody fragments, antigens, oligonucleotide segments, and protein-conjugated haptens), is a critical element for a stable, reproducible, sensitive, and specific test.

The most important parameters to measure when evaluating a solid-phase ligand binding reagent are the total binding activity of the immobilized binding molecules and their binding affinity for the analyte of interest or other binding molecule. Total binding activity can be determined, for example, by measuring how many analyte molecules can be specifically bound by the binding molecules attached to the solid phase. If the number of binding molecules attached to the solid phase can be determined, the fraction of their original binding activity that was retained following the immobilization procedure can be calculated. Introducing a radioactive label into the binding molecules before the immobilization procedure is the most direct means of measuring the number of binding molecules on the solid-phase reagent. For example, a tritium label can usually be introduced into an antibody by oxidation of the carbohydrate side chains with periodate to produce aldehyde groups. These groups are then reduced with tritium-labeled sodium borohydride to produce tritium-labeled hydroxyls. Radioactive counting of the coated solid phase then directly yields the quantity of antibodies present. In practice, radiolabels are used less and less because of cost and regulatory safety issues. Alternatively, nonradioactive labels such as fluorescein can be used for this purpose, but the extent of surface quenching of the fluorescence signal cannot be accurately predicted.

A second method to determine the quantity of binding molecules attached to the solid phase is to measure their

depletion from solution during the immobilization procedure. A calculation of total solid-phase surface area and an assumption of an individual binding molecule's "footprint" area provides an estimate of the total surface concentration that should be present if monolayer coverage is complete.

Inevitably, because of denaturation or immobilization with improper orientation, some binding molecules will be inactivated during the coating process. To evaluate the efficiency of coating procedures, the retained specific binding activity of the immobilized binding molecules must be determined. Again, the most straightforward method is to directly measure the quantity of radiolabeled ligand captured by the solid-phase reagent using liquid scintillation counting. An alternative approach, which avoids radiolabels, is to force the immobilized binding molecules of the solid-phase reagent in question to compete for analyte binding with the immobilized binding molecules of a different solid phase. Microparticle solid phases especially lend themselves to this approach, an example of which is illustrated in Fig. 9. In format A, antibodies (1) specific for a particular analyte (A) are immobilized onto the bottom of a microtiter plate well. Analyte is captured by the antibodies on the well bottom, then a second antibody (2), conjugated to an enzyme (E) is captured by the captured analyte, i.e., the classic "sandwich" immunoassay format. The captured enzyme generates a signal in the presence of a substrate (S), the intensity of which is proportional to the quantity of analyte originally captured by the solid phase. In format B, capture of the analyte by the solid phase is inhibited by the presence of soluble capture antibody (1), which will occupy binding sites on the analyte, preventing its binding to the immobilized antibody (1) on the solid phase. As a result, less of the antibody-enzyme conjugate becomes bound to the solid phase and the intensity of the resulting signal is diminished. Usually, the concentration of soluble antibody necessary to achieve a 50% signal inhibition is determined. This quantity is a measure of the binding activity of the soluble antibody. In format C, microparticles (MP) coated with the same antibody (1) can be used to inhibit the assay in the same way. The number of antibody-coated microparticles necessary to achieve 50% signal inhibition is displaying the same binding activity as the quantity of soluble antibody necessary to achieve the same 50% signal inhibition. Comparison of this quantity of soluble antibody to that actually on the microparticles is a measure of the loss of binding activity resulting from the immobilization procedure. Even without knowledge of the actual quantity of antibody on the microparticles, such determinations can be used to compare the efficiency of different immobilization procedures. Using the methods just described, comparisons of the binding activity of two particulate immunoreagents were demonstrated (Pope *et al.*, 1996).

CONCLUSION

The medical diagnostic industry is under unprecedented pressure to reduce the cost and to maximize the throughput speed of clinical assays. The response has been the centralization of clinical testing and the concomitant development of highly automated, high-throughput clinical analyzers.

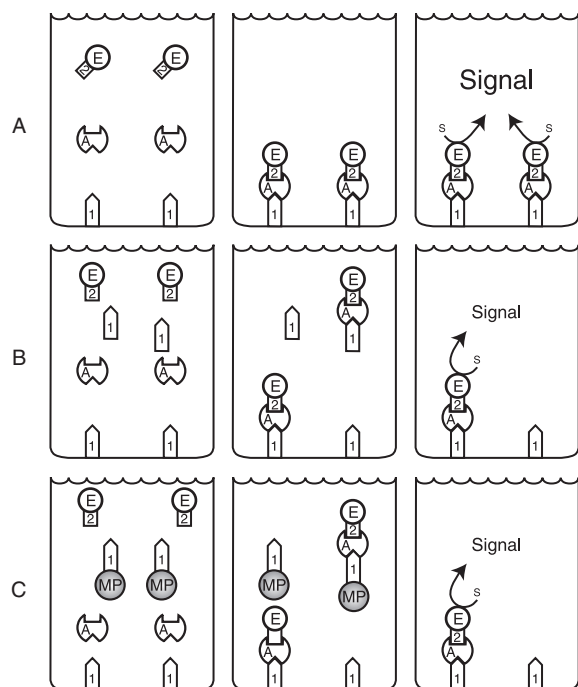

FIG. 9. Measurement of retained binding activity of antibodies immobilized on microparticles by inhibition. (Format A) A typical sandwich immunoassay in which immobilized antibodies (1) capture analyte (A), which in turn captures a second antibody (2) conjugated to an enzyme label (E) to form an immobilized immune complex. After removal of unbound antibody-label conjugate, conversion of the substrate (S) by the immobilized enzyme generates the signal. (Format B) Inhibition of immune complex capture by soluble antibody (competition assay). Soluble antibody (1) binds to the same site on the analyte as does the immobilized antibody (1), inhibiting its capture. As a result, less conjugated enzyme becomes immobilized and a less intense signal is generated. (Format C) Inhibition of immune complex capture by antibody-coated microparticles. Antibody (1) attached to microparticles (MP) binds to the same site on the analyte as does immobilized antibody (1), inhibiting its capture on the surface of the well. As a result, less conjugated enzyme is captured and a less intense signal is generated.

The development and application of specialized biomaterials has been instrumental in the successful design of these machines. Although much more efficient than their predecessors, these new designs primarily automate previous assay technology. To meet future demands in both the high-volume testing lab and low-volume point-of-care setting, the next generation of tests will have to depart from past designs.

Biologically derived binding molecules will remain the major source of the specificity needed to measure small quantities of analytes in complex biological mixtures, although synthesized polypeptides and polynucleic acid probes will find increasing use.

Technologies maturing in both related and distant fields, such as the lithographic layering techniques developed for the semiconductor industry, the automated optical scanning of miniaturized arrays used for drug discovery, and advances in the field of implantation biology, holographic optics, surface-enhanced spectroscopies, surface patterning using self-assembled monolayers, and pattern recognition, will

all provide new approaches to biomaterials development for clinical diagnostic assays.

7.19 MEDICAL APPLICATIONS OF SILICONES

Jim Curtis and André Colas

MEDICAL APPLICATIONS

Silicones, with their unique material properties, have found widespread application in health care. Properties attributed

to silicone include *biocompatibility* and *biodurability*, which can be expressed in terms of other material properties such as hydrophobicity, low surface tension, and chemical and thermal stability. These properties were the basis for silicone's initial use in the medical field. For example, their hydrophobic (water-repellent) character caused silicones to be considered for blood coagulation prevention in the mid-1940s. Researchers from the Universities of Toronto and Manitoba obtained a methylchlorosilane from the Canadian General Electric Company and coated syringes, needles, and vials with the material. When rinsed with distilled water, the silane hydrolyzed, forming a silicone coating on the substrate. The researchers published results from their clotting time study in 1946, finding that the silicone treatment "on glassware and needles gives a surface which preserves blood from clotting for many hours" (Jaques *et al.*, 1946). Researchers at the Mayo Clinic took notice of the work by their Canadian colleagues, indicating that silicone "was the most practical of any known [substance] for coating needle, syringe and tube" (Margulies and Barker, 1949). They also demonstrated that leaving blood in silicone-coated syringes had no significant effect on the blood as measured by coagulation time after being dispensed from the syringe. Soon the use of silicone precoating of needles, syringes, and blood collection vials became commonplace. In addition to the silicone's blood-preserving quality, it was soon discovered that silicone-coated needles were less painful. Today most hypodermic needles, syringes, and other blood-collecting apparatus are coated and/or lubricated with silicone.

Silicone's chemical stability and elastic nature are beneficial for many applications involving long-term implantation. The first published report of silicone elastomers being implanted in humans was in April 1946, when Dr. Frank H. Lahey told of his use of these materials for bile duct repair. He obtained the material, called "bouncing clay" at the time, from the experimental laboratory of the General Electric Company (GE). Citing its elastic properties, he reported, "It is flexible, it will stretch, it will bounce like rubber and it can be cast in any shape" (Lahey, 1946).

In 1948, Dr. DeNicola implanted an artificial urethra fashioned from the same type of GE silicone tubing used previously by Lahey. The first apparently successful replacement of the human male urethra by artificial means was conducted under general anesthesia. The 3¾ inch (9.5 cm) long silicone tube was threaded over a narrow catheter whose distal end was in the bladder. Fourteen months after implantation, the artificial urethra "had been retained with normal genito-urinary function. . . . There is no evidence at this time that the tube is acting as a foreign body irritant. . ." (DeNicola, 1950).

A particularly notable early silicone implant was the hydrocephalus shunt, which benefited from silicone's thermal stability. This application became quite celebrated when tenderly described in *Reader's Digest* (LaFay, 1957). Charles Case "Casey" Holter was born on the seventh of November 1955 with a neural tube defect called lumbo-sacral myelomeningocele. By December, the baby had contracted meningitis, and surgeons at the Children's Hospital of Philadelphia closed the defect. A few weeks later, hydrocephalus caused young Casey's head to swell as cerebrospinal fluid (CSF) collected in his brain.

At the time, there were few treatment options and this affliction was fatal for most children who contracted it. After infection concerns with the daily venting of CSF through the fontanelles (spaces between cranial bones that have not completely fused), Dr. Eugene Spitz implanted a polyethylene shunt catheter in Casey to drain excess CSF from the brain into the atrium of the heart. A valve was needed to allow the CSF to drain when pressure would begin to build in the brain, but close to prevent backflow when the pressure equalized. Spitz had been a neurosurgery resident at the University of Pennsylvania in 1952 and had gained clinical experience with a ball and spring valve developed by the Johnson Foundation, an arm of Johnson & Johnson. So it was this valve that was first implanted in young Casey. Basically a scaled-down version of an automotive pressure relief valve, it frequently clogged with tissue. Casey's father John, a machinist by profession, asked Spitz about the valve, the CSF, and the pressures involved. Spitz confided in Holter that "a competent one-way valve" that would be stable in the human body was needed (Baru *et al.*, 2001).

It is said that necessity is the mother of invention, and this is a poignant example. A desperately concerned father went home to his garage workshop that evening and constructed a prototype valve from two rubber condoms and flexible tubing. However, autoclaving caused the material to shrink a bit and the valve to leak. Holter discussed the shrinkage problem with a local rubber company, where the head of research suggested he replace the natural rubber with a thermally stable material known as silicone. Holter obtained Silastic brand silicone elastomer and tubing free of charge from Dow Corning. In March of 1956, Holter believed the valve that would come to bear his name was ready. At the time, Holter's son was too ill to undergo the surgery; however, Spitz saw promise in the valve design and successfully implanted the ventriculo-atrial shunt in another hydrocephalic child (Baru *et al.*, 2001). The Holter valve was so successful that its production began that summer and the valve is still being made in almost unchanged form today (Aschoff *et al.*, 1999).

These early health-care applications resulted in substantial interest in the emerging silicone materials and their promising properties. The two leading silicone suppliers, General Electric and Dow Corning, began receiving inquiries from the medical field at unprecedented rates. By 1959, Dow Corning was so inundated with requests for materials and information that the Dow Corning Center for Aid to Medical Research was established to act as a clearing house for all information on medical uses of silicone, and to supply medical scientists with research quantities of various silicone materials, all without cost to the researcher. The Center corresponded with more than 35,000 physicians and researchers from all over the world and in numerous areas of health care (Braley, 1973).

The upsurge of interest in silicones for health-care applications continued in the early 1960s. Before the end of the decade, silicone materials were being employed or evaluated in numerous health-care applications—in orthopedics, catheters, drains and shunts of numerous descriptions, as components in kidney-dialysis, blood-oxygenator, and heart-bypass machines, heart valves, and aesthetic implants, to name just a few.

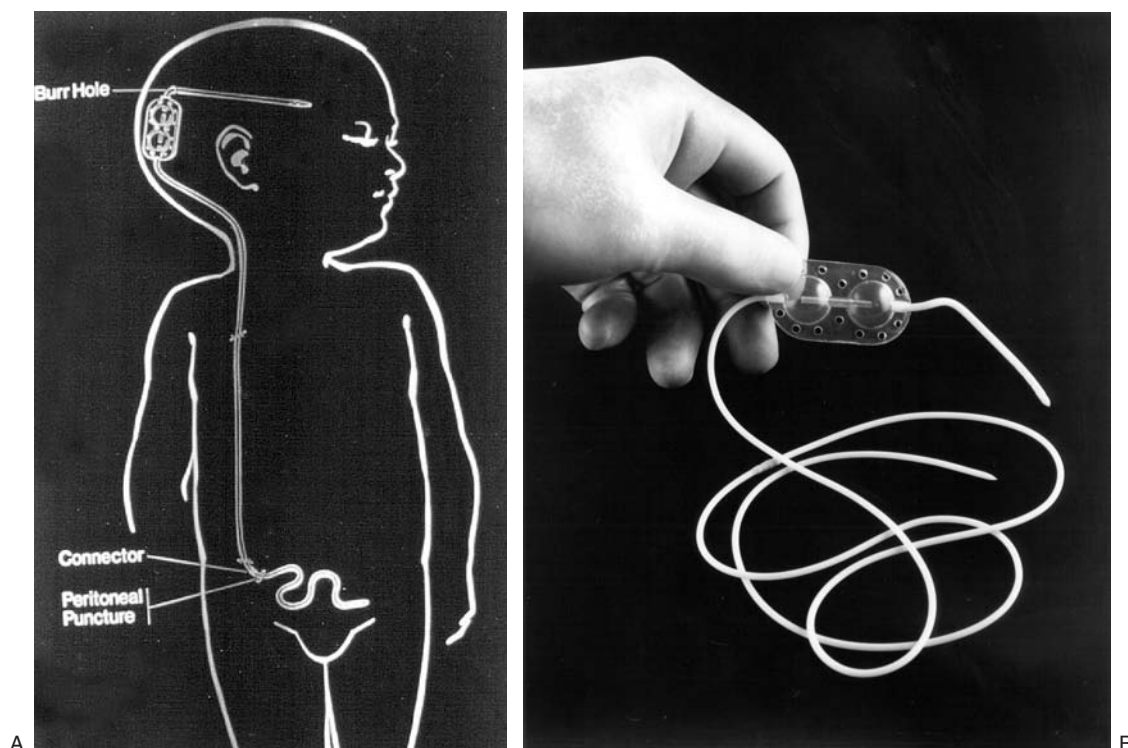

FIG. 1. (A) Schematic and (B) photograph of silicone shunt for treatment of hydrocephalus.

Orthopedic Applications of Silicone

The most significant orthopedic applications of silicone are the hand and foot joint implants. Dr. Alfred Swanson, with assistance from Dow Corning, developed silicone finger joint implants such as those shown in Fig. 2 (Swanson, 1968). Similar implants were developed for the other small joints of the foot and hand. In addition to the double-stemmed finger joint implants in each of the metacarpophalangeal joints (large arrow), Fig. 2D also shows a single-stemmed Silastic ulnar head implant at the distal terminus of the ulna (small arrow).

Nearly four decades later, silicone remains the most prevalent type of small joint implant.

Another early orthopedic application of silicone was in 1969, when the French GUEPAR (Group d'Utilisation et d'Etude des Prothèses Articulaires) posterior-offset hinged total knee implant was introduced. This design was constructed of the metal Vitallium with a shock-absorbing silicone bumper that prevented impact of the anterior portions of the tibial and femoral components during knee extension (Mazas, 1973).

Catheters, Drains and Shunts

The properties of silicone elastomers have also found application in numerous catheters, shunts, drains, and the like (Fig. 3). These included devices fabricated with silicone extrusions, as well as devices with nonsilicone substrates that had been silicone-coated to provide less host reaction. For example,

although several all-silicone urology catheters have been utilized, the Silastic Foley is a latex catheter whose exterior and interior had been coated with silicone elastomer (Fig. 4).

Figure 5 shows the various components of the Cystocath suprapubic drainage system, which was used for bladder drainage after gynecological surgery that complicated or prevented normal urethral urination. The system included (a) the catheter, a silicone tube whose nonwetting surface minimized encrustation, (b) the body seal made of flexible silicone elastomer that conformed easily to the body contour and allowed patient freedom of movement, (c) pressure-sensitive silicone adhesive that adhered well to skin, and (d) the trocar needle used to pierce the bladder and overlying tissue. After vaginal surgery the bladder was inflated and located. The Silastic Medical Adhesive B was applied by brush to the clean abdomen over the bladder and the bottom of the body seal component. The pressure-sensitive adhesive—a reaction product of silicone polymers and silicone resin dispersed in a solvent to facilitate application and spreading—had excellent properties conducive to the application. It provided good adherence to dry or wet skin without causing irritation or sensitization, and good permeability to oxygen, carbon dioxide and moisture vapor; it also formed a waterproof and urine-proof seal. After a short wait for the solvent to evaporate allowing the adhesive to become tacky, the body seal was adhered to the abdomen. The trocar was advanced through the center of the body seal and pierced through the skin and bladder. The stylet was removed and the silicone catheter threaded through the needle

and well into the bladder. The needle was withdrawn leaving the catheter in place. The silicone tube was secured in the retention groove and the distal end attached to a siphon drainage system.

Silicone pressure-sensitive adhesives (PSAs) based on this early material are in common use today, in transdermal drug delivery and other applications.

Extracorporeal Equipment

Silicone tubing and membranes found application in numerous extracorporeal machines, due in large part to their hemocompatibility and permeability properties. Silicone has been used in kidney dialysis, blood oxygenator, and heart bypass machines (Fig. 6). Blood compatibility was also a factor in silicone's application in several mechanical heart valves (Fig. 7).

FIG. 6. Heart bypass machine, circa 1964.

FIG. 7. Examples of early heart valves containing silicone elastomer.

The use of silicone in extracorporeal applications continues today. Hemocompatibility testing has suggested that platinum-cured silicone tubing may be superior to PVC in several respects (Harmand and Briquet, 1999).

Aesthetic Implants

Silicones have been used extensively in aesthetic and reconstructive plastic surgery for over 40 years, and they continue to

be so utilized. Silicone elastomer is used in implanted prosthetics of numerous descriptions. Silicone implants are widely used in the breast, scrotum, chin, nose, cheek, calf, and buttocks. Some of these devices may also employ a softer-feeling substance known as silicone gel. The gel is a lightly cross-linked silicone elastomer, without silica or other reinforcing filler, that is swollen with polydimethylsiloxane fluid. The gel is contained within an elastomer shell in breast, testicular, and chin implants. Surgeons implant these medical devices for

FIG. 8. Silastic mammary prosthesis, 1964.

aesthetic reasons, to correct congenital deformity, or during reconstructive surgery after trauma or cancer treatment.

The most prominent of these aesthetic implants is the silicone breast implant. Breast enlargement by artificial means has occurred for over a century. In 1895, Czerny reported transplanting a lipoma to a breast in order to correct a defect resulting from the removal of a fibroadenoma (Gerow, 1976). The insertion of glass balls into the breasts was described by Schwarzmann in 1930 and again by Thorek in 1942. The Ivalon sponge, introduced by Pangman in 1951, was the first augmentation prosthesis to be retained fairly consistently. This surgical sponge, formulated of poly(vinyl alcohol) cross-linked with formaldehyde, was at first hand-trimmed to the desired shape by the implanting surgeon and later preformed by Clay Adams, Inc. There was some early recognition of the tendency for tissue growth into the open-cell foam, and in 1958, Pangman patented the concept of encapsulating the foam with an alloplastic (manmade) envelope. His patent also contemplated the use of other fill materials in place of foam, materials such as silicones. The Polystan and Etheron polyurethane sponge implants began to be used as breast implants in 1959 and 1960, respectively. These sponge implants became popular in the early 1960s.

With silicone materials and prototypes supplied free of charge from Dow Corning, Doctors Cronin and Gerow developed and tested their silicone gel-filled breast implant in 1961. They implanted the first pair in a woman in 1962 (Cronin and Gerow, 1963). Word of their success and the superiority of these silicone implants to the existing foam type led to the popularity of the silicone gel breast implant.

Figure 8 shows the appearance of these implants in 1964. The shells of Cronin-type implants were vacuum-molded with anterior and posterior elastomer pieces sealed together creating a seam around the perimeter of the base. The posterior shell had exposed loops of Dacron mesh attached. The surgeons believed that prosthesis fixation to the chest wall was necessary to prevent implant migration.

Since this early 1964 design, Dow Corning and the numerous other companies that manufactured silicone breast implants made prosthesis design improvements, including elimination of the seam and realization that fixation is frequently not needed.

In the early 1990s, these popular devices became the subject of a torrent of contentious allegations regarding their safety. Although the legal controversy regarding silicone gel-filled implants continues in the United States, these medical devices are widely available worldwide and are available with some restriction in the United States. The controversy in the 1990s initially involved breast cancer, then evolved to autoimmune connective tissue disease, and continued to evolve to the frequency of local or surgical complications such as rupture, infection, or capsular contracture. Epidemiology studies have consistently found no association between breast implants and breast cancer (McLaughlin *et al.*, 1998; Brinton *et al.*, 2000; Mellemjkaer *et al.*, 2000; Park *et al.*, 1998). In fact, some studies suggest that women with implants may have decreased risk of breast cancer (Deapen *et al.*, 1997; Brinton *et al.*, 1996). Reports of cancer at sites other than the breast are inconsistent or attributed to lifestyle factors (Herdman and Fahey, 2001). The epidemiologic research on autoimmune or connective-tissue disease has also been remarkably uniform and concludes there is no causal association between breast implants and connective-tissue disease (Hennekens *et al.*, 1996; Sánchez-Guerrero *et al.*, 1995; Gabriel *et al.*, 1994; Nyrén *et al.*, 1998; Edworthy *et al.*, 1998; Kjoller *et al.*, 2001).

Largely without any specific safety concern or allegation critical of it, another silicone gel-filled implant was swept up in the breast implant controversy. At the time, most testicular implants were constructed of the same materials as silicone gel breast implants. Silicone artificial testicles had been used nearly as long as the breast implants. Dow Corning, one of several companies that manufactured these implants, was producing them as early as 1964. These devices served to ameliorate psychological stress associated with testicle loss due to cancer,

FIG. 9. Silicone testicular implants.

traumatic injury, or those absent at birth. The Teflon strips seen in Fig. 9 shield each implant shell during suturing through an elastomer loop at the superior pole to achieve fixation for proper anatomical orientation in the scrotum.

BIOCOMPATIBILITY

There has been much discussion regarding the various definitions of the term *biocompatibility*. We now take it to mean “the ability of a material to perform with an appropriate host response in a specific situation” (Black, 1992; Remes and Williams, 1992). Historically it has been tacitly understood that silicone materials are intrinsically biocompatible since they have been utilized successfully in so many health-care applications. However, given the modern definition of the term, no material can be assumed to be universally biocompatible, since such implies that it is suitable for every conceivable health-care application involving contact with the host patient.

Numerous silicone materials have undergone biocompatibility testing. Many of these materials have passed every bio-qualification test; however, others have not. There are several factors that can affect the results of such testing, including the material’s composition. As described in Chapter 2.3, the basic polydimethylsiloxane (PDMS) polymer can be modified to replace methyl with other functional groups. In some cases, those groups may be responsible for untoward host

response. There may be by-products from the preparation of silicone materials that might trigger tissue reaction. For example, these could come from the use of a peroxide initiator under inappropriate temperature and processing conditions.

Purity is another factor that can affect bio-test results. Medical silicone materials, including fluids, gels, elastomers, and adhesives, are manufactured by several companies today. Some of these firms manufacture these medical materials following GMP principles in dedicated, registered, and inspected facilities. Others sell materials generated on their industrial production line into the health-care market.

Selection of appropriate preclinical material bio-qualification tests for their application is the responsibility of the medical device or pharmaceutical manufacturer. Several national, international, and governmental agencies have provided guidance and/or regulation. Several silicone manufacturers offer special grades of materials that have met their specific requirements. The buyer should carefully investigate the supplier’s definition since there are no universal special grade definitions. At Dow Corning, Silastic BioMedical Grade materials have been qualified to meet or exceed the requirements of ISO 10993-1, USP (United States Pharmacopeia) Class V Plastics tests (acute systemic toxicity and intracutaneous reactivity), hemolysis, cell culture, skin sensitization, mutagenicity, pyrogenicity, and 90-day implant testing. Other physiochemical qualification tests have been conducted, such as certain tests from the European Pharmacopeia. Specific information

TABLE 1 Biodurability Studies of Silicone Elastomer and Medical Implants.

Year	Researcher	Synopsis
1960	Ames	Explant examination of a clinical silicone ventriculocisternostomy shunt used in the treatment of hydrocephalus showed “the silicone rubber tubing was unchanged by three years implantation in the tissues of the brain and in the cervical subarachnoid space.” Similarly, after over 3 years implantation of silicone tubing in the peritoneal cavity of dogs, Ames wrote, “The physical properties of the tubing itself are apparently unchanged by prolonged contact with tissues.”
1963	Sanislow and Zuidema	Silastic T-tubes were placed in the common ducts of dogs and explanted 9 months later. They were found to be free of bile-salt precipitation and completely patent. Four were tested for tensile strength and compared with a control sample from the same lot of elastomer. “These tests suggested that little physical change occurred in the Silastic as a result of prolonged contact with animal bile.” The tensile strength after 9 months was reported as 1130 psi (7.8 MPa), the same value as reported for the unimplanted control.
1964	Leininger <i>et al.</i>	The Battelle Memorial Institute examined the biodurability of five plastics by implanting films in dogs for 17 months’ duration. The materials tensile strength and elongation were measured and compared with unimplanted controls. Although large deterioration was seen in the tensile properties of polyethylene, Teflon, and nylon, the results for Mylar and Silastic remained essentially the same.
1974	Swanson and LeBeau	“Dog-bone”-shaped specimens of medical grade silicone rubber were implanted subcutaneously in dogs. Tensile properties and lipid content were measured at 6 months and 2 years postimplantation. A slight but statistically significant decrease in measured ultimate tensile strength and elongation were observed, as well as a small weight increase attributed to lipid absorption.
1976	Langley and Swanson	Mechanical test specimens were implanted in dogs for 2 years. Tensile strength, elongation, and tear resistance showed no statistically significant changes. Lipid absorption into the elastomer ranged from 1.4 to 2.6%.
2000	Curtis <i>et al.</i>	Six silicone breast implants surgically excised after 13.8 to 19.3 years and 10 similar nonimplanted units were tested to determine shell tensile properties and molecular weight of silicone gel extracts. The “study observed only minor changes (less than the explant or implant lot-to-lot variation range) in the tensile strength of Dow Corning silicone breast implants after nearly twenty years of human implantation.” The gel extract molecular weight was either unchanged by implantation or increased slightly.
2003	Brandon <i>et al.</i>	In the most comprehensive study of breast implant biodurability heretofore published, the authors reported their results of tensile, cross-link density, and percent extractable measurements made on 42 explants and 51 controls. The study included some of the oldest explants, with human implantation durations up to 32 years. The researchers also performed a literature search and plotted all published explant tensile modulus data against implantation duration, finding no temporal relationship. Neither was a relationship with implant time seen for the cross-link density results, supporting the biodurability of the silicone elastomer utilized in the implant shells. The researchers concluded, “There was little or no degradation of the base polydimethylsiloxane during <i>in vivo</i> aging in any of the implants we examined.”

regarding material biotesting can be found in other chapters of this text. Testing of the device in finished form should follow material bio-qualification tests such as those described above.

BIODURABILITY

Traditionally we have thought of *biocompatibility* as the situation in which the biomaterial has minimal adverse impact on the host. Conversely, *biodurability* is where the host has a minimal adverse effect on the biomaterial (see Chapter 6.2). Silicone’s material properties, such as hydrophobicity, have been related to biocompatibility properties such as hemolytic potential, and its relative purity and high-molecular-weight polymeric nature and chemical structure provide a theoretical basis for its lack of toxicity. Silicone’s biodurability in medical applications is probably related to its exceptional thermal and chemical stability properties.

Silicones are used in numerous applications requiring high temperature resistance (Noll, 1968; Stark *et al.*, 1982). During thermogravimetric analysis and in absence of impurities, polydimethylsiloxane degradation starts only at around 400°C. Thus, silicones remain essentially unaffected by repeated sterilization by autoclaving, and they can usually be dry-heat sterilized as well. Other sterilization methods can also be utilized, such as ethylene oxide exposure and gamma and e-beam irradiation—although care must be taken to ensure complete sterility outgassing in the former and that dosage does not affect performance properties in the latter.

Although silicones can be chemically degraded, particularly at elevated temperatures, by substances capable of acting as depolymerization catalysts (Stark *et al.*, 1982), their hydrophobic nature limits the extent of their contact with many aqueous solutions. Typically the biologic milieu does not present a particularly hostile chemical environment for silicone. A notable exception, however, is the stomach, which excretes large

amounts of hydrochloric acid, capable of attacking PDMS if it remains resident there too long.

Based on silicone elastomer performance in long-term implantation applications, its biodurability is generally considered excellent (Table 1).

The chemical stability associated with silicones became so well established that it has been formulated into other biomaterials, such as polyurethane, to enhance their biodurability (Pinchuk *et al.*, 1988; Ward, 2000; Christenson *et al.*, 2002).

Notwithstanding the chemical stability of silicone, certain factors have been shown to affect its durability in terms of long-term *in vivo* performance. The hydrophobic elastomer is somewhat lipophilic and can be swollen by lipids or other nonpolar agents. Early experience with *in vivo* failure of silicone-containing heart valves was traced to elastomer absorption of lipids from the blood that resulted in significant dimensional swelling (McHenry *et al.*, 1970). In most cases the absorption was low and failures did not occur, but in a small percentage of cases, the silicone was absorbing quantities sufficient to render the valves variant. Researchers speculated that variations in silicone poppet manufacture, such as cure, might have been a factor (Carmen and Mutha, 1972). Absorption of lipids was a variable reported by Swanson and LeBeau (1974) and Langley and Swanson (1976). The work of Brandon *et al.* (2002, 2003) has shown that the shells of silicone gel-filled breast implants also absorb silicone fluid (from the gel) causing a minor diminution in mechanical properties, one that is reversed after extraction of the elastomer.

CONCLUSION

A variety of silicone materials have been prepared, many possessing excellent properties including chemical and thermal stability, low surface tension, hydrophobicity, and gas permeability. These characteristics were the origin of silicone's use in the medical field and are key to the materials' reported biocompatibility and biodurability. Since the 1960s silicones have enjoyed expanded medical application and today are one of the most thoroughly tested and important biomaterials.

Acknowledgments

The authors thank Doctors S. Hoshaw and P. Klein, both from Dow Corning, for their contribution regarding breast implant epidemiology.

8.1 INTRODUCTION

Frederick J. Schoen

Biomaterials investigation and development has been stimulated and informed by a logical evolution of cell and molecular biology, materials science, and engineering, and an understanding of the interactions of materials with the physiological environment. These developments have permitted the evolution of concepts of tissue–biomaterials interactions to evolve through three stages, overlapping over time, yet each with a distinctly different objective (Fig. 1) (Hench and Pollak, 2002). The logical and rapidly progressing state-of-the-art, called *tissue engineering*, is discussed in this chapter.

The goal of early biomaterials development and use in a wide variety of applications was to achieve a suitable combination of functional properties to adequately match those of the replaced tissue without deleterious response by the host. The “first generation” of modern biomaterials (beginning in the mid-20th century) used largely off-the-shelf, widely available, industrial materials that were not developed specifically for their intended medical use. They were selected because of a desirable combination of physical properties specific to the clinical use, and they were intended to be *bioinert* (i.e., they elicited minimal response from the host tissues). The widely used elastomeric polymer silicone rubber is prototypical (see Chapter 2.2). Pyrolytic carbon, originally developed in the 1960s as a coating material for nuclear fuel particles and now widely used in mechanical heart valve substitutes, exemplifies one of the first biomaterials whose formulation was studied, modified, and controlled according to engineering and biological principles specifically for medical application (Bokros, 1977).

Subsequently, technology enabled and certain applications benefited by “second-generation” biomaterials that were intended to elicit a nontrivial and controlled reaction with the tissues into which they were implanted, in order to induce a desired therapeutic advantage. In the 1980s, *bioactive* materials were in clinical use in orthopedic and dental surgery as various compositions of bioactive glasses and ceramics (Hench and Pollak, 2002), in controlled-localized drug release applications such as the Norplant hormone-loaded contraceptive formulation (Meckstroth, 2001), and in devices such

as the HeartMate® left ventricular assist device for patients with congestive heart failure, with an integrally-textured polyurethane surface that fosters a controlled thrombotic reaction to minimize the risk of thromboembolism (Rose *et al.*, 2001). Recently, drug-eluting endovascular stents have been shown to markedly limit in-stent proliferative restenosis following balloon angioplasty (Sousa *et al.*, 2003). The need for maximally effective dosing regimens, new protein- and nucleic acid-based drugs (which cannot be taken in classical pill form), and elimination of systemic toxicities have stimulated development of new implantable polymers and innovative systems for controlled drug delivery and gene therapy (LaVan *et al.*, 2002). Controlled drug delivery is now capable of providing a wide range of drugs that can be targeted (e.g., to a tumor, to a diseased blood vessel, to the pulmonary alveoli) on a one-time or sustained basis with highly regulated dosage and can regulate cell and tissue responses through delivery of growth factors and plasmid DNA containing genes that encode growth factors (Bonadio *et al.*, 1999; Richardson *et al.*, 2001).

The second generation of biomaterials also included the development of resorbable biomaterials with variable rates of degradation matched to the requirements of a desired application. Thus, the discrete interface between the implant site and the host tissue could be eliminated in the long term, because the foreign material would ultimately be degraded by the host and replaced by tissues. A biodegradable suture composed of poly(glycolic acid) (PGA) has been in clinical use since 1974. Many groups continue to search for biodegradable polymers with the combination of strength, flexibility, and a chemical composition conducive to tissue development (Hubbell, 1999; Griffith, 2000; Langer, 1999).

With engineered surfaces and bulk architectures tailored to specific applications, “third generation” biomaterials are intended to stimulate highly precise reactions with proteins and cells at the molecular level. Such materials provide the scientific foundation for molecular design of scaffolds that could be seeded with cells *in vitro* for subsequent implantation or specifically attract endogenous functional cells *in vivo*. A key concept is that a scaffold can contain specific chemical and structural information that controls tissue formation, in a manner analogous to cell–cell communication and patterning during embryological development. The transition from

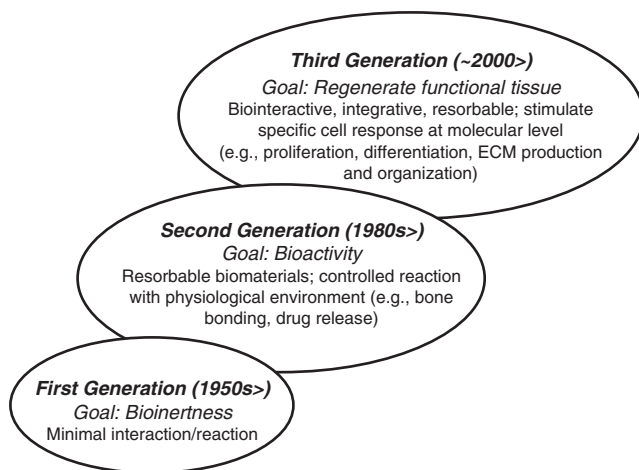

FIG. 1. Evolution of biomaterials science and technology. (From Rabkin, E., and Schoen, F. J. 2002. Cardiovascular tissue engineering. *Cardiovasc. Pathol.* 11: 305.)

second- to third-generation biomaterials is exemplified by advances in controlled delivery of drugs or other biologically active molecules. Nanotechnology and the development of microelectromechanical systems (MEMS) have opened new possibilities for fine control of cell behavior through manipulation of surface chemistry and the mechanical environment (Chen *et al.*, 1997; Bhatia *et al.*, 1999; Huang and Ingber, 2000; Chiu *et al.*, 2000, 2003).

Tissue engineering is a broad term describing a set of tools at the interface of the biomedical and engineering sciences that use living cells or attract endogenous cells to aid tissue formation or regeneration, and thereby produce therapeutic or diagnostic benefit. In the most frequent paradigm, cells are seeded on a scaffold composed of synthetic polymer or natural material (collagen or chemically treated tissue), a tissue is matured *in vitro*, and the construct is implanted in the appropriate anatomic location as a prosthesis (Langer and Vacanti, 1993; Fuchs *et al.*, 2001; Griffith and Naughton, 2002; Rabkin and Schoen, 2002; Vacanti and Langer, 1999). A typical scaffold is a bioresorbable polymer in a porous configuration in the desired geometry for the engineered tissue, often modified to be adhesive for cells, in some cases selective for a specific circulating cell population.

The first phase is the *in vitro* formation of a tissue *construct* by placing the chosen cells and scaffold in a metabolically and mechanically supportive environment with growth media (in a *bioreactor*), in which the cells proliferate and elaborate extracellular matrix. In the second phase, the construct is implanted in the appropriate anatomic location, where remodeling *in vivo* is intended to recapitulate the normal functional architecture of an organ or tissue. The key processes occurring during the *in vitro* and *in vivo* phases of tissue formation and maturation are (1) cell proliferation, sorting, and differentiation, (2) extracellular matrix production and organization, (3) degradation of the scaffold, and (4) remodeling and potentially growth of the tissue. The general paradigm of tissue engineering is illustrated in Fig. 2. Biological and engineering challenges in tissue engineering are focused on the

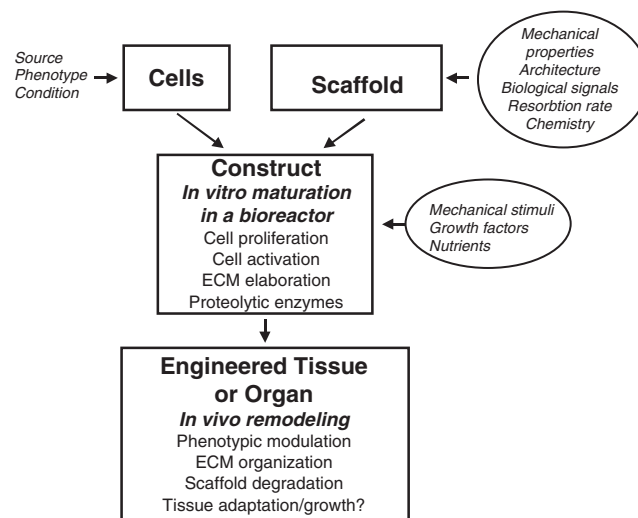

FIG. 2. Tissue engineering paradigm. In the first step of the typical tissue engineering approach, differentiated or undifferentiated *cells* are seeded on a bioresorbable *scaffold* and then the *construct* matured *in vitro* in a bioreactor. During maturation, the cells proliferate and elaborate extracellular matrix to form a “new” tissue. In the second step, the construct is implanted in the appropriate anatomical position, where remodeling *in vivo* is intended to recapitulate the normal tissue/organ structure and function. The key variables in the principal components—cells, scaffold, and bioreactor—are indicated. (From Rabkin, E., and Schoen, F. J., 2002, Cardiovascular tissue engineering. *Cardiovasc. Pathol.* 11: 305.)

TABLE 1 Control of Structure and Function of an Engineered Tissue

Cells	Biodegradable matrix/scaffold
<i>Source</i>	<i>Architecture/porosity/chemistry</i>
Allogenic	Composition/charge
Xenogenic	Homogeneity/isotropy
Autologous	Stability/resorption rate
<i>Type/phenotype</i>	Bioactive molecules/ligands
Single versus multiple types	Soluble factors
Differentiated cells from primary or other tissue	<i>Mechanical properties</i>
Adult bone-marrow stem cells	Strength
Pluripotent embryonic stem cells	Compliance
Density	Ease of manufacture
Viability	Bioreactor conditions
Gene expression	<i>Nutrients/oxygen</i>
Genetic manipulation	Growth factors
	Perfusion and flow conditions
	<i>Mechanical factors</i>
	Pulsatile
	Hemodynamic shear stresses
	Tension/compression

three principal components that comprise the “cell–scaffold–bioreactor system”; control of the various parameters in device fabrication (Table 1) may have major impact on the ultimate result. Exciting new possibilities are opened by advances in

stem cell technology (Blau *et al.*, 2001; Bianco and Robey, 2001) and the recent evidence that some multipotential cells possibly capable of tissue regeneration are released by the bone marrow and circulating systemically (Hirschi *et al.*, 2002) while others may be resident in organs such as heart and the central nervous system formally not considered capable of regeneration (Hirschi and Goddell, 2002; Grounds *et al.*, 2002; Nadal-Ginard *et al.*, 2003; Johansson, 2003; Orlic *et al.*, 2003).

Tissue-engineered configurations for skin replacement have achieved clinical use. Further examples of previous and ongoing clinical tissue engineering approaches include cartilage regeneration using autologous chondrocyte transplantation (Brittberg, *et al.*, 1994) and a replacement thumb with bone composed of autologous periosteal cells and natural coral (hydroxyapatite) (Vacanti *et al.*, 2001). A key challenge in tissue engineering is to understand quantitatively how cells respond to molecular signals and integrate multiple inputs to generate a given response, and to control nonspecific interactions between cells and a biomaterial, so that cell responses specifically follow desired receptor–ligand interactions. Another approach uses biohybrid extracorporeal artificial organs using functional cells that are isolated from the recipient's blood or tissues by an impermeable membrane (Colton, 1995; Humes *et al.*, 1999; Strain and Neuberger, 2002). *Tissue engineering* also seeks to understand structure/function relationships in normal and pathological tissues (particularly those related to embryological development and healing) and to control cell and tissue responses to injury, physical stimuli, and biomaterials surfaces, through chemical, pharmacological, mechanical, and genetic manipulation. This is an immensely exciting field.

8.2 OVERVIEW OF TISSUE ENGINEERING

Simon P. Hoerstrup and Joseph P. Vacanti

INTRODUCTION

The loss or failure of an organ or tissue is a frequent, devastating, and costly problem in health care, occurring in millions of patients every year. In the United States, approximately 9 million surgical procedures are performed annually to treat these disorders, and 40 to 90 million hospital days are required. The total national health-care costs for these patients exceed \$500 billion per year (Langer and Vacanti, 1993, 1999). Organ or tissue loss is currently treated by transplanting organs from one individual to another or performing surgical reconstruction by transferring tissue from one location in the human body to the diseased site. Furthermore, artificial devices made of plastic, metal, or fabrics are utilized. Mechanical devices such as dialysis machines or total joint replacement prostheses are used, and metabolic products of the lost tissue, such as insulin, are supplemented. Although these therapies have saved and improved millions of lives, they remain imperfect solutions.

Tissue engineering represents a new, emerging interdisciplinary field applying a set of tools at the interface of the biomedical and engineering sciences that use living cells or attract endogenous cells to aid tissue formation or regeneration (Rabkin *et al.*, 2002) to restore, maintain, or improve tissue function.

Engineered tissues using the patient's own (autologous) cells or immunologically inactive allogeneic or xenogeneic cells offer the potential to overcome the current problems of replacing lost tissue function and to provide new therapeutic options for diseases such as metabolic deficiencies.

CURRENT THERAPEUTIC APPROACHES FOR LOST TISSUE OR ORGAN FUNCTION

Transplantation

Organs or parts of organs are transplanted from a cadaveric or living-related donor into the patient suffering from lost organ function. Many innovative advances have been made in transplantation surgery during recent years and organ transplantation has been established as a curative treatment for end-stage diseases of liver, kidney, heart, lung, and pancreas (Starzl, 2001; Starzl *et al.*, 1989; Stratta *et al.*, 1994). Unfortunately, transplantation is substantially limited by a critical donor shortage. For example, fewer than 5200

liver donors are available annually for the approximately 18,500 who were on the waiting list in the year 2001 (<http://www.ustransplant.org/annual.html>). Besides the donor shortage, the other major problem of organ transplantation remains the necessity of lifelong immunosuppression therapy with a number of substantial and serious side effects (Keeffe, 2001).

Surgical Reconstruction

Organs or tissues are moved from their original location to replace lost organ function in a different location (e.g., saphenous vein as coronary bypass graft, colon to replace esophagus or bladder, myocutaneous flaps or freegrafts for plastic surgery). Nevertheless there are a number of problems associated with this method of therapy, since the replacement tissues, consisting of a different tissue type, cannot replace all of the functions of the original tissue. Moreover, long-term complications occur, such as the development of a malignant tumor in colon tissue replacing bladder function (Kato *et al.*, 1993; Kusama *et al.*, 1989) or calcification and resulting stenosis of vascular grafts (Kurbaan *et al.*, 1998). Finally, there is also the risk of complications and surgical morbidity at the donor site.

Artificial Prosthesis

The use of artificial, nonbiological materials in mechanical heart valves, blood vessels, joint replacement prostheses, eye lenses, or extracorporeal devices such as dialysis or plasmapheresis machines has improved and prolonged patients' lives dramatically. However, these methods are complicated by infection, limited durability of the material, lack of mechanism of biological repair and remodeling, chronic irritation, occlusion of vascular grafts, and the necessity of anticoagulation therapy and its side effects (Kudo *et al.*, 1999; Mow *et al.*, 1992). Regarding the pediatric patient population, not all artificial implants can provide a significant growth or remodeling potential, which often results in repeated operations associated with substantial morbidity and mortality (Mayer, 1995).

Supplementation of Metabolic Products of Diseased Tissues or Organs

In the case of the loss of endocrine tissue function, hormonal products such as insulin or thyroid, adrenal, or gonadal hormones can be successfully supplemented by oral or intravenous medication. In most cases, chronic supplementation is necessary. Unfortunately, supplementation therapy cannot replace natural feedback mechanisms, frequently resulting in dysregulation of hormone levels. As a consequence, clinical conditions such as hypo- or hyperglycemic crises or the long-term complications of chronic hormonal imbalances nephropathy or microvascular disease in patients with insulin-dependent diabetes mellitus continue to occur (Orchard *et al.*, 2002, 2003).

TISSUE ENGINEERING AS AN APPROACH TO REPLACE LOST TISSUE OR ORGAN FUNCTION

In the most frequent paradigm of tissue engineering, isolated living cells are used to develop biological substitutes for the restoration or replacement of tissue or organ function. Generally, cells are seeded on bioabsorbable scaffolds, a tissue is matured *in vitro*, and the construct is implanted in the appropriate anatomic location as a prosthesis. Cells used in tissue engineering may come from a variety of sources including application-specific differentiated cells from the patients themselves (autologous), human donors (allogeneic) or animal sources (xenogeneic), or undifferentiated cells comprising progenitor or stem cells. The use of isolated cells or cell aggregates enables manipulation prior to implantation, e.g., transfection of genetic material or modulation of the cell surface in order to prevent immunorecognition. Three general strategies have been adopted for the creation of new tissues including cell injection, closed, or flow-through systems, and tissue engineering using biodegradable scaffolds.

Cell Injection Method

The cell injection method avoids the complications of surgery by allowing the replacement of only those cells that supply the needed function. Isolated, dissociated cells are injected into the bloodstream or a specific organ of the recipient. The transplanted cells will use the vascular supply and the stroma provided by the host tissue as a matrix for attachment and reorganization (Matas *et al.*, 1976). This method offers opportunities for a number of applications in replacing metabolic functions as occurs in liver disease, for example (Grossman *et al.*, 1994). However, cell mass sufficient to replace lost metabolic functions is difficult to achieve and its application for replacing functions of structural tissues such as heart valves or cartilage is rather limited. Several cell types may be used for injection, such as bone marrow cells, blood-derived progenitor cells, and muscle satellite cells (see also the later subsection on tissue engineering of muscle).

Whole bone marrow contains multipotent mesenchymal stem cells (marrow stromal cells) that are derived from somatic mesoderm and are involved in the self-maintenance and repair of various mesenchymal tissues. These cells can be induced *in vitro* and *in vivo* to differentiate into cells of mesenchymal lineage, including fat, cartilage and bone, and cardiac and skeletal muscle. The first successful allogeneic bone marrow transplant in a human was carried out in 1968. More than 40,000 transplants (from bone marrow, peripheral blood, or umbilical cord blood) were carried out worldwide in 2000 (<http://www.ibmtr.org/newsletter/pdf/2002Feb.pdf>). The most common indications for allotransplants are acute and chronic leukemias, myelodysplasia (MDS), and nonmalignant diseases (aplastic anemia, immune deficiencies, inherited metabolic disorders). Autotransplants are generally used for non-Hodgkin's lymphoma (NHL), multiple myeloma (MM), Hodgkin's lymphoma, and solid tumors.

Experimental studies suggested that bone marrow-derived or blood-derived progenitor cells may also contribute,

e.g., to the regeneration of infarcted myocardium (Orlic *et al.*, 2001a).

Closed-System Method

Closed systems can be either implanted or used as extracorporeal devices. In this approach, cells are isolated from the body by a semipermeable membrane that allows diffusion of nutrients and the secreted cell products but prevents large entities such as antibodies, complement factors, or other immunocompetent cells from destroying the isolated cells. Protection is also provided to the recipient when potentially pathological (e.g., tumorigenic) cells are transplanted. Implantable systems (encapsulation systems) come in a variety of configurations, basically consisting of a matrix that cushions the cells and supports their survival and function and a surrounding porous membrane (Fig. 1). In vascular-type designs the transplanted secretory cells are housed in a chamber around a vascular conduit separated from the bloodstream by a semipermeable membrane. As blood flows through, it can absorb substances secreted by the therapeutic cells while the blood provides oxygen and nutrients to the cells. In macroencapsulation systems, a semipermeable membrane is used to encapsulate a relatively large (up to 50–100 million per unit) number of transplanted cells. Microcapsules are basically microdroplets of hydrogel with a diameter of less than 0.5 mm housing smaller numbers of cells. Macrocapsules are far more durable than microcapsule droplets and can be designed to be refillable in the body. Moreover, they can be retrieved, providing opportunities for

FIG. 1. Configurations of implantable closed-system devices for cell transplantation. (Reprinted with permission from Langer, R., and Vacanti, J. P., 1993. *Science* 260: 920–926.)

more control than microcapsules. Their main limitation is the number of cells they can accommodate. In animal experiments, implantable closed-system configurations have been successfully used for the treatment of Parkinson's disease as well as diabetes mellitus (Aebischer *et al.*, 1991, 1988; Kordower *et al.*, 1995; Date *et al.*, 2000). If islets of Langerhans are used, they will match the insulin released to the concentration of glucose in the blood. This has been successfully demonstrated in small and large animals with maintenance of normoglycemia even in long-term experiments (Kin *et al.*, 2002; Lacy *et al.*, 1991; Lanza *et al.*, 1999; Sullivan *et al.*, 1991). Major drawbacks of these systems are fibrous tissue overgrowth and resultant impaired diffusion of metabolic products, nutrients, and wastes, as well as the induction of a foreign-body reaction with macrophage activation resulting in destruction of the transplanted cells within the capsule (Wiegand *et al.*, 1993).

In extracorporeal systems (vascular or flow-through designs) cells are usually separated from the bloodstream. Great progress is being made in the development of extracorporeal liver assist devices for support of patients with acute liver failure. Currently four devices that rely on allogenic or xenogenic hepatocytes cultured in hollow-fiber membrane technology are in various stages of clinical evaluation (Patzner, 2001; Rozga *et al.*, 1994).

Tissue Engineering Using Scaffold Biomaterials

Open systems of cell transplantation with cells being in direct contact to the host organism aim to provide a permanent solution to the replacement of living tissue. The rationale behind the use of open systems is based on empirical observations: dissociated cells tend to reform their original structures when given the appropriate environmental conditions in cell culture. For example, capillary endothelial cells form tubular structures and mammary epithelial cells form acini that secrete milk on the proper substrata *in vitro* (Folkman and Haudenschild, 1980). Although isolated cells have the capacity to reform their respective tissue structure, they do so only to a limited degree since they have no intrinsic tissue organization and are hindered by the lack of a template to guide restructuring. Moreover, tissue cannot be transplanted in large volumes because diffusion limitations restrict interaction with the host environment for nutrients, gas exchange, and elimination of waste products. Therefore, the implanted cells will survive poorly more than a few hundred microns from the nearest capillary or other source of nourishment (Vacanti *et al.*, 1988). With these observations in mind, an approach has been developed to regenerate tissue by attaching isolated cells to biomaterials that serve as a guiding structures for initial tissue development. Ideally, these scaffold materials are biocompatible, biodegradable into nontoxic products, and manufacturable (Rabkin *et al.*, 2002). Natural materials used in this context are usually composed of extracellular matrix components (e.g., collagen, fibrin) or complete decellularized matrices (e.g., heart valves, small intestinal submucosa). Synthetic polymer materials are advantageous in that their chemistry and material properties (biodegradation profile, microstructure) can be well controlled. The majority of scaffold-based tissue

engineering concepts utilize synthetic polymers [e.g., poly (glycolic acid) (PGA), poly (lactid acid) (PLA), or poly (hydroxy alkanate) (PHA)]. In general, these concepts involve harvesting of the appropriate cell types and expanding them *in vitro*, followed by seeding and culturing them on the polymer matrices. The polymer scaffolds are designed to guide cell organization and growth allowing diffusion of nutrient to the transplanted cells. Ideally, the cell-polymer matrix is prevascularized or would become vascularized as the cell mass expands after implantation. Vascularization could be a natural response to the implant or be artificially induced by sustained release of angiogenic factors from the polymer scaffold (Langer and Vacanti, 1999). Since the polymer scaffold is designed to be biodegradable, concerns regarding long-term biocompatibility are obviated.

Cells used in tissue engineering may come from a variety of sources including cell lines from the patients themselves (autologous), human donors (allogeneic), or animal sources (xenogeneic). However, allogeneic and xenogeneic tissue may be subjected to immunorejection. Cell-surface modulation offers a possible solution to this problem by deleting immunogenic sites and therefore preventing immunorecognition. A bank of cryopreserved cells would then be possible and genetic engineering techniques could be used to insert genes (Raper and Wilson, 1993) to replace proteins, such as the LDL receptor (Chowdhury *et al.*, 1991) or factor IX (Armentano *et al.*, 1990).

APPLICATIONS OF TISSUE ENGINEERING:

Investigators have attempted to engineer virtually every mammalian tissue. In the following summary, we discuss replacement of ectodermal, endodermal, and mesodermal derived tissues.

Ectodermal Derived Tissue

Nervous System

Diseases of the central nervous system, such as a loss of dopamine production in Parkinson's disease, represent an important target for tissue engineering. Transplantation of fetal dopamine-producing cells by stereotactically guided injection into the appropriate brain region has produced significant reversal of debilitating symptoms in humans (Lindvall *et al.*, 1990). Further benefit regarding survival, growth, and function has been demonstrated when implantation of dopamine-producing cells was combined with polymer-encapsulated cells continuously producing human glial cell line-derived growth factor (GDNF) (Sautter *et al.*, 1998). In the animal model PC12 cells, an immortalized cell line derived from rat pheochromocytoma, have been encapsulated in polymer membranes and implanted in the guinea pig striatum (Aebischer *et al.*, 1991) or primates (Date *et al.*, 2000; Kordower *et al.*, 1995), resulting in a dopamine release from the capsule detectable for many months. Similarly, encapsulated bovine adrenal chromaffin cells have been implanted into the subarachnoid space in rats, where through their continuous production of enkephalins

and catecholamines they appeared to relieve chronic intractable pain (Sagen, 1992). Finally, investigations have been undertaken to achieve brain tissue by immobilization of neuronal and glia cells in *N*-methacrylamide polymer hydrogels. These cells have shown cell viability and maintained differentiation *in vitro* (Woerly *et al.*, 1996).

Nerve regeneration is another field of current investigations. When nerve injury results in gaps that are too wide for healing, autologous nerve grafts are used as a bridge. Several laboratories have shown in animal models that artificial guiding structures composed of natural polymers (laminin, collagen, chondroitin sulfate) or synthetic polymers can enhance nerve regeneration (Valentini *et al.*, 1992). Moreover, this process can be aided by placing Schwann cells seeded in polymer membranes (Guenard *et al.*, 1992). Polymers can also be designed so that they slowly release growth factors, possibly allowing regrowth of the damaged nerve over a greater distance (Aebischer *et al.*, 1989; Haller and Saltzman, 1998). In the case of neurodegenerative diseases such as amyotrophic lateral sclerosis (ALS), progression of the motor neuron disease could be successfully delayed in the animal model by polymer encapsulation of genetically modified cells to secrete neurotrophic factors. This suggests that encapsulated cell delivery of neurotrophic factors may provide a general method or effective administration of therapeutic proteins for the treatment of neurodegenerative diseases (Aebischer *et al.*, 1996a, b; Tan *et al.*, 1996).

Recently, a phase I/II clinical trial has been performed in 12 amyotrophic lateral sclerosis (ALS) patients to evaluate the safety and tolerability of intrathecal implants of encapsulated genetically engineered baby hamster kidney (BHK) cells releasing human ciliary neurotrophic factor (CNTF) (Aebischer *et al.*, 1996b, Zurn *et al.*, 2000). No adverse side effects have been observed in these patients in contrast to the systemic delivery of large amount of CNTF. However, antibodies against bovine fetuin have been detected because the capsules have been kept in a medium containing fetuin before transplantation.

Micorencapsulated cells may also be used for the treatment of malignant brain tumors (Thorsen *et al.*, 2000). Genetically modified cells secrete tumor controlling/suppressing substances such as the anti-angiogenic protein endostatin (Read *et al.*, 2001).

Cornea

The cornea is a transparent window covering the front surface of the eye that protects the intraocular contents and is the main optical element that focuses light onto the retina. Worldwide, millions of people suffer from bilateral corneal blindness. Transplant donors are limited and there is a risk of infectious agent transmission. Moreover, in the case that the limbal epithelial stem cells of the recipient are damaged (alkali burns, autoimmune conditions, or recurrent graft failures), the donor corneal epithelium desquamates and is replaced by conjunctivization and fibrovascular scarring in the recipient.

The cornea is avascular and immunologically privileged, making this tissue an excellent candidate for tissue engineering. Ideally, an artificial cornea would consist of materials that support adhesion and proliferation of corneal epithelial cells so that an intact continuous epithelial layer forms.

In addition, these materials should have appropriate nutrient and fluid permeability, light transparency, low light scattering, and no toxicity. Artificial cornea has been developed that consisted of a peripheral rim of biocolonizable microporous fluorocarbon polymer (polytetrafluoroethylene, PTFE) fused to an optical core made of polydimethylsiloxane coated with polyvinylpyrrolidone (Legeais and Renard, 1998). In contrast to this “hybrid” cornea, another group used poly-(2-hydroxyethyl methacrylate) (PHEMA) for both the porous skirt (opaque sponge, 10–30 μm) and the optical core (transparent gel) (Chirila, 2001; Crawford *et al.*, 2002). PHEMA is a biomaterial with a long record of ocular tolerance in applications such as contact lenses, intraocular lenses, and intracorneal inlays. The use of this material as porous sponge allowed cellular invasion, production of collagen, and vascularization, without the formation of a foreign-body capsule. Both devices have been tested preclinically.

Furthermore, tissue-engineered implantable contact lenses could obviate the need for surgery in patients who seek convenient, reversible correction of refractive error. An onlay involves debridement of the central corneal epithelium and placement of a synthetic lenticule on the exposed stromal surface, leaving Bowman’s zone intact. The anterior surface of the lenticule is then covered by the recipient eye’s corneal epithelium, incorporating the lenticule to achieve the desired refractive correction by altering the curvature of the anterior corneal surface. Porous collagen-coated perfluoropolyether (PFPE) was successfully tested in cats (Evans *et al.*, 2002) and Lidifilcon A, a copolymer of methyl methacrylate and *N*-vinyl-2-pyrrolidone (Allergan Medical Optics, Irvine, CA) was implanted in monkeys (McCarey *et al.*, 1989).

The multistep procedure of corneal reconstruction has been demonstrated using corneal cells from rabbit (Zieske *et al.*, 1994) and from fetal pig (Schneider *et al.*, 1999), human cells from donor corneas (Germain *et al.*, 1999), or immortalized cell lines from the main layers of the cornea (Griffith *et al.*, 1999). In these studies collagen matrices or collagen-chondroitin sulfate substrates cross-linked with glutaraldehyde have been tested. More recently, carbodiimide cross-linking and composites using urethane/urea techniques have been evaluated for biocompatibility and epithelial ingrowth (Griffith *et al.*, 2002).

Skin

Several new types of tissue transplants are being studied for treatment of burns, skin ulcers, deep wounds, and other injuries. One approach to skin grafts involves the *in vitro* culture of epidermal cells (keratinocytes). Small skin biopsies are harvested from burn patients and expanded up to 10,000-fold. This expansion is achieved, e.g., by cultivating keratinocytes on a feeder layer of irradiated NIH 3T3 fibroblasts, which, in conjunction with certain added media components, stimulates rapid cell growth. This approach allows coverage of extremely large wounds. A disadvantage is the 3- to 4-week period required for cell expansion, which may be too long for a severely burned patient. Cryopreserved allografts may help to circumvent this problem (Nave, 1992). Another promising approach uses human neonatal dermal fibroblasts grown on

poly(glycolic acid) mesh. In deep injuries involving all layers of skin the grafts are placed onto the wound bed and a skin graft is placed on top followed by vascularization of the graft. This results in formation of an organized tissue resembling dermis. Clinical trials have shown good graft acceptance without evidence of immune rejection (Hansbrough *et al.*, 1992). Fibroblasts have also been placed on hydrated collagen gel. Upon implantation, the cells migrate through the gel by enzymatic digestion of collagen, which results in reorganization of collagen fibrils (Bell *et al.*, 1979). ApliGraf, formerly known as Graftskin, is a commercially available two-layered tissue-engineered skin product composed of type I bovine collagen that contains living human dermal fibroblasts and an overlying cornified epidermal layer of living human keratinocytes. Both cell types are derived from neonatal foreskin and grow in a special mold that limits lateral contraction (Bell *et al.*, 1991a, b). ApliGraf has been investigated in a multicenter study after excisional surgery for skin cancer with good results (Eaglstain *et al.*, 1999).

The artificial skin developed by Burke and Yannas (Burke *et al.*, 1981), now called Integra, consists of collagen-chondroitin 6-sulfate fibers obtained from bovine hide (collagen) and shark cartilage (chondroitin 6-sulfate). It has been engineered into an open matrix of uniform porosity and thickness and covered with a uniformly thick (0.1-mm) silicone sheet. This artificial skin has been studied extensively in humans (Heimbach *et al.*, 1988; Sheridan *et al.*, 1994) and was approved for use in burn patients in 1997.

Besides clinical use of artificial skin, several companies have explored the possibilities of dermal substitutes for diagnostic purposes. There is particular interest in minimizing the use of animals for topological irritation, corrosivity, and other testing (Fentem *et al.*, 2001; Portes *et al.*, 2002). Gene therapy for genodermatoses (Spirito *et al.*, 2001), junctional epidermolysis bullosa (Robbins *et al.*, 2001), and ichthyosis (Jensen *et al.*, 1993) remains a topic of great interest using either transgenic fibroblasts or keratinocytes.

Endoderm

Liver

Liver transplantation is a routine treatment for end-stage liver disease, but donor organ shortage remains a serious problem. Many patients die while waiting for a transplant and those with chronic disease often deteriorate resulting in low survival rates after transplantation. Therefore a "bridging" device that would support liver function until a donor liver became available or the patient's liver recovered is of great interest. Most liver support systems remove toxins normally metabolized by the liver through dialysis, charcoal hemoperfusion, immobilized enzymes, or exchange transfusion. However, none of these systems can offer the full functional spectrum performed by a healthy liver. Hepatocyte systems aiming at replacement of liver function by transplantation of isolated cells are being studied for both extracorporeal and implantable applications. Extracorporeal systems can be used when the patient's own organ is recovering or as a bridge to transplantation. These systems provide a good control of the medium surrounding the cell

system and a minimized risk of immune rejection. Their design is primarily based on hollow-fiber, spouted-bed, or flat-bed devices (Bader *et al.*, 1995). Implantable hepatocyte systems, on the other hand, offer the possibility of permanent liver replacement (Yarmush *et al.*, 1992a). Successful hepatocyte transplantation depends on a number of critical steps. After cell harvest the hepatocytes must be cultured and expanded *in vitro* prior to transplantation. Hepatocyte morphology can be maintained by cultivating the cells on three-dimensional structures, such as sandwiching them between two hydrated collagen layers. Under these conditions the hepatocytes have been shown to secrete functional markers at physiological levels (Dunn *et al.*, 1991). Moreover the hepatocytes must be attached to the polymer substrata so that they maintain their differentiated function and viability. A sufficient mass of hepatocytes must become engrafted and remain functional to achieve metabolic replacement and vascularization, which is critical for graft survival (Yarmush *et al.*, 1992b). Finally, hepatocyte transplantation per se provides neither all cell types nor the delicate and complex structural features of the liver. Products normally excreted through bile may accumulate because of the difficulty in reconstructing the biliary tree solely from hepatocytes. However, hepatocytes placed on appropriate polymers can form tissues resembling those in the natural organ and have shown evidence of bile ducts and bilirubin removal (Uyama *et al.*, 1993). More recently, model systems in which the vascular architecture is mimicked in the device have been tested using three-dimensional printing, hepatocytes, and endothelial cells (Fig. 2; Kim *et al.*, 1998).

Four bioartificial liver devices have entered sustained clinical trials. The device rely all on hollow-fiber membranes to isolate hepatocytes from direct contact with patient fluids. They differ in source and treatment of hepatocytes prior to patient use and in the choice of perfusate: plasma or whole blood. Three devices are perfused with the patient's plasma. The HepatAssist is filled with freshly thawed cryopreserved primary porcine hepatocytes along with collagen-coated dextran beads for cell attachment (Chen *et al.*, 1997; Rozga *et al.*, 1993; Watanabe *et al.*, 1997). The ELAD system uses a HepG2 human hepatocyte cell line that has been grown to confluence in the extracellular space (Ellis *et al.*, 1996; Sussman *et al.*, 1994). The Gerlach BELS run either with human hepatocytes (if available) or with porcine primary hepatocytes embedded in a collagen matrix in the extraluminal space (Gerlach, 1997; Gerlach *et al.*, 1997). In contrast, the bioartificial liver support system (BLSS) is perfused with whole blood. This has the advantage that a greater rate of blood concentration reduction and lower endpoint blood concentration at equivalent perfusion times is achieved compared to systems using plasma perfusion. The detoxification is performed with primary porcine hepatocytes (Mazariegos *et al.*, 2001; Patzer *et al.*, 2002, 1999).

Pancreas

Each year more than 700,000 new cases of diabetes are diagnosed in the United States and approximately 150,000 patients die from the disease and its complications. Diabetes is characterized by pancreatic islet destruction leading to more

FIG. 2. Histologic photomicrograph demonstrating viable hepatic cells after 2 days under flow conditions (hematoxylin and eosin; original magnification $\times 300$). (Reprinted with permission from Kim, S. S., *et al.*, 1998. *Ann. Surg.* 228: 8–13.)

or less complete loss of glucose control. Tissue engineering approaches to treatment have focused on transplanting functional pancreatic islets, usually encapsulated to avoid immune reaction. Three general approaches have been tested in animal experiments. In the first, a tubular membrane was coiled in a housing that contained islets. The membrane was connected to a polymer graft that in turn connected the device to blood vessels. This membrane had a 50-kDa molecular mass cutoff, thereby allowing free diffusion of glucose and insulin but blocking passage of antibodies and lymphocytes. In pancreatectomized dogs treated with this device, normoglycemia was maintained for more than 150 days (Sullivan *et al.*, 1991). In a second approach, hollow fibers containing rat islets were immobilized in polysaccharide alginate. When the device was placed intraperitoneally in diabetic mice, blood glucose levels were lowered for more than 60 days and good tissue biocompatibility was observed (Lacy *et al.*, 1991). Finally, islets have been enclosed in microcapsules composed of alginate or polyacrylate. This method offers a number of distinct advantages over the use of other biohybrid devices, including greater surface-to-volume ratio and ease of implantation (simple injection) (Kin *et al.*, 2002; Lanza *et al.*, 1999, 1995). All of these transplantation strategies require a large, reliable source of donor islets. Porcine islets are used in many studies and genetically engineered cells that overproduce insulin are also under investigation (Efrat, 1999).

Tubular Structures

The current concept of using tubular structures of other organs for reconstruction of bladder, ureter and urethra, trachea, esophagus, intestine, and kidney represents a major

therapeutic improvement. A diseased esophagus, for example, can be treated clinically with autografts from the colon, stomach, skin, or jejunal segments. However, such procedures carry a substantial risk of graft necrosis, inadequate blood supply, infection, lack of peristaltic activity, and other complications. Copolymer tubes consisting of lactic and glycolic acid have been sutured into dogs after removal of esophageal segments, over time resulting in coverage of the polymer with connective tissue and epithelium (Grower *et al.*, 1989). Alternatively, elastin-based acellular aortic patches have been successfully used in experimental esophagus injury in the pig. While mucosal and submucosal coverage took place within 3 weeks, the majority of the elastin-based biomaterial degraded. However, the muscular layer did not regenerate (Kajitani *et al.*, 2001). In a similar approach fetal intestinal cells have been placed onto copolymer tubes and implanted in rats. Histological examination after several weeks revealed differentiated intestinal epithelium lining of the tubes and this epithelium appeared to secrete mucus (Vacanti *et al.*, 1988). Furthermore, intestinal epithelial organoid units transplanted on porous biodegradable polymer tubes have been shown to vascularize and to regenerate into complex tissue resembling small intestine (Kim *et al.*, 1999), and successful anastomosis between tissue-engineered intestine and native small bowel has been performed (Fig. 3; Kaihara *et al.*, 1999). Finally, Perez *et al.* demonstrated that tissue-engineered small intestine is capable of developing a mature immunocyte population and that mucosal exposure to luminal stimuli is critical to this development (Perez *et al.*, 2002). Despite these promising findings, the regeneration of the muscle layer seems to be a major problem. Autologous mesenchymal stem cells seeded onto a collagen sponge graft induced only a transient distribution

FIG. 3. Histology of a tissue-engineered intestine 10 weeks after implantation characterized by crypt villus structures. Arrow indicates anastomosis site; left site of the arrow is tissue-engineered intestine and right is native small bowel. (Reprinted with permission from Kaihara, S., *et al.*, 1999. *Transpl. Proc.* 31: 661–662.)

of cells positive for α -smooth muscle actin (Hori *et al.*, 2002).

Tubular structures have also been used in kidney replacement. As a first step toward creating a bioartificial kidney, renal tubular cells have been grown on acrylonitrile–vinyl chloride copolymers or microporous cellulose nitrate membranes. *In vitro*, these cells transported glucose and tetraethylammonium cation in the presence of a hemofiltrate of uremic patients (Uludag *et al.*, 1990). In a further attempt to create bioartificial renal tubule, renal epithelial cells have been grown on hollow fibers and formed an intact monolayer exhibiting functional active transport capabilities (MacKay *et al.*, 1998). Finally, an extracorporeal device was developed using a standard hemofiltration cartridge containing renal tubule cells (Humes *et al.*, 1999; Nikolovski *et al.*, 1999). The pore size of the hollow fibers allows the membranes to act as scaffolds for the cells and as an immunoprotective barrier. *In vitro* and *in vivo* studies have shown that the cells keep differentiated active transport, differentiated metabolic transport, and important endocrine processes (Humes *et al.*, 2002, 2003).

For replacement of urether, urothelial cells were seeded onto degradable polyglycolic acid tubes and implanted in rats and rabbits resulting in two or three layers of urothelial cell lining (Atala *et al.*, 1992). More recently, an acellular collagen matrix from bladder submucosa seeded with cells from urethral tissue was also successfully used for tubularized replacement in the rabbit. In contrast, unseeded matrices lead to poor tissue development (de Filippo *et al.*, 2002). A neo-bladder has been created from urothelial and smooth muscle cells *in vitro* and after implantation in the animal, functional evaluation for up to 11 months has demonstrated a normal capacity to retain urine, normal elastic properties, and normal histologic architecture (Oberpenning *et al.*, 1999).

Mesoderm

Cartilage

More than 1 million surgical procedures in the United States each year involve cartilage replacement. Current therapies include cartilage transplantation and implantation of artificial polymer or metal prostheses. Unfortunately, donor tissue is limited and artificial implants may result in infection and adhesive breakdown at the host–prosthesis interface. Finally, a prosthesis cannot adapt in response to environmental stresses as does cartilage (Mow *et al.*, 1992). The need for improved treatments has motivated research aiming at creating new cartilage that is based on collagen–glycosaminoglycan templates (Stone *et al.*, 1990), isolated chondrocytes (Grande *et al.*, 1989), and chondrocytes attached to natural or synthetic polymers (Cancedda *et al.*, 2003; Vacanti *et al.*, 1991; Wakitani *et al.*, 1989). It is critical that the cartilage transplant have an appropriate thickness and attachment to be mechanically functional. Chondrocytes grown in agarose gel culture have been shown to produce tissues with stiffness and compressibility comparable to those of articular cartilage (Freed *et al.*, 1993). The use of bioreactors for cultivating chondrocytes on polymer scaffolds *in vitro* enables nutrients to penetrate the center of this nonvascularized tissue, leading to relatively strong and thick (up to 0.5 cm) implants (Buschmann *et al.*, 1992). Moreover, it has been shown that the hydrodynamic conditions in tissue-culture bioreactors can modulate the composition, morphology, mechanical properties, and electromechanical function of engineered cartilage (Vunjak-Novakovic *et al.*, 1999). In other studies, chondrocytes were seeded onto PGA meshes and conditioned for several weeks on an orbital shaker. The functional cartilage was then combined with an osteoconductive support made of ceramic/collagen sponge. The composite

was press-fitted in a large experimental osteochondral injury in a rabbit knee joint, where it showed good structural and functional properties (Schaefer *et al.*, 2002). With regard to the needs of reconstructive surgery, tissue-engineered autologous cartilage has been generated *in vitro* from tiny biopsies (Naumann *et al.*, 1998). Finally, some research has been undertaken to evaluate tissue engineering of cartilage even in space in order to elucidate the influence of micro/gravitation on tissue formation (Freed *et al.*, 1997).

Bone

Current therapies of bone replacement include the use of autogenous or allogenic bone. Moreover, metals and ceramics are used in several forms: biotolerant (e.g., titanium), bioresorbable (e.g., tricalcium phosphate), porous (e.g., hydroxyapatite-coated metals), and bioactive (e.g., hydroxyapatite and glasses). Synthetic and natural polymers have been investigated for bone repair, but it has been difficult to create a polymer displaying optimal strength and degradation properties. Another approach involves implantation of demineralized bone powder (DBP), which is effective in stimulating bone growth. By inducing and augmenting formation of both cartilage and bone (including marrow), bone morphogenic proteins (BMP) or growth factors such as transforming growth factor- β (TGF- β) represent other promising strategies (Toriumi *et al.*, 1991; Yasko *et al.*, 1992). Bone growth can also be induced when cells are grown on synthetic polymers and ceramics. For example, when human marrow cells are grown on porous hydroxyapatite in mice, spongy bone formation was detectable inside the pores within 8 weeks (Casabona *et al.*, 1998). Femoral shaft reconstruction has been demonstrated using bioresorbable polymer constructs seeded with osteoblasts as bridges between the bone defect (Puelacher *et al.*, 1996), and similar experiences have been reported for craniofacial applications (Breitbart *et al.*, 1998). Formation of phalanges and small joints has been demonstrated with selective placement of periosteum, chondrocytes, and tenocytes into a biodegradable synthetic polymer scaffold (Isogai *et al.*, 1999). Large bone defects in tibia of sheep were successfully reconstructed using combinations of autologous marrow stromal cells and coral (Petite *et al.*, 2000). Similar results were obtained by Kadiyala *et al.*, who have treated experimentally induced nonunion defects in adult dog femora with autologous marrow-derived cells grown on a hydroxyapatite:beta tricalcium phosphate (65:35) scaffold (Kadiyala *et al.*, 1997). This approach was also successful in patients suffering from segmental bone defects. Abundant callus formation along the implants and good integration at the interface with the host bones was observed 2 months after surgery (Quarto *et al.*, 2001).

Muscle

The ability to generate muscle fibers has possible application regarding the treatment of muscle injury, cardiac disease, disorders involving smooth muscle of the intestine or urinary tract, and systemic muscular diseases such as Duchenne muscular dystrophy (DMD). Myoblasts from unaffected relatives have been transplanted into Duchenne patients and shown to produce dystrophin several months following the implantation.

Myoblasts can migrate from one healthy muscle fiber to another (Gussoni *et al.*, 1992); thus cell-based therapies may be useful in treating muscle atrophies. Creation of a whole hybrid muscular tissue was achieved by a sequential method of centrifugal cell packing and mechanical stress-loading resulting in tissue formation strongly resembling native muscle in terms of cell density, cell orientation, and incorporation of capillary networks (Okano *et al.*, 1998). Kim and Mooney demonstrated with regard to smooth muscle cells the importance of matching both the initial mechanical properties and the degradation rate of a predefined three-dimensional scaffold to the specific tissue that is being engineered (Kim and Mooney, 1998).

Loss of heart muscle tissue in the course of ischemic heart disease or cardiomyopathies is a major factor of morbidity and mortality in numerous patients. Once patients become symptomatic, their life expectancy is usually markedly shortened. This decline is mostly attributed to the inability of cardiomyocytes to regenerate after injury. Necrotic cells are replaced by fibroblasts leading to scar tissue formation and regional contractile dysfunction. In contrast, skeletal muscle has the capacity of tissue repair, presumably because of satellite cells that have regenerative capability. Satellite cells are undifferentiated skeletal myoblasts, which are located beneath the basal lamina in skeletal muscles. These cells have also been tested for myocardial repair (Chiu *et al.*, 1995; Menasche, 2003; Menasche *et al.*, 2001; Taylor *et al.*, 1998). In rats, myoblast grafts can survive for at least 1 year (Al Attar *et al.*, 2003). However, satellite cells transplanted into nonreperfused scar tissue do not transdifferentiate into cardiomyocytes but show a switch to slow-twitch fibers, which allow sustained improvement in cardiac function (Hagege *et al.*, 2003; Reinecke *et al.*, 2002).

Recent studies have suggested that bone marrow-derived or blood-derived progenitor cells contribute to the regeneration of infarcted myocardium and enhance neovascularization of ischemic myocardium (Kawamoto *et al.*, 2001; Orlic *et al.*, 2001a, b). In a pilot trial it was shown that also in patients with reperfused acute myocardial infarction, intracoronary infusion of autologous progenitor cells beneficially affected postinfarction left-ventricle remodeling processes (Assmus *et al.*, 2002).

An alternative approach to cell grafting techniques is the generation of cardiac tissue grafts *in vitro* and implanting them as spontaneously and coherently contracting tissues. As a model system, rat neonatal or embryonic chicken cardiomyocytes may be seeded on three-dimensional polymeric scaffolds (Carrier *et al.*, 1999) or collagen disks formed as a sponge (Radisic *et al.*, 2003) or by layering cell sheets three-dimensionally (Shimizu *et al.*, 2002). The latter two approaches are suitable for producing thicker cardiac tissue with more evenly distributed cells at a higher density. A principally different approach to generate engineered heart tissue was developed by Eschenhagen and colleagues. Neonatal or embryonic cardiomyocytes were mixed with freshly neutralized collagen I and cast into a cylindrical mold. After a few days the tissue patches were transferred to a stretching device, which induced hypertrophic growth and increased cell differentiation (Eschenhagen *et al.*, 2002b, 1997; Zimmermann *et al.*, 2000). Interestingly, the response to isoprenaline of stretched tissue was much more

pronounced than in unstretched tissue (Eschenhagen *et al.*, 2002b; Zimmermann *et al.*, 2002).

Blood Vessels

Peripheral vascular disease represents a growing health and socioeconomic burden in most developed countries (Ounpuu *et al.*, 2000). Today, artificial prostheses made of expanded polytetrafluoroethylene (ePTFE) and poly(ethylene terephthalate) (PET, Dacron) are the most widely used synthetic materials. Although successful in large diameter (> 5-mm) high-flow vessels, in low-flow or smaller diameter sites they are compromised by thrombogenicity and compliance mismatch (Edelman, 1999). To circumvent these problems numerous modifications and techniques to enhance hemocompatibility and graft patency have been evaluated both *in vitro* and *in vivo*. These include chemical modifications, coatings (Gosselin *et al.*, 1996; Ye *et al.*, 2000), and surface seeding with endothelial cells (Pasic *et al.*, 1996; Zilla *et al.*, 1999). *In vitro* endothelialization of ePTFE grafts may result in patency rates comparable to state-of-the-art venous autografts (Meinhart *et al.*, 1997). Polymer surface modifications involving protein adsorption may also be desirable. Unfortunately, materials that promote endothelial cell attachment often simultaneously promote attachment of platelets and smooth muscle cells associated with the adverse side effects of clotting and pseudointimal thickening. A possible solution has been demonstrated with polymers containing adhesion molecules (ligands) specific for endothelial cells (Hubbell *et al.*, 1991).

To overcome the limitations just mentioned, tissue engineering procedures could lead to completely biological vascular grafts. In fact, there have already been case reports regarding first human pediatric applications of tissue-engineered large-diameter vascular grafts (Naito *et al.*, 2003; Shin'oka *et al.*, 2001). As to small-caliber grafts, there are three principal approaches involving (1) synthetic biodegradable scaffolds, (2) biological scaffolds, and (3) completely autologous methods.

1. Niklason *et al.* have shown in animal models that by utilizing flow bioreactors to condition biodegradable polymers loaded with vascular cells, it is possible to generate arbitrary lengths of functional vascular grafts with significant extracellular matrix production, contractile responses to pharmacological agents, and tolerance of suprathysiologic burst pressures (Mitchell and Niklason, 2003; Niklason *et al.*, 2001, 1999). Similar *in vitro* experiments based on human vascular-derived cells seeded on PGA/PHA copolymers demonstrated the feasibility of viable, surgically implantable human small-caliber vascular grafts and the important effect of a "biomimetic" *in vitro* environment on tissue maturation (Hoerstrup *et al.*, 2001).
2. A different approach to tissue engineering of vascular grafts comprises the use of decellularized natural matrices as initially introduced by Rosenberg *et al.* (1996). Histological examination of chemically decellularized carotid arteries revealed well-preserved structural matrix proteins. This provides an acellular scaffold that can be successfully repopulated *in vitro* prior to implantation

(Teebken *et al.*, 2000). Such scaffolds have also been shown to be repopulated *in vivo* (Bader *et al.*, 2000). Recently, successful utilization of endothelial precursor cells for tissue engineering of vascular grafts based on decellularized matrices has been demonstrated (Kaushal *et al.*, 2001).

3. L'Heureux *et al.* cultured and conditioned sheets of vascular smooth muscle cells and their native extracellular matrix without any scaffold material in a flow system. Subsequently these sheets were placed around a tubular support device and after maturation the tubular support was removed and endothelial cells were seeded into the lumen. Thereby a complete scaffold-free vessel was created with a functional endothelial layer and a burst strength of more than 2000 mm Hg (L'Heureux *et al.*, 1998).

Angiogenesis (the formation of new blood vessels) is essential for growth, tissue repair, and wound healing. Therefore, many tissue-engineering concepts involve angiogenesis for the vascularization of the newly generated tissues. Unfortunately, so far advances have been compromised by the inability to vascularize thick, complex tissues, particularly those comprising large organs such as the liver, kidney, or heart. To overcome these limitations, several approaches have been investigated. Vacanti and co-workers used local delivery of basic fibroblast growth factor (bFGF) to increase angiogenesis and engraftment of hepatocytes in tissue-engineered polymer devices (Lee *et al.*, 2002). In another study sustained and localized delivery of vascular endothelial growth factor (VEGF) combined with the transplantation of human microvascular endothelial cells was used to engineer new vascular networks (Peters *et al.*, 2002). Using micromachining technologies on silicon, Kaihara *et al.* demonstrated *in vitro* generation of branched three-dimensional vascular networks formed by endothelial cells (Kaihara *et al.*, 2000).

Heart Valves

For treatment of heart-valve disease, mechanical or biological valves are currently in use. The drawbacks of mechanical valves include the need for lifelong anticoagulation, the risk of thromboembolic events, prosthesis failure, and the inability of the device to grow. Biological valves (homograft, xenograft, fixed by cryopreservation or chemical treatment) have a limited durability due to their immunogenic potential and the fact that they represent nonliving tissues without regeneration capacities. All types of contemporary valve prostheses basically consist of nonliving, foreign materials, posing specific problems to pediatric applications when devices with growth potential are required for optimal treatment.

The basic concept currently used for tissue engineering of heart valve structures is to transplant autologous cells onto a biodegradable scaffold, to grow and to condition the cell-seeded scaffold device *in vitro*, and finally to implant the tissue-like construct into the donor patient.

The heart-valve scaffold may be based on either biological or synthetic materials. Donor heart valves or animal-derived valves depleted of cellular antigens can be used as a scaffold material. Removing the cellular components results in

a material composed of essentially extracellular matrix proteins that can serve as an intrinsic template for cell attachment (Samouillan *et al.*, 1999). In general, nonfixed acellularized valve leaflets have shown recellularization by the host, as demonstrated in dogs (Wilson *et al.*, 1995) and sheep (Elkins *et al.*, 2001; Goldstein *et al.*, 2000). However, first clinical applications of this concept in children resulted in rapid failure of the heart valves due to severe foreign-body-type reactions associated with a 75% mortality (Simon *et al.*, 2003). In a further approach, specific biological matrix constituents can be used as scaffold material. Collagen is one of the materials that show biodegradable properties and can be used as a foam (Rothenburger *et al.*, 2002), gel or sheet (Hutmacher *et al.*, 2001), or sponge (Taylor *et al.*, 2002), and even as a fiber-based scaffold (Rothenburger *et al.*, 2001). It has the disadvantage that it is difficult to obtain from the patient. Therefore, most of the collagen scaffolds are of animal origin. Another biological material displaying good controllable biodegradable properties is fibrin. Since fibrin gels can be produced from the patient's blood to serve as autologous scaffold, no toxic degradation or inflammatory reactions are expected (Lee and Mooney, 2001).

The use of synthetic materials as scaffolds has already been broadly demonstrated for cardiovascular tissue engineering. Initial attempts to create single heart-valve leaflets were based on synthetic scaffolds, such as polyglactin, PGA [poly(glycolic acid)], PLA [poly(lactic acid)], or PLGA (copolymer of PGA and PLA). To create complete trileaflet heart-valve conduits, PHA-based materials (polyhydroxyalkanoates) were used (Sodian *et al.*, 2000). These materials are thermoplastic and can therefore be easily molded into any desired three-dimensional shape. A combined polymer scaffold consisting of nonwoven PGA and P4HB (poly-4-hydroxybutyrate) has shown promising *in vivo* results (Hoerstrup *et al.*, 2000a).

In most cardiovascular tissue-engineering approaches cells are harvested from donor tissues, e.g., from peripheral arteries, and mixed vascular cell populations consisting of myofibroblasts and endothelial cells are obtained. Out of these, pure viable cell lines can be easily isolated by cell sorters (Hoerstrup *et al.*, 1998) and the subsequent seeding onto the biodegradable scaffold is undertaken in two steps. First, the myofibroblasts are seeded and grown *in vitro*. Second, the endothelial cells are seeded on top of the generated neotissue, leading to the formation of a native leaflet-analogous histological structure (Zund *et al.*, 1998).

Successful implantation of a single tissue-engineered valve leaflet has been demonstrated in the animal model (Shinoka *et al.*, 1996) and based on a novel *in vitro* conditioning protocol of the tissue-engineered valve constructs in bioreactor flow systems (pulse-duplicator) completely autologous, living heart-valves were generated (Fig. 4). Interestingly, these tissue-engineered valves showed good *in vivo* functionality and strongly resembled native heart valves with regard to biomechanical and morphological features (Hoerstrup *et al.*, 2000b; Rabkin *et al.*, 2002). With regard to clinical applications, several human cell sources have been investigated (Schnell *et al.*, 2001). Recently, cells derived from bone marrow or umbilical cord have been successfully utilized to generate heart valves and conduits *in vitro* (Hoerstrup *et al.*, 2002a, b). In contrast to vascular cells, these cells can be obtained without surgical

FIG. 4. Photograph of a living, tissue engineered heart valve after 14 days of biomimetic conditioning in a pulse-duplicator-bioreactor based on a rapidly biodegradable synthetic scaffold material. (Reprinted with permission from Hoerstrup *et al.*, 2000. *Circulation* 102: III-44–III-49.)

interventions representing an easy-to-access cell source in a possible routine clinical scenario. Because of their good proliferation and progenitor potential, these cells are expected to be an attractive alternative for cardiovascular tissue-engineering applications.

Blood

There is a critical need for blood cell substitutes since donor blood suffers from problems such as donor shortage, requirements for typing and cross-matching, limited storage time, and, even more importantly in the era of AIDS, infectious disease transmission. Oxygen-containing fluids or materials as a substitute for red blood cells offer important applications in emergency resuscitation, shock, tumor therapy, and organ preservation. Several oxygen transporters are under investigation. Hemoglobin is a primary candidate, which not only serves as the natural oxygen transporter in blood but also functions in carbon dioxide transport, as a buffer, and in regulating osmotic pressure. Early clinical trials of cell-free hemoglobin were complicated by its lack of purity, instability, high oxygen affinity, and binding nitric oxide (NO), leading to cardiovascular side effects. These problems have been subsequently addressed by various chemical modifications such as intra- and intermolecular cross-linking using diacid, glutaraldehyde, or *o*-raffinose or conjugation to dextran or polyethylene glycol. Because of the limited hemoglobin availability, genetically engineered human hemoglobin or hemoglobin from bovine sources may represent a valid alternative. Several products are now in phase II/III clinical studies (Winslow, 2000). The latest

developments include nanoencapsulated genetically engineered macromolecules of poly (hemoglobin-catalase-superoxide dismutase). Biodegradable polylactides and polyglycolides are used as carriers leading to artificial red blood cells containing hemoglobin and protective enzymes (Chang, 2003). Furthermore, perfluorocarbons (PFC) may be an alternative characterized by a high gas dissolving capacity (O₂, CO₂, and others), chemical and biological inertness, and low viscosity. However, hemoglobin binds significantly more oxygen at a given partial oxygen pressure than can be dissolved in PFC. Research to create functional substitutes for platelets by encapsulating platelet proteins in lipid vesicles has also been conducted (Baldassare *et al.*, 1985). Finally, stem cells have the potential to differentiate into the various cellular elements of blood (Thomson *et al.*, 1998).

FUTURE PERSPECTIVES

Current methods of transplantation and reconstruction are among the most time-consuming and costly therapies available today. Tissue-engineering offers future promise in the treatment of loss of tissue or organ function as well as for genetic disorders with metabolic deficiencies. Besides that, tissue engineering offers the possibility of substantial future savings by providing substitutes that are less expensive than donor organs and by providing a means of intervention before patients are critically ill. Few areas of technology will require more interdisciplinary research or have the potential to affect more positively the quality and length of life. Much must be learned from cell biology, especially with regard to what controls cellular differentiation and growth and how extracellular matrix components influence cell function. Immunology and molecular genetics will contribute to the design of cells or cell transplant systems that are not rejected by the immune system. With regard to the cell source, transplanted cells may come from cell lines or primary tissue, from the patients themselves, or from other human donors, animal tissue, or fetal tissue. In choosing the cell source a balance must be found between ethical issues, safety issues, and efficacy. These considerations are particularly important when introducing new techniques in the tissue-engineering field such as the generation of histocompatible tissue by cloning (nuclear transfer) (Lanza *et al.*, 2002) or by the creation of oocytes from embryonic stem cells (Hubner *et al.*, 2003).

The materials used in tissue engineering represent a major field of research regarding, e.g., polymer processing, development of controlled-release systems, surface modifications, and mathematical models possibly predicting *in vivo* cellular events.

8.3 IMMUNOISOLATION

Michael J. Lysaght and David Reim

INTRODUCTION

In the context of tissue engineering and cellular medicine, the terms *immunoisolation* and *encapsulation* usually refer to devices and therapies in which living cells are separated from a host by a selective membrane barrier. This barrier permits bidirectional trafficking of small molecules between host and grafted cells, and protects foreign cells from effector agents of a host's immune system. In analogy with pharmacological immunosuppression, the degree of protection afforded by immunoisolation barriers depends upon the circumstances of application and may be total or partial, long-term or short-term. Occasional reference to the concept, which is illustrated in Fig. 1, can be found as early as the late 1930s and appears sporadically in the literature of the 1950s and 1960s. The approach first received serious investigational attention in the mid-1970s. Interest has expanded considerably in the past two decades. Encapsulation currently encompasses a daunting array of therapy formats, device configurations, and biomaterials.

The first modern efforts involving cell encapsulation were directed at development of a long-term implant to replace the endocrine function of a diabetic pancreas. Other investigators quickly expanded this field of study to include short-term extracorporeal replacement of the failing liver. Later applications include the use of encapsulated cells for *in situ* synthesis and local delivery of naturally occurring and recombinant cell products for the treatment of chronic pain, Parkinson's disease, macular degeneration, and similar disorders. Devices employed for encapsulated cell therapy vary in size over several orders of

magnitude from small spheres, with a volume of 10^{-5} cm³, to large extracorporeal devices with a net volume of ~ 10 cm³. Their anticipated service life ranges from a few hours in the case of the liver to several years for other therapeutic implants. In some cases, the immunoisolation vehicles simply serve as constitutive sources of bioactive molecules; in other cases, regulated release is required; and for still others, host detoxification is the goal. Despite such a spectrum of application parameters, devices containing immunoisolated cells share many common features and design principles: (1) Cells are rarely deployed more than 500 μ m (5×10^{-2} cm) from the host; cells much farther than this critical distance either undergo necrosis or cease to synthesize and release protein. (2) Cells generally are supported on a matrix or scaffold to provide some of the functions of normal extracellular matrix and to prevent the formation of large, unvascularized cellular aggregates. (3) Separative membranes are invariably self-supporting, thus requiring a design trade-off between transport characteristics and mechanical strength. (4) Both the membrane and the matrices usually are prepared from either hydrogels or reticulated foams, themselves chosen from relatively few among the many available candidates.

In the remainder of this overview, we will describe the immunological challenge of protecting cells with barrier materials; summarize critical components of immunoisolate devices, i.e., cells, membranes, and matrices; review the more common device configurations; and conclude with a short survey of the development status of principal applications.

THE CHALLENGE OF IMMUNOISOLATION

The immune system is a network that deploys a complex, redundant phalanx of pathways to distinguish self from non-self and to destroy non-self. Membrane barriers have proven remarkably effective in preventing immune destruction of *allogenic* cells, i.e., cells originating from the same species as the host. Protection of allogenic cells is possible because they normally will not be subjected to immune destruction in the absence of cell-cell contact between graft and host. Even protein-permeable membranes have been found to allow long-term function and survival of allogenic cells. This happy circumstance is marred by the reality that the supply of transplantable human cells is very limited, just as is the supply of human solid organs, and thus therapies based upon transplanted human cells are not likely to have much therapeutic impact. There has been some effort to create dividing cell lines from protein secreting human cells, or to genetically engineer naturally dividing human cells (e.g., fibroblasts) to produce useful proteins. In the future, stem cells may provide unconstrained supply of tissue. In the main, however, investigators have responded to the scarcity of human cells by turning to cells of animal origins. Such so-called *xenogenic* cells are far more difficult to encapsulate and success is constrained to special cases. [Examples are devices containing xenogenic cells implanted in certain immunoprivileged sites (spinal fluid, ventricles, eyes) where the avidity of the immune response is muted or placed in contact with acellular fluid (or flowing blood) to minimize

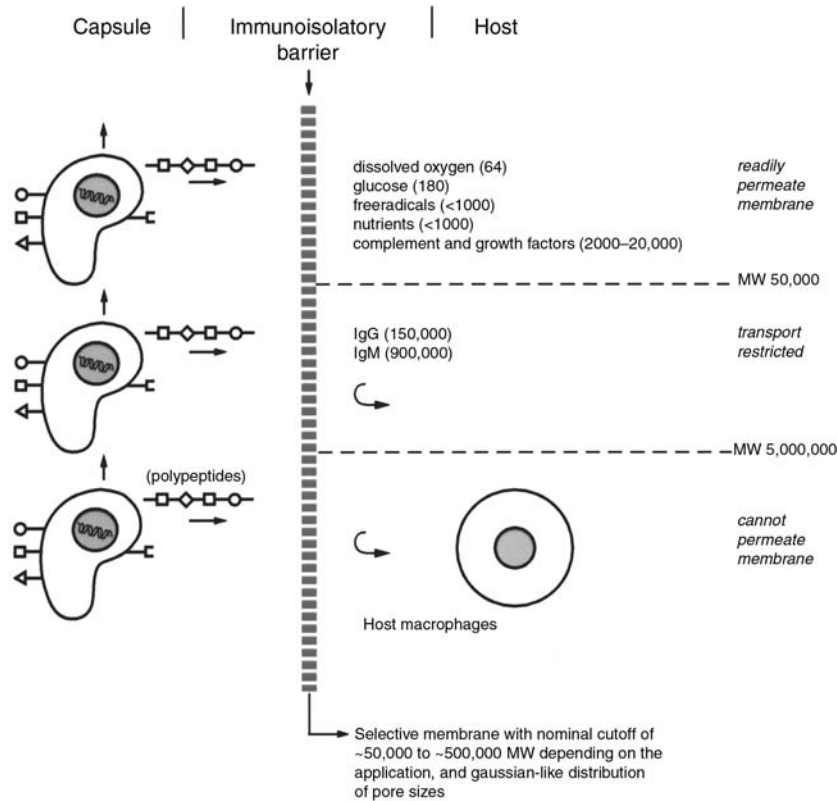

FIG. 1. The concept of encapsulation. A biocompatible selective membrane barrier surrounds naturally occurring or genetically modified cells. Nutrients, oxygen, and small bioactive materials freely transit the membrane but immunologically active species are too large to penetrate. Although such perfect selectivity is clearly an idealization, techniques have been successfully developed to the point of large-scale clinical evaluation.

the localized inflammatory reaction.] Or, in the case of the liver, xenogenic cells are utilized for periods of time that are much shorter than that required for the development of fulminant immune responses. All such strategies have proven successful, and there is abundant evidence of survival of xenogenic cells, in these limited circumstances, for 3 to 6 months or longer. In contrast, encapsulated xenogenic cells rarely survive much beyond 14 to 28 days when implanted subcutaneously or intraperitoneally in immunocompetent hosts.

Two mechanisms are invoked to explain the inability of membranes to universally protect xenogenic implants, and the different fates of encapsulated allogeneic and xenogenic cells. First, membranes are not ideally semipermeable and thus allow passage of small quantities of large immunomolecules, including complement and both elicited and preformed immunoglobulins. Such agents are far more active against xenogenic cells than against allogeneic grafts. A second problem is that soluble antigens “leak” from cell surfaces or are released upon cell necrosis. These protein constituents are not conserved between species and are, in varying degrees, immunogenic. Their gradual release results in a localized inflammatory response in the neighborhood of the membrane, readily visualized by histology. Inflammatory cells express a number of

low-molecular-weight toxins (including free radicals and cytotoxic cytokines) that pass through the membrane and attack the cells inside. Note that this mechanism requires a local nidus of inflammatory tissue and is thus unlikely to be encountered when implants are placed in cell-free fluid cavities. It is also not significant with allogeneic cells whose only non-self proteins are confined to the MHC system.

Interestingly, pharmacological immunosuppression has rarely been used in conjunction with encapsulation, though on theoretical grounds the combination of mechanical and chemical agents would likely prove highly effective.

DEVICES FOR IMMUNOISOLATION

Depending on size and shape, implantable immunoisolation device designs can be categorized as either microcapsules or macrocapsules. Microcapsule beads are illustrated in Fig. 2 (upper right), along with other materials popular for immunoisolation. A current macrocapsule design is shown in Fig. 3. These different designs all share the common components of a permselective membrane, an internal matrix, and the living encapsulated tissue. Macrocapsules are small (100–600 μm ,

FIG. 2. Materials used as matrices or barrier materials. Micrographs or photomicrographs of hydrophilic materials in the form of matrices (top left) and microcapsules (top right) and of hydrophobic materials in the form of foams (bottom left) and membranes for use in macrocapsules (bottom right).

FIG. 3. Photograph of an implantable macrocapsule. The pencil and tweezers are included for scale.

0.01–0.06 $\times 10^{-4}$ cm in diameter) spherical beads containing up to several thousand cells. Typically, hundreds to thousands of microcapsules are implanted into the host to achieve a therapeutic dose. This design minimizes transport resistance, allows for easy implantation, and provides good dose control. However, microcapsules are difficult to explant and are usually quite fragile. Macrocapsules are much larger in size with the capacity to hold millions of cells, generally requiring a single device for a given therapy. These devices are implanted as tubular or flat sheet diffusion chambers with an inner diameter dimension of 0.5–2.0 mm and a length of 1–10 cm. Macrocapsules provide mechanical and chemical stability superior to those of microcapsules and are easily retrieved. A significant concern with this design is the geometric resistance to mass transport, which limits viability of encapsulated tissue. An alternative macrocapsule design involves connecting the device directly to the patient's circulatory system. The cells are contained in a chamber surrounding the macrocapsule, and the flowing blood can provide an efficient means of nutrient transport. A major challenge with this vascular design is maintaining shunt patency of the device.

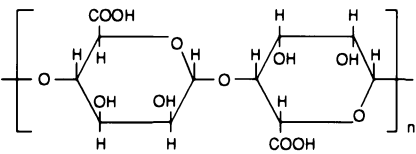

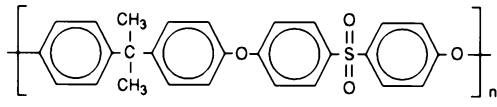

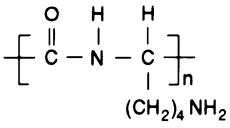

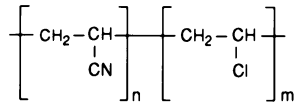

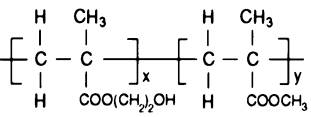

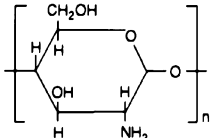

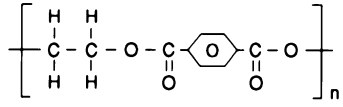

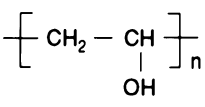

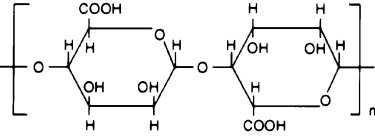

Membranes

A wide variety of different materials have been used to formulate the permselective membranes for microcapsules and macrocapsules. In general, the membranes for macrocapsules have been engineered from synthetic thermoplastics,

whereas those for microcapsules have been engineered using hydrogel-based materials. Table 1 and Fig. 2 illustrate the materials and appearance of hydrophilic and hydrophobic membrane materials used for immunoisolation.

The process to manufacture microcapsules typically starts with the creation of a slurry of the living cells in a dilute

TABLE 1 Materials Commonly Used in Encapsulation

<p>Alginate</p> 	

hydrogel solution. Next, small droplets are formed by extruding this mixture through an appropriate nozzle, followed by the cross-linking of the hydrogel to form the mechanically stable microcapsules with an immunoisolatory layer. In an alternative process, water-insoluble synthetic polymers are used in place of hydrogels to prepare the cell slurry. These microcapsules and the immunoisolatory layer are then formed upon interfacial precipitation of the polymer solution. The process to manufacture macrocapsules typically involves phase inversion of a thermoplastic polymer solution cast as a flat sheet or extruded as a hollow fiber. During phase inversion, the polymer solution is placed in controlled contact with miscible nonsolvent, resulting in the formation of the mechanically stable and immunoisolatory membrane. At a later stage, the living cells are aseptically introduced into the fiber or chamber, which is subsequently sealed.

The processes developed to manufacture macrocapsules and microcapsules are very versatile and allow for the formation of membranes with a wide variety of different transmembrane pore structures and outer surface microgeometries. Membrane selection has a strong influence on microcapsule or macrocapsule device performance and is characterized in terms of membrane chemistry, transport properties, outer surface morphology, and strength. Optimum parameters are dictated by the metabolic requirements of the encapsulated cells, the size of the therapeutic agent to be delivered, the required immunoprotection, and the desired biocompatibility. Membrane transport properties are chosen to maintain viability and functionality of the encapsulated cells and provide release of the therapeutic agent. This selection involves designing membranes that provide sufficient nutrient flux to meet the requirements of the encapsulated cells, while preventing flux of immunological species that would reject the tissue.

Biocompatibility is defined by the host reaction to the implant and has a significant impact upon device performance. Biocompatibility depends upon the nature of the encapsulated cell and both the transport properties and outer morphology of the membrane barrier.

Transport properties are routinely evaluated in combination with a physical characterization of the membrane to develop structure–property relations. Physical parameters such as inner diameter, wall thickness, wall morphology, and surface morphology can influence the transport behavior. Light microscopy is used to characterize membrane geometry, and scanning electron microscopy is used to analyze membrane morphology. The high-resolution techniques of atomic force microscopy and low-voltage scanning electron microscopy have been exploited to image the porosity and pore size of the permselective skin of ultrafiltration membranes. A wide range of membrane wall morphologies can be produced using the phase inversion process: most common are foamlite or trabecular structures. Outer surface morphology is generally characterized as rough (microgeometries $> 2 \mu\text{m}$) or smooth. Implanted into a host tissue site, rough surface will frequently evoke a significant host fibrotic reaction, whereas smooth surfaces will evoke a relatively mild reaction. In some cases, a vascularized host reaction can actually improve encapsulated device viability, by providing nutrients and oxygen to the perimembrane region.

Matrices

The second component of an immunoisolation device is the internal matrix. Hydrogels and solid scaffolds have been widely used and can be produced from synthetic or naturally derived materials (Table 1). Examples of hydrogel matrices include alginate, agarose, and poly(ethylene oxide), and examples of scaffold matrices include poly(ethylene terephthalate) yarn, poly(vinyl alcohol) foam, and cross-linked chitosan. This matrix serves two basic functions. The first is to provide mechanical support for the encapsulated cells in order to maintain a uniform distribution within the device. In the absence of this support, the cells often gravitate toward one region of the device and form a large necrotic cluster. The matrix also serves a biological function by stimulating the cells to secrete their own extracellular matrix, regulating cell proliferation, regulating secretory function, and maintaining the cells in a differentiated phenotype.

Selection of a matrix for a particular cell type involves several design considerations. Generally, suspension cell cultures prefer a hydrogel-based matrix, whereas anchorage-dependent cells prefer the attachment surfaces of a solid scaffold. The matrix must also be physically and chemically compatible with the permselective membrane. For example, scaffold matrices should not damage the integrity of the permselective membrane and soluble matrix components should not significantly affect the pore size. The stability of the matrix should also be considered and in general must at least match the lifetime of the device. Finally, the transport characteristics of the matrix candidates need to be considered. Certain matrices may exhibit significant resistance to the transport of small or large solutes, and thus affect overall performance.

Cells

The final component of the immunoisolation device is the encapsulated cells used to secrete the therapeutic molecules. These cells may be derived from “primary” cells, (i.e., postmitotic cells dividing very slowly if at all), continuously dividing cell lines, or genetically engineered tissue. All three cell types have been successfully encapsulated. Cell sourcing for a device begins with a definition of the desired secretory function of the implant. For example, chromaffin cells are a known source of the opoid peptide norepinephrine and have been used as a cellular delivery system to treat chronic pain. Such chromaffin cells are obtained as primary cultures from an enzymatic isolation of the bovine adrenal gland. Islets of Langerhans for the delivery of insulin to replace pancreatic function represent another widely investigated primary cell type. The PC12 rat pheochromocytoma line is an example of an immortalized cell line derived from a tumor that has been used for the delivery of L-dopa and dopamine in the treatment of Parkinson’s disease. Cells engineered to secrete a variety of neurotrophic factors have been used in an encapsulated environment for the treatment of neurodegenerative diseases and include the Chinese hamster ovary (CHO) line, the Hs27 human foreskin fibroblast, and the baby hamster kidney (BHK) line.

Different cell types have different requirements for survival and function in a device and may result in a variety of levels

of performance in any given implant site. These cell-specific considerations include metabolic requirements, proliferation rate within a device, and antigenicity and are assessed to ensure long-term device performance. For example, a highly antigenic encapsulated cell may be rapidly rejected in a nonimmunoprivileged site, such as the peritoneal cavity. This same encapsulated tissue may result in very satisfactory performance in an immunoprivileged site, such as the central nervous system. Similarly, a cell with a high nutrient requirement may provide superior performance in a nutrient-rich site, such as a subcutaneous pouch, and fail in a nutrient-poor site such as the cerebral spinal fluid.

Safety is another consideration in sourcing cells for eventual human implants. Grafts must be derived from healthy donors or from stable, contaminant-free cell lines. Before approving human clinical trials, regulatory bodies require testing for known transmittable diseases, mycoplasma, reverse transcriptase, cultivable viruses, and microbial contaminants.

APPLICATIONS

At this writing (mid-1999) several applications of immunoisolated cell therapy are in clinical trials but none have reached the stage of approval by regulatory agencies and routine clinical utilization. Table 2 summarizes the application status of the bioartificial liver, the bioartificial pancreas, and the delivery of cell and gene therapy. As in all areas of tissue engineering, technology is moving rapidly and Table 2 should be appreciated in historical rather than current context.

The bioartificial liver currently is being evaluated as a “bridge to transplant,” i.e., to extend the lifetime of patients who are medically eligible for liver transplantation until a donor organ becomes available. Several designs and treatment protocols have been proposed; one appealing format is shown in Fig. 4. The extracorporeal circuit is broadly similar to

that used in dialysis for the treatment of kidney failure. Blood is continuously withdrawn from the patient’s vasculature, at a rate of 200–300 ml/min, treated in a hollow-fiber bioartificial liver, and ultimately returned to the patient. A charcoal filter may be added to further detoxify the blood. Treatments are performed daily for 4 hours. Results in early human trials were quite encouraging and several cases of recovery without transplantation were observed. No results are yet available from the controlled and blinded trials.

The bioartificial pancreas has enjoyed very impressive success in rodent studies—so much so that no fewer than five reports on “proof of principle” experiments have appeared in the hallowed pages of *Science* magazine. Unfortunately, results from larger animal models and human studies have been disappointing. Investigators have not been able to reliably isolate the number of islets (500,000 to 1,000,000 or $\sim 2 \times 10^9$ cells) required for a large recipient. Moreover, species scaling of device design has proven difficult: formats that were suitable in rodents generally have been unsatisfactory in large animals. Some investigators believe that use of genetically engineered cells or their transgenic cohorts may solve the problem of cell source. Genetically engineered cells might be more productive than islets and ease some of the constraints on device design. Development of a clinically beneficial bioartificial pancreas remains an important challenge for biomedical engineering in the early 21st century.

Encapsulation is also being developed for the delivery of cell and gene therapy. Small quantities of cells producing a desired therapeutic molecule are placed inside the lumen of a sealed hollow fiber or encapsulated in microspheres. A therapeutic dose may involve a very manageable $1\text{--}10 \times 10^6$ cells (roughly two orders of magnitude fewer cells than would be required for a bioartificial pancreas). From one perspective, these devices represent a form of drug delivery providing point-source, time-constant, and site-specific delivery with the added benefit of a “regenerable” source of bioactive “drug.” In another sense, when recombinant cells are involved, this approach can be considered a form of gene therapy in which the transplanted gene resides in cells housed in a capsule rather than directly in the cells of the recipient. The technical issues involved in this form of encapsulated cell therapy are largely resolved. Several successful preclinical and clinical trials have been reported. However, to date no blinded study with a control study has shown efficacy.

TABLE 2 Application Status of Immunoisolation (Late 1999)

Bioartificial liver	Several reports of clinical investigations in literature for bridge to transplant two successful phase I ^a trials. Two “pivotal ^b trials” underway.
Bioartificial pancreas	One case report of a single patient receiving a therapeutic dose of islets (and immunosuppression). Several reports of “survival studies” at smaller doses. Preclinical trials report outstanding success in rodents but not in dogs and nonhuman primates.
Delivery of cell and gene therapy	Pain: Successful phase I study completed; pivotal trial failed to show efficacy. ALS: Human clinical trials reported; Huntington trial is in progress. Numerous studies in primates, other large animals, and rodents.

^aPhase I. Small trial to determine safety in ~ 10 patients.

^bPivotal. Large trial to determine efficacy. Includes control arm.

8.4 SYNTHETIC BIORESORBABLE POLYMER SCAFFOLDS

Antonios G. Mikos, Lichun Lu, Johnna S. Temenoff,
and Joerg K. Tessmar

SCAFFOLD DESIGN

Tissue engineering involves the development of functional substitutes to replace missing or malfunctioning human tissues and organs (Langer and Vacanti, 1993). Most strategies in tissue engineering have focused on using biomaterials as scaffolds to direct specific cell types to organize into three-dimensional (3D) structures and perform differentiated function of the targeted tissue. Synthetic bioresorbable polymers that are fully degradable into the body's natural metabolites by simple hydrolysis under physiological conditions are the most attractive scaffold materials. These scaffolds offer the possibility to create completely natural tissue or organ equivalents and thus overcome the problems such as infection and fibrous tissue formation associated with permanent implants.

These synthetic polymers must possess unique properties specific to the tissue of interest as well as satisfy some basic requirements in order to serve as an appropriate scaffold. One essential criterion is biocompatibility, i.e., the polymer scaffold should not invoke an adverse inflammatory or immune response once implanted (Babensee *et al.*, 1998). Some important factors that determine its biocompatibility, such as the chemistry, structure, and morphology, can be affected by polymer synthesis, scaffold processing, and sterilization. Toxic residual chemicals involved in these processes (e.g., monomers, stabilizers, initiators, cross-linking agents, emulsifiers, organic solvents) may be leached out from the scaffold with detrimental effects to the engineered and surrounding tissue.

The primary role of a scaffold is to provide a temporary substrate to which transplanted cells can adhere. Most organ cell types are anchorage-dependent and require the presence of a suitable substrate in order to survive and retain their ability to proliferate, migrate, and differentiate. Cell morphology correlates with cellular activities and function; strong cell adhesion and spreading often favor proliferation while a rounded cell shape is required for cell-specific function. For example, it has been demonstrated that the use of substrates with patterned surface morphologies or varied extracellular matrix (ECM) surface coatings can modulate cell shape and function (Chen *et al.*, 1998; Mooney *et al.*, 1992; Singhvi *et al.*, 1994).

For epithelial cells, cell polarity is essential for their function. Polarity refers to the distinctive arrangement, composition, and function of cell-surface and intracellular domains. This typically corresponds to a heterogeneous extracellular environment. For example, retinal pigment epithelium (RPE) cells have three major surface domains: the apical surface is covered with numerous microvilli; the lateral surface is joined with neighboring cells by junctional complexes; and the basal surface is convoluted into basal infoldings and connected to the basal lamina. The polymer scaffold for RPE transplantation should therefore provide proper surface chemistry and surface microstructure for optimal cell-substrate interaction and,

along with appropriate culture conditions, be able to induce proper cell polarity (Lu *et al.*, 1998).

Besides cell morphology, the function of many organs is dependent on the 3D spatial relationship of cells with their ECM. The shape of a skeletal tissue is also critical to its function. Gene expression in cells is regulated differently by 2D versus 3D culture substrates. For instance, the differentiated phenotype of human epiphyseal chondrocytes is lost on 2D culture substrates but reexpressed when cultured in 3D agarose gels (Aulhouse *et al.*, 1989). A polymer scaffold should be easily and reproducibly processed into a desired shape that can be maintained after implantation so that it defines the ultimate shape of the regenerated tissue. A suitable scaffold should therefore act as a template to direct cell growth and ECM formation and facilitate the development of a 3D structure.

Porosity, pore size, and pore structure are important factors to be considered with respect to nutrient supply to transplanted and regenerated cells. To regenerate highly vascularized organs such as the liver, porous scaffolds with large void volume and large surface-area-to-volume ratio are desirable for maximal cell seeding, attachment, growth, ECM production, and vascularization. Small-diameter pores are preferable to yield high surface area per volume provided the pore size is greater than the diameter of a cell in suspension (typically 10 μm). However, topological constraints may require larger pores for cell growth. Previous experiments have demonstrated optimal pore sizes of 20 μm for fibroblast ingrowth, 20–125 μm for adult mammalian skin regeneration, and 200–400 μm for bone ingrowth (Boyan *et al.*, 1996; Whang *et al.*, 1995). The rate of tissue invasion into porous scaffold also depends on the pore size and polymer crystallinity (Mikos *et al.*, 1993c; Park and Cima, 1996; Wake *et al.*, 1994). Compared to isolated pore structure, an interconnected pore network enhances the diffusion rates to and from the center of the scaffold and facilitates vascularization, thus improving oxygen and nutrient supply and waste removal. The vascularization of an implant is a prerequisite for regeneration of most 3D tissues except for cartilage, which is avascular.

Mechanical properties of the polymer scaffold should be similar to the tissue or organ intended for regeneration. For load-bearing tissues such as bone, the scaffold should be strong enough to withstand physiological stresses to avoid collapse of the developing tissue. Also, transfer of load to the scaffold (stress shielding) after implantation may result in lack of sufficient mechanical stimulation to the ingrowing tissue. For the regeneration of soft tissues such as skin, the scaffolds are required to be pliable or elastic. The stiffness of the scaffold may affect the mechanical tension generated within the cell cytoskeleton, which is critical for the control of cell shape and function (Chicurel *et al.*, 1998). A more rigid surface may facilitate the assembly of stress fibers and enhance cell spreading and dividing. Scaffold compliance may also affect cell-cell contacts and aggregation (Moghe, 1996).

Understanding and controlling the degradation process of a scaffold and the effects of its degradation products on the body is crucial for long-term success of a tissue-engineered cell-polymer construct. The local drop in pH due to the release of acidic degradation products from some implants may cause tissue necrosis or inflammation. Polymer particles

formed after long-term implantation of a scaffold or due to micromotion at the implantation site may elicit an inflammatory response. Microparticles of polymers have been shown to suppress initial rat-marrow stromal osteoblast proliferation in culture (Wake *et al.*, 1998). The mechanism by which the scaffold degrades should also be considered. For example the degradation products are released gradually by surface erosion, whereas during bulk degradation, the release of degradation products occurs only when the molecular weight of the polymer reaches a critical value. This late-stage burst effect may cause greater local pH drop.

The rate of scaffold degradation is tailored to allow cells to proliferate and secrete their own ECM while the polymer scaffold vanishes over a desired time period (from days to months) to leave enough space for new tissue growth. Since the mechanical strength of a scaffold usually decreases with degradation time, the degradation rate may be required to match the rate of tissue regeneration in order to maintain the structural integrity of the implant. The degradation rate of a scaffold can be affected by various factors listed in Table 1.

The design requirements of a tissue engineering scaffold are specific to the structure and function of the tissue to be regenerated. The polymer scaffold is typically engineered to mimic the natural ECM of the body. ECM proteins play crucial roles in the control of cell growth and function (Hay, 1993; Howe *et al.*, 1998). However, most synthetic polymer scaffolds do not possess the specific signals (ligands) that can be recognized by cell-surface receptors. It is therefore preferable that the polymer chain have chemically modifiable functional groups onto which sugars, proteins, or peptides can be attached. In addition, polymer-peptide hybrid molecules may be created or the ligand may be immobilized on the scaffold surface to

generate a biomimetic microenvironment (Shakesheff *et al.*, 1998; Shin *et al.*, 2003b).

SCAFFOLD MATERIALS

The range of physical, chemical, mechanical, and degradative properties that may be achieved using synthetic bioresorbable polymers renders them extremely versatile as scaffold materials. Their molecular weight and chemical composition may be precisely controlled during polymer synthesis. Copolymers, polymer blends, and composites with other materials may be manufactured to give rise to properties that are advantageous over homopolymers for certain applications. Moreover, many polymers can be functionalized by converting end groups or addition of side chains with various chemical groups to obtain polymers that can be self-cross-linked or cross-linked with proteins and other bioactive molecules (Behravesh *et al.*, 1999). By choosing an appropriate processing technique, scaffolds of specific architecture and structural characteristics may be fabricated.

Not all types of currently available synthetic bioresorbable polymers can be manufactured into 3D scaffolds because of their chemical and physical properties and processability (Table 2). The most widely utilized scaffold materials are poly(α -hydroxy esters) such as PGA, PLA, and PLGA. They have been fabricated into thin films, fibers, porous foams, and conduits and investigated as scaffolds for regeneration of several tissues. Furthermore, the lysine groups in poly(lactic acid-co-lysine) provide sites for addition of cell-adhesion sequences such as RGD peptides (Barrera *et al.*, 1995; Cook *et al.*, 1997).

Poly(propylene fumarate) (PPF), an unsaturated linear polyester that can be cross-linked through its fumarate double bonds, has been investigated as a bioresorbable bone cement (Peter *et al.*, 1997a). The cross-linking, mechanical, and degradative properties of an injectable composite scaffold made of PPF and β -tricalcium phosphate have been characterized (Peter *et al.*, 1999, 1998b, 1997b). The mechanical properties of PPF scaffolds can be further modified depending on the cross-linking parameters employed. An increase in compressive modulus was observed with the use of a cross-linking agent, PPF-diacrylate, and the choice of a photo-(light-based) initiator, rather than a thermally based initiator system (Timmer *et al.*, 2003).

Poly(ethylene glycol) (PEG), although nondegradable, is often used to fabricate copolymers or polymer blends to increase the hydrophilicity, biocompatibility, and/or softness of the scaffold. Poly(propylene fumarate-co-ethylene glycol) [P(PF-co-EG)] hydrogels have been developed for cardiovascular applications (Suggs *et al.*, 1998a, 1997, 1999). When used in combination with a pore-forming agent and modified with cell-adhesion ligands, P(PF-co-EG) has also been used in highly porous scaffolds for bone tissue engineering (Behravesh and Mikos, 2003). Results indicate that this hydrogel supported the proliferation, osteogenic differentiation and matrix production from seeded bone-marrow stromal cells during 28 days of *in vitro* culture (Behravesh and Mikos, 2003).

TABLE 1 Factors Affecting Scaffold Degradation

Polymer chemistry	Scaffold structure
Composition	Density
Structure	Shape
Configuration	Size
Morphology	Mass
Molecular weight	Surface texture
Molecular weight distribution	Porosity
Chain motility	Pore size
Molecular orientation	Pore structure
Surface-to-volume ratio	Wettability

Type and density of cultured cells	Enzymes

TABLE 2 Scaffold Materials and Their Applications^a

Materials	Applications
Poly(α -hydroxy esters)	
Poly(L-lactic acid) (PLLA)	Bone, cartilage, nerve
Poly(glycolic acid) (PGA)	Cartilage, tendon, urothelium, intestine, liver, bone
Poly(D,L-lactic-co-glycolic acid) (PLGA)	Bone, cartilage, urothelium, nerve, RPE
PLLA-bonded PLGA fibers	Smooth muscle
PLLA coated with collagen or poly(vinyl alcohol) (PVA)	Liver
PLLA and poly(ethylene glycol) (PEG) block copolymer	Bone
PLGA and PEG blends	Soft tissue and tubular tissue
Poly(L-lactic acid-co- ϵ -caprolactone) (PLLACL)	Meniscal tissue, nerve
Poly(D,L-lactic acid-co- ϵ -caprolactone) (PDLLACL)	Vascular graft
Polyurethane/poly(L-lactic acid)	Small-caliber arteries
Poly(lysine-co-lactic acid)	Bone, cartilage, nerve
Poly(propylene fumarate) (PPF)	Bone
Poly(propylene fumarate-co-ethylene glycol) [P(PF-co-EG)]	Cardiovascular, bone
PPF/ β -tricalcium phosphate (PPF/ β -TCP)	Bone
Poly(ϵ -caprolactone)	Drug delivery
Polyhydroxyalkanoate (PHA)	Cardiovascular
Polydioxanone	Bone
Polyphosphates and polyphosphazenes	Skeletal tissue, nerve
Pseudo-poly(amino acids)	Bone
Tyrosine-derived polyiminocarbonates	
Tyrosine-derived polycarbonate	
Tyrosine-derived polyacrylates	

^aAdapted from Babensee *et al.* (1998).

In addition, another material including PEG, oligo [poly(ethylene glycol) fumarate] (OPF), has been developed and characterized (Jo *et al.*, 2001). Because of the chemical structure of this oligomer, it can be used to form biodegradable hydrogels with a high degree of swelling (Jo *et al.*, 2001; Temenoff *et al.*, 2003). This material may find uses in guided tissue regeneration applications because it demonstrates relatively low general cell adhesion, but at the same time, possesses an ability to be modified with peptides that could encourage adhesion of specific cell types (Shin *et al.*, 2002; Temenoff *et al.*, 2003).

Poly(ϵ -caprolactone) (PCL) as well as blends and copolymers containing PCL have also been studied as scaffold materials (Suggs and Mikos, 1996). Polyphosphates and polyphosphazenes have been processed into scaffolds for bone tissue engineering (Behravesch *et al.*, 1999; Renier and Kohn, 1997). Pseudo-poly(amino acids), in which amino acids are linked by both amide and nonamide bonds (such as urethane, ester, iminocarbonate, and carbonate), are amorphous and soluble in organic solvents and thus processable into scaffolds. The most studied among these polymers are tyrosine-derived polycarbonates and polyacrylates (James and Kohn, 1996). By structural modifications of the backbone and pendant chains, polymer families with systematically and gradually varied properties can be created.

APPLICATIONS OF SCAFFOLDS

Tissue Induction

Tissue induction is the process by which ingrowth of surrounding tissue into a porous scaffold is effected (Fig. 1A). The scaffold provides a substrate for the migration and proliferation of the desired cell types. For example, an osteoinductive material can be used to selectively induce bone formation. This approach has been employed to regenerate several other tissues including skin and nerve.

Cell Transplantation

The concept is that cells obtained from patients can be expanded in culture, seeded onto an appropriate polymer scaffold, cultured, and then transplanted (Bancroft and Mikos, 2001) (Fig. 1B). The time at which transplantation takes place varies with a specific application. Usually the cells are allowed to attach to the scaffold, proliferate, and differentiate before implantation. A scaffold for bone cell transplantation should be osteoconductive, meaning that it has the capacity to direct the growth of osteoblasts *in vitro* and allow the integration of the transplant with the host bone. This strategy is the most

FIG. 1. Applications of bioresorbable polymers as porous scaffolds in tissue engineering. (A) Tissue induction. (B) Cell transplantation. (C) Prevascularization. (D) *In situ* polymerization. In all cases, the porous scaffolds allow tissue ingrowth as they degrade gradually.

widely used in tissue engineering and has been investigated for the transplantation of many cell types including osteoblasts, chondrocytes, hepatocytes, fibroblasts, smooth muscle cells, and RPE. This method also offers the possibility that genetically modified cells could be transplanted, thereby simultaneously presenting both the cells and the bioactive factors they produce to the site of interest, with the potential of further enhancing regeneration of the injured area (Blum *et al.*, 2003). This approach may be considered a combination of the applications

of cell transplantation and delivery of bioactive molecules, discussed later.

Prevascularization

The major obstacle in the development of large 3D transplants such as liver is nutrient diffusion limitation, because cells will not survive farther than a few hundred microns from

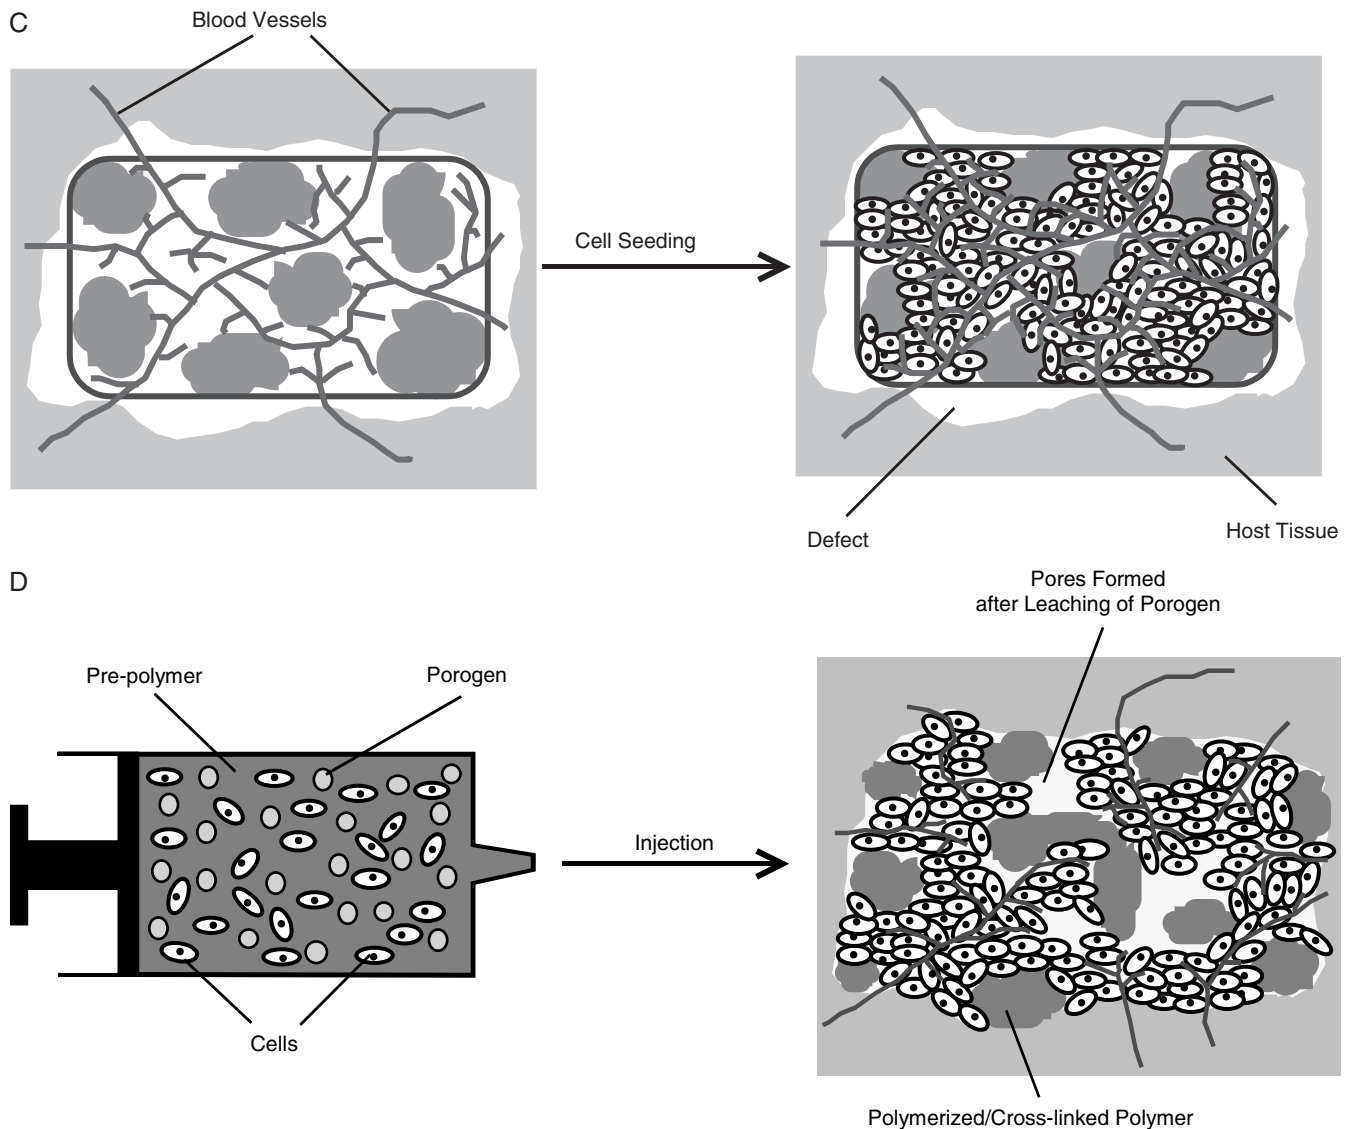

FIG. 1.—continued

the nutrient supply. Although the scaffold can be vascularized postimplantation, the rate of vascularization is usually insufficient to prevent cell death inside the scaffold. In this case, prevascularization of the scaffold may be necessary to allow the ingrowth of fibrovascular tissue or uncommitted vascular tissue such as periosteum (layer of connective tissue covering bone) before cell seeding by injection (Fig. 1C). The prevascularized scaffold will provide a substrate for cell attachment, growth, and function. The extent of prevascularization has to be optimized to allow sufficient nutrient diffusion as well as enough space for cell seeding and tissue growth (Mikos *et al.*, 1993c).

Some complex osseous defects created by bone tumor removal or extensive tissue damage exceed the critical size for normal healing and require a large transplant to restore function. A novel strategy is to prefabricate vascularized bone

flaps by implanting a mold containing bioresorbable polymers with osteoinductive elements onto a periosteal site remote from the defect where prevascularization and ectopic bone formation can occur over a period of time as the scaffold degrades (Thomson *et al.*, 1999). The created autologous bone can then be transplanted to the defect site where vascular supply can be attached via microsurgery to existing vessels.

In Situ Polymerization

Injectable, in situ polymerizable, bioresorbable materials can be utilized to fill defects of any size and shape with minimal surgical intervention (Fig. 1D). For instance, PPF has been developed as an injectable bone cement that hardens within

10 to 15 minutes under physiological conditions. These materials do not require prefabrication but must meet additional requirements since polymerization or cross-linking reactions occur *in vivo*. All reagents and products must be biocompatible, and the reaction conditions such as temperature, pH, and heat release should not damage implanted cells or the surrounding tissue.

The hardened material (scaffold) must be highly porous and have interconnected pore structure in order to serve as a suitable template for guiding cell growth and differentiation. This can be achieved by combining a porogen such as sodium chloride crystals in the injectable paste that are eventually leached out, leaving a porous polymer matrix. Since the leaching step occurs *in vivo*, local high salt concentration may lead to high osmolarity and tissue damage. The amount of porogen incorporated has to be optimized to ensure biocompatibility, while enough porosity needs to be achieved to allow sufficient nutrient diffusion and vascularization.

PPF has also been developed for use in combination with cell transplantation applications through the incorporation of cells within the material during the cross-linking procedure. Because of the potentially non-cytocompatible conditions that may be present during the curing reaction, a composite material has been developed in which cells are first encapsulated in gelatin microspheres, and these are then included with the PPF during cross-linking (Payne *et al.*, 2002a, b). It has been shown that this encapsulation procedure enhances the viability, proliferation, and osteogenic differentiation of rat-marrow stromal cells (as compared to nonencapsulated cells) when cultured on cross-linking PPF *in vitro* (Payne *et al.*, 2002a, b).

Delivery of Bioactive Molecules

Cellular activities can be further modulated by various soluble bioactive molecules such as DNA, cytokines, growth factors, hormones, angiogenic factors, or immunosuppressant

drugs (Babensee *et al.*, 2000; Holland and Mikos, 2003; Kasper and Mikos, 2003). For instance, bone morphogenetic proteins (BMPs) have been identified as a family of growth factors that regulate differentiation of bone cells (Ripamonti and Duneas, 1996). Controlled local delivery of these tissue inductive factors to transplanted and regenerated cells is often desirable. This has led to the concept of incorporation of bioactive molecules into scaffolds for implantation. These factors can be bound into polymer matrix during scaffold processing (Behravesh *et al.*, 1999; Shin *et al.*, 2003a) (Fig. 2A). Alternatively, biore-sorbable microparticles or nanoparticles loaded with these molecules can be impregnated into the substrates (Hedberg *et al.*, 2002; Holland *et al.*, 2003; Lu *et al.*, 2000) (Fig. 2B). By incorporating BMPs or other osteogenic molecules into the injectable paste, PPF can also serve as a delivery vehicle for bone growth factors to induce a bone-regeneration cascade (Hedberg *et al.*, 2002). The release of bioactive molecules *in vivo* is governed by both diffusion and polymer degradation (Hedberg *et al.*, 2002; Holland *et al.*, 2003). In addition, if the molecules are encapsulated within microparticles that are degraded through enzymatic actions, such as gelatin (Holland *et al.*, 2003), the concentration and activity of these enzymes may also affect the release profile of the factors from composite scaffolds.

SCAFFOLD PROCESSING TECHNIQUES

The technique used to manufacture synthetic bioresorbable polymers into suitable scaffolds for tissue regeneration depends on the properties of the polymer and its intended application (Table 3). Scaffold processing usually involves (1) heating the polymers above their glass transition or melting temperatures; (2) dissolving them in organic solvents; and/or (3) incorporating and leaching of porogens (gelatin microspheres, salt crystals, etc.) in water (Temenoff and Mikos, 2000).

FIG. 2. Localized delivery of bioactive molecules from scaffolds. (A) Release directly from the supporting matrix. (B) Microparticles or nanoparticles loaded with bioactive molecules are impregnated into scaffolds and serve as delivery vehicles.

TABLE 3 Examples of Scaffolds Processed by Various Techniques

Processing technique	Examples
Fiber bonding	PGA fibers; PLA-reinforced PGA fibers
Solvent casting and particulate leaching	PLA, PLGA, PPF foams
Superstructure engineering	PLA, PLGA membranes
Compression molding	PLA, PLGA foams
Extrusion	PLA, PLGA conduits
Freeze-drying	PLGA foams
Phase separation	PLA foams
High-pressure gas foaming	PLGA, P(PF-co-EG) scaffolds
Solid freeform fabrication	Complex 3D PLA, PLGA structures

These processes usually result in decrease in molecular weight and have profound effects on the biocompatibility, mechanical properties, and other characteristics of the formed scaffold. Incorporation of large bioactive molecules such as proteins into the scaffolds and retention of their activity have been a major challenge.

Fiber Bonding

Fibers provide a large surface-area-to-volume ratio and are therefore desirable as scaffold materials. PGA fibers in the form of tassels and felts have been utilized as scaffolds to demonstrate the feasibility of organ regeneration (Cima *et al.*, 1991; Vacanti *et al.*, 1991). However, these fibers lack the structural stability necessary for *in vivo* uses, which has led to the development of a fiber bonding technique (Mikos *et al.*, 1993a). With this method, PGA fibers are aligned in the shape of the desired scaffold and then embedded in a PLA/methylene chloride solution. After evaporation of the solvent, the PLA-PGA composite is heated above the melting temperatures of both polymers. PLA is removed by selective dissolution after cooling, leaving the PGA fibers physically joined at their cross-points without any surface or bulk modifications while maintaining their initial diameter. Stipulations concerning the choice of solvent, immiscibility of the two polymers, and their relative melting temperatures restrict the general application of this technique to other polymers.

An alternative method of fiber bonding has also been developed to prepare tubular scaffolds for the regeneration of intestine, blood vessels, and ureters (Mooney *et al.*, 1996b, 1994a). In this technique, a nonwoven mesh of PGA fibers is attached to a rotating Teflon cylinder. The scaffolds are reinforced by spray casting with solutions of PLA or PLGA, which results in a thin coat that bonds the cross-points of PGA fibers. The behavior of transplanted cells is therefore determined by the PLA or PLGA coating instead of the PGA mesh. The mechanical strength of the scaffold is provided by both

fibers and coating and is designed in such a way to withstand mechanical stresses or compromise degradation of PLA or PLGA. For example, PGA fiber-based matrices alone did not withstand contractile forces exerted by cultured smooth muscle cells, while scaffolds stabilized by spray-coating atomized PLA solution over the sides of the PGA matrices maintained their desired size and shape over 7 weeks in culture (Kim and Mooney, 1998). This method is very useful for fabrication of thin scaffolds; however, it does not allow the creation of complex 3D scaffolds since only a thin layer at the surface may be engineered by coating.

Solvent Casting and Particulate Leaching

In order to overcome some of the drawbacks associated with fiber bonding, a solvent-casting and particulate-leaching (SC/PL) technique has been developed to prepare porous scaffolds with controlled porosity, surface-area-to-volume ratio, pore size, and crystallinity for specific applications (Mikos *et al.*, 1994b). This method can be applied to PLA, PLGA, and any other polymers that are soluble in a solvent such as chloroform or methylene chloride. For example, sieved salt particles are dispersed in a PLA/chloroform solution that is used to cast a membrane onto glass petri dishes. After evaporating the solvent, the PLA/salt composite membranes are heated above the PLA melting temperature and then quenched or annealed by cooling at controlled rates to yield amorphous or semicrystalline foams with regulated crystallinity. The salt particles are eventually leached out by selective dissolution in water to produce a porous polymer matrix.

Highly porous PLA foams with porosities up to 93% and median pore diameters up to 500 μm have been prepared using the above technique (Mikos *et al.*, 1994b; Wake *et al.*, 1994). Porous PLGA foams fabricated by the same method have been shown to support osteoblasts growth both *in vitro* and *in vivo* (Ishaug *et al.*, 1997; Ishaug-Riley *et al.*, 1997, 1998). The porosity and pore size can be controlled independently by varying the amount and size of the salt particles, respectively. The surface-area-to-volume ratio depends on both initial salt weight fraction and particle size. In addition, the crystallinity, which affects both degradation and mechanical strength of the polymer, can be tailored to a particular application. A disadvantage of this method is that it can only be used to produce thin wafers or membranes with uniform pore morphology up to 3 mm thick (Wake *et al.*, 1996). The preparation of thicker membranes may result in the formation of a solid skin layer characteristic of asymmetric membranes. The two controlling phenomena are solvent evaporation of the surface and solvent diffusion in the bulk.

This method has been modified to fabricate tubular scaffolds (Mooney *et al.*, 1995a, 1994b). Porous PLGA membranes prepared using SC/PL are wrapped around Teflon cylinders, and the overlapping ends are fused together with chloroform. The Teflon core is then removed to leave a hollow tube. Because of the relatively brittle nature of the porous membranes used, this method is limited to tubular scaffolds with a low ratio of wall thickness to inner diameter.

To increase the pliability of the porous membranes, PEG has been blended with PLGA in the SC/PC process (Wake *et al.*, 1996). Micropores resulted from dissolution of PEG during leaching are believed to alter the structure of the pore walls and increase the pliability of the scaffold. These membranes can be rolled over into tubular scaffolds with a significantly higher ratio of wall thickness to inner diameter. The membranes fabricated from the polymer blend do not show any macroscopic damage during rolling as is observed for tubes made of PLGA alone.

Highly porous PPF scaffolds have also been formed using the SC/PL technique for both tissue induction and delivery of bioactive factors (Fisher *et al.*, 2003; Hedberg *et al.*, 2002). In this procedure, the PPF is cross-linked around the salt particles in molds of desired size. The samples are then removed from the molds and the salt is leached in water. Mechanical and degradation properties of the resulting scaffolds, with pore sizes ranging from 300 to 800 μm and porosities of 60–70%, have been characterized *in vitro* (Fisher *et al.*, 2003). These scaffolds were also found to induce a mild tissue response when implanted for up to 8 weeks either subcutaneously or in cranial defects in rabbits (Fisher *et al.*, 2002).

Superstructure Engineering

Polymer scaffolds with complex 3D architecture (superstructures) can be formed by superimposing defined structural elements such as pores, fibers, or membranes in order according to stochastic, fractal, or periodic principles (Wintermantel *et al.*, 1996). This approach may provide optimal spatial organization and nutritional conditions for cells. The coherence of structural elements determines the anisotropic structural behavior of the scaffold. The major concern in engineering superstructures is the spatial organization of the elements in order to obtain desired pore sizes and interconnected pore structure.

A simple example of this technique is membrane lamination to construct foams with precise anatomical shapes (Mikos *et al.*, 1993b). A contour plot of the particular 3D shape is first prepared. Highly porous PLA or PLGA membranes with the shapes of the contour are then manufactured using SC/PL. The adjacent membranes are bonded together by coating chloroform on their contacting surfaces. The final scaffold is thus formed by laminating the constituent membranes in the proper order. It has been shown that continuous pore structures are formed with no boundary between adjacent layers. In addition, the bulk properties of the 3D scaffold are identical to those of the individual membranes.

Compression Molding

Compression molding is an alternative technique of constructing 3D scaffolds. In this method, a mixture of fine PLGA powder and gelatin microspheres is loaded in a Teflon mold and then heated above the glass transition temperature of the polymer (Thomson *et al.*, 1995). The PLGA/gelatin composite is subsequently removed from the mold and gelatin microspheres

are leached out. In this way, porous PLGA scaffolds with a geometry identical to the shape of the mold can be produced.

Polymer scaffolds of various shapes can be constructed by simply changing the mold geometry. This method also offers the independent control of porosity and pore size by varying the amount and size of porogen used, respectively. In addition, it is possible to incorporate bioactive molecules in either polymer or porogen for controlled delivery, because this process does not utilize organic solvents and is carried out at relatively low temperatures for amorphous PLGA scaffolds. This manufacturing technique may also be applied to PLA or PGA. However, higher temperatures are required (above the polymer melting temperatures) because these polymers are semicrystalline.

Compression molding can be combined with the SC/PL technique to form porous 3D foams. The dried PLGA/salt composites obtained by SC are broken into pieces of less than 5 mm in edge length and compression-molded into a desired 3D shape (Widmer *et al.*, 1998). The resulted composite material can then be cut into desired thickness. Subsequent leaching of the salt leaves an open-cell porous foam, with more uniform pore distribution than those obtained by SC/PL for increased thickness.

Highly porous poly(α -hydroxy ester) scaffolds, though desirable in many tissue engineering applications, may lack required mechanical strength for the replacement of load bearing tissues such as bone. Hydroxyapatite and β -tricalcium phosphate are biocompatible and osteoconductive materials and can be incorporated into these foams to improve their mechanical properties. Because the macroscopic mixing of three solid particulates (polymer powder, porogen, and ceramic) is difficult, a combined SC, compression-molding, and PL technique described earlier has been employed to fabricate an isotropic composite foam scaffold of PLGA reinforced with short hydroxyapatite fibers (15 μm in diameter and 45 μm in length) (Thomson *et al.*, 1998). Within certain range of fiber contents, these scaffolds have superior compressive strength compared to nonreinforced materials of the same porosity.

Extrusion

Various extrusion methods such as ram (piston-cylinder) extrusion, hydrostatic extrusion, or solid-state-extrusion (die drawing) have been applied to increase the orientation of polymer chains and thus produce high-strength, high-modulus materials (Ferguson *et al.*, 1996). More recently, an extrusion process has been successfully combined with the SC/PL technique to manufacture porous tubular scaffolds for guided tissue such as peripheral nerve regeneration (Widmer *et al.*, 1998). First the dry polymer/salt composite wafers obtained from SC are cut into pieces and placed in a customized piston extrusion tool (Fig. 3). The tool is then mounted into a hydraulic press and heated to the desired processing temperature. The temperature is allowed to equilibrate and the polymer/salt composite is then extruded by applying pressure. The extruded tubes are cut to appropriate lengths. Finally, the salt particles are leached out to yield highly porous conduits.

The pressure for extrusion at a constant rate is dependent on the extrusion temperature. High temperature may result in

FIG. 3. Piston extrusion tool for the manufacture of tubular polymer/salt composite structures: 1, extruded polymer/salt construct; 2, nozzle defining the outer diameter of the tubular construct; 3, tool body; 4, melted polymer/salt mixture; 5, rod defining the inner diameter of the tubular construct; 6, heat band with temperature control; and 7, piston moving the melted polymer/salt mixture. The arrows indicate the attachment points for the forces involved in the extrusion process.

thermal degradation of the polymer. The porosity and pore size of the extruded conduits are determined by salt weight fraction, salt particle size, and processing temperatures. The fabricated conduits have an open-pore structure and are suitable for incorporation of cells or microparticles loaded with tissue inductive factors.

Freeze-Drying

Low-density polymer foams have been produced using a freeze-drying technique (Hsu *et al.*, 1997). Polymer is first

dissolved in a solvent such as glacial acetic acid or benzene to form a solution of desired concentration. The solution is then frozen and the solvent is removed by lyophilization under high vacuum. Several polymers including PLGA and PLGA/PPF have been prepared into porous foams with this method. The foams have either leaflet or capillary structures depending on the polymer and solvent used in fabrication. These foams are generally not suitable as scaffolds for cell transplantation. Subsequent compression of the foams by grinding and extrusion can generate matrices with varied densities. Foam density has been shown to determine the kinetics of drug release from these matrices.

An emulsion freeze-drying technique has also been developed to fabricate porous scaffolds (Whang *et al.*, 1995). In this technique, water is added to a PLGA/methylene chloride solution and the immiscible phases are homogenized. The created emulsion (water-in-oil) is then poured into a copper mold maintained in liquid nitrogen (-196°C). After quenching, the samples are freeze-dried to remove methylene chloride and water. Using this technique, PLGA foams with porosity in the range of 91–95% and median pore diameters of 13–35 μm with larger pores greater than 200 μm have been made by varying processing parameters such as water volume fraction, polymer weight fraction, and polymer molecular weight. Compared to the SC/PL technique, this method produces foams with smaller pore sizes but higher specific pore surface area and can produce thick (>1 cm) foams.

Phase Separation

The ability to deliver bioactive molecules from a degrading polymer scaffold is desirable for tissue regeneration. However, the activity of the molecule is often dramatically decreased because of the harsh chemical or thermal environments used in some polymer processing techniques. Using a novel phase separation technique, scaffolds loaded with small hydrophilic and hydrophobic bioactive molecules have been manufactured (Lo *et al.*, 1995). The polymer is dissolved in a solvent such as molten phenol or naphthalene, followed by dispersion of the bioactive molecule in this homogeneous solution. A liquid-liquid phase separation is induced by lowering the solution temperature. The resulting bicontinuous polymer and solvent phases are then quenched to create a two-phase solid. Subsequent removal of the solidified solvent by sublimation leaves a porous polymer scaffold loaded with bioactive molecules.

The fabricated PLA foams have pore sizes up to 500 μm with relatively uniform distributions. The properties of the foams depends on the polymer type, molecular weight, concentration, and solvent used. It has been shown that proteins such as alkaline phosphatase retain as much as 75% of their activity after scaffold fabrication with the naphthalene system, but the activity is completely lost in the phenol system. Although phenol has a lower melting temperature than naphthalene, it is a more polar solvent and can interact with proteins and weaken the hydrogen bonding within the protein structure, resulting in a loss of protein activity. The phenol system may be useful for the entrapment of small drugs or short peptides instead.

Gas Foaming

In one example of the gas foaming (GF) technique, solid disks of PLGA prepared by either compression molding or solvent casting are exposed to high-pressure CO₂ (5.5 MPa, 25°C) environment to allow saturation of CO₂ in the polymer (Mooney *et al.*, 1996a). A thermodynamic instability is then created by reducing the CO₂ gas pressure to ambient level, which results in nucleation and expansion of dissolved CO₂ pores in the polymer particles. PLGA sponges with a porosity of up to 93% and a pore size of about 100 μm have been fabricated. The porosity and pore structure are dependent on the amount of CO₂ dissolved, the rate and type of gas nucleation, and the rate of gas diffusion to the pore nuclei.

The major advantage of this technique is that it involves no organic solvent or high temperature and therefore is promising for incorporating tissue induction factors in the polymer scaffolds. However, the effects of high pressure on the retention of activity of proteins still need to be assessed. In addition, this process yields mostly nonporous surfaces and a closed pore structure inside the polymer matrix, which is undesirable for cell transplantation. In an improved method, a porogen such as salt particles can be combined with the polymer to form composite disks before gas foaming (Harris *et al.*, 1998). The expansion and fusion of the polymer particles lead to the formation of a continuous matrix with entrapped salt particles, which are subsequently leached out. The GF/PL process produces porous matrices with predominately interconnected macropores (created by leaching out salt) and smaller, closed pores (created by the nucleation and growth of gas pores in the polymer particles). The fabricated matrices have a more uniform pore structure and higher mechanical strength than those obtained with SC/PL.

For injectable scaffolds, a combination of ascorbic acid, ammonium persulfate, and sodium bicarbonate has been used at atmospheric conditions to form highly porous hydrogel materials for bone tissue engineering (Behravesh *et al.*, 2002). In this case, as the hydrogel is cross-linked, carbon dioxide is produced, causing pore formation. The ratio of the three components just listed determines the final porosity (43–84%) and pore size (50–200 μm) of the scaffolds (Behravesh *et al.*, 2002). As mentioned previously, these porous [P(PF-co-EG)] foams supported rat-marrow stromal cell differentiation and bone matrix production during *in vitro* culture (Behravesh and Mikos, 2003).

Solid Freeform Fabrication

Solid freeform fabrication (SFF) refers to computer-aided design, computer-aided manufacturing (CAD/CAM) methodologies such as stereolithography, selective laser sintering (SLS), ballistic particle manufacturing, and 3D printing (3DP) for the creation of complex shapes directly from CAD models. SFF techniques, although mainly investigated for industrial applications such as rapid prototyping, offer the possibility to fabricate polymer scaffolds with well-defined architecture because local composition, macrostructure, and microstructure can be specified and controlled at high resolution in the interior of the components. These methods build complex

3D objects by material addition and fusion of cross-sectional layers (2D slices decomposed from CAD models). In addition, they allow the formation of multimaterial structures by selective deposition. Prefabricated structures can also be embedded during material buildup. By carefully controlling the processing conditions, cells, bioactive molecules, or synthetic vasculature may be included directly into layers of polymer scaffolds during fabrication.

An example of the use of stereolithography is the development of a diethyl fumarate/PPF resin as a liquid base material for a custom-designed apparatus using a computer-controlled, ultraviolet laser and suitable photoinitiator (Cooke *et al.*, 2002). In this case, the machine builds the desired structure from the bottom toward the top, with the resin allowed to wash over the sample after each layer is formed. This provides new base material to be photo-cross-linked in the desired geometry for the next layer using the computer-driven laser. The spatial resolution of such a system is 100 μm (Cooke *et al.*, 2002).

In the SLS technique, a thin layer of evenly distributed fine powder is first laid down (Bartels *et al.*, 1993; Berry *et al.*, 1997). A computer-controlled scanning laser is then used to sinter the powder within a cross-sectional layer. The energy generated by the laser heats the powder into a glassy state and individual particles fuse into a solid. Once the laser has scanned the entire cross section, another layer of powder is laid on top and the whole process is repeated.

In the 3DP process, each layer is created by adding a layer of polymer powder on top of a piston and cylinder containing a powder bed and the part being fabricated. This layer is then selectively joined where the part is to be formed by ink-jet printing of a binder material such as an organic solvent. The printed droplet has a diameter of 50–80 μm. The printhead position and speed are controlled by computer. The piston, powder bed, and part are lowered and a new layer of polymer powder is laid on top of the already processed layer and selectively joined. The layered printing process is repeated until the desired part is completed.

The local microstructure within the component can be controlled by varying the printing conditions. The resolution of features currently attainable by 3DP for degradable polyesters is about 200 μm (Griffith *et al.*, 1997). Using this technique, scaffolds with complex structures may be fabricated (Giordano *et al.*, 1996). A model drug (dye) with a concentration profile specified by a CAD model has been successfully incorporated into a scaffold during the 3DP process, demonstrating the feasibility of producing complex release regimes using a single drug-delivery device (Wu *et al.*, 1996). By mixing salt particles in the polymer powder and their subsequent leaching after 3DP process, porous PLGA scaffolds with an intrinsic network of interconnected branching channels have been fabricated for cell transplantation (Kim *et al.*, 1998). This network of channels and micropores could provide a structural template to guide cellular organization, enhance neovascularization, and increase the capacity for mass transport. Furthermore, multiple printheads containing different binder materials can be used to modify local surface chemistry and structure. Patterned PLA substrates with selective cell-adhesion domains have been fabricated by 3DP (Park *et al.*, 1998).

CHARACTERIZATION OF PROCESSED SCAFFOLDS

Various techniques are available to characterize the fabricated polymer scaffolds (Table 4). The molecular weight and polydispersity index of the polymer can be measured by gel permeation chromatography (GPC). Information on chemical composition and structure can be obtained by nuclear magnetic resonance (NMR) spectroscopy, X-ray diffraction, Fourier transform infrared (FTIR), and FT-Raman (FTR) spectroscopy. The thermal properties of the polymer such as glass transition temperature (T_g), melting temperature (T_m), and crystallinity (X_c) can be determined by differential scanning calorimeter (DSC). Porosity and pore size distribution of a porous scaffold are measured by mercury intrusion porosimetry. Scanning electron microscopy (SEM) is the most common method to view the pore structure and morphology. The 3D microstructure of porous PLGA matrices has been analyzed by confocal microscopy (Tjia and Moghe, 1998). Mechanical properties of the scaffolds such as tensile strength and modulus, compression strength and modulus, compliance/hardness, flexibility, elasticity, and stress and strain at yield can be measured using mechanical testing equipment. Some tests require the processing of scaffolds into a particular shape and dimensions specified by ASTM standards.

The *in vitro* degradation properties can be evaluated by placing the bioresorbable scaffolds in simulated body fluid, typically pH 7.4 phosphate-buffered saline (PBS). Changes in sample weight, molecular weight, morphology, and thermal and mechanical properties can then be measured at various time points until degradation process is completed. In addition, characterization of the chemical makeup of the degradation products may be possible through the use of GPC or high-performance liquid chromatography (HPLC) (Timmer *et al.*, 2002). However, such studies do not allow for the continuous

observation of changes within the scaffolds. An *in vivo* study is often necessary to predict the degradation behavior of the scaffolds for cell transplantation (Shin *et al.*, 2003b).

Material surfaces, which are usually different from the bulk, play a crucial role in regulating cell response. Electron spectroscopy for chemical analysis (ESCA) and static secondary ion mass spectrometry (SIMS) are the most powerful tools for analyzing surface chemistry and composition. Information on the orientation of chemical groups can be obtained by polarized IR and near-edge X-ray absorption fine structure (NEXAFS). Surface morphology can be characterized by SEM, scanning probe microscopy (SPM), and atomic force microscopy (AFM). Surface wettability and energy are assessed by contact-angle measurements.

CELL SEEDING AND CULTURE IN 3D SCAFFOLDS

The major obstacles to the *in vitro* development of 3D cell-polymer constructs for the regeneration of large organs or defects have been obtaining uniform cell seeding at high densities and maintaining nutrient transport to the cells inside the scaffolds. To achieve desired spatial and temporal distribution of cells and molecular cues affecting cellular function, cell culture conditions should provide control over hydrodynamic and biochemical factors in the cell environment.

Static Culture

The conventional static cell seeding technique involves the placement of the scaffold in a cell suspension to allow the absorption of cells. However, the resulting cell distribution in the scaffold is often not uniform, with the majority of the cells attached only to the outer surfaces (Wald *et al.*, 1993). Wetting hydrophobic polymer scaffolds with ethanol and water prior to cell seeding allows for displacement of air-filled pores with water and thus facilitates penetration of cell suspension into these pores (Mikos *et al.*, 1994a). Infiltration with hydrophilic polymers or surface hydrolysis of scaffolds has also been shown to increase the cell seeding density (Gao *et al.*, 1998; Mooney *et al.*, 1995b). Seeding cells by injection or applying vacuum to ensure penetration of the cell suspension through the 3D matrix could result in uniform cell seeding initially. However, the uniformity is lost under static culture conditions because of the nutrient and oxygen diffusion limitation within the scaffold.

Several dynamic cell seeding and culture techniques have been developed to ensure uniform cell distribution, which will lead to uniform tissue regeneration (Fig. 4). Compared to static culture conditions, mass transfer rates can be maintained at higher levels and cell growth is not restricted by the rate of nutrient supply under well-mixed culture conditions. These methods can be scaled up and are suitable for cell cultivation using multiple scaffolds.

Spinner Flask Culture

In a spinner flask, 3D polymer scaffolds are first fixed to needles attached to the cap of the flask, and then exposed to

TABLE 4 Characterization of Bioresorbable Polymer Scaffolds

Properties	Techniques
<i>Bulk properties</i>	
Molecular weight	GPC
Polydispersity index	GPC
Chemical composition, structure	NMR, X-ray diffraction, FTIR, FTR
Thermal properties (T_g , T_m , X_c , etc.)	DSC
Porosity, pore size	Mercury intrusion porosimetry
Morphology	SEM, confocal microscopy
Mechanical properties	Mechanical testing
Degradative properties	<i>In vitro</i> , <i>in vivo</i>
<i>Surface properties</i>	
Surface chemistry	ESCA, SIMS
Distribution of chemistry	Imaging methods (e.g., SIMS)
Orientation of groups	Polarized IR, NEXAFS
Texture	SEM, AFM, STM
Surface energy and wettability	Contact-angle measurement

FIG. 4. Dynamic cell seeding and culture techniques in 3D scaffolds. (A) Spinner flask. (B) Rotary vessel. (C) Perfusion system.

a uniform, well-mixed cell suspension (Fig. 4A) (Freed *et al.*, 1993). Using this method, porous PGA scaffolds have been uniformly seeded with chondrocytes at high yield and high kinetic rate (to minimize the time that cells stay in the suspension) (Vunjak-Novakovic *et al.*, 1998). Mixing has been found to promote the formation of cell aggregates with sizes of 20–32 μm . The spin rate, however, needs to be well adjusted to minimize cell damage under high shear stress. The spinner flask is also suitable for suspension culture of hepatocyte spheroids that exhibit enhanced liver function compared to monolayer culture in the long-term (Kamihira *et al.*, 1997).

Rotary Vessel Culture

The rotating-wall vessel (RWV) also allows enhanced mass transport and is useful for 3D cell culture (Fig. 4B). The polymer scaffolds are loaded into the vessel and a uniform cell suspension is added. Vessel rotation is initiated to allow dynamic cell seeding and increased to maintain a high rate of nutrient and oxygen diffusion. Alternately, the scaffolds can be preseeded with cells under static conditions before loading (Goldstein *et al.*, 1999). Several configurations of RWV have been used in microgravity tissue engineering (Freed and Vunjak-Novakovic, 1997).

Perfusion Culture

A flow perfusion culture system has been used for *in vitro* regeneration of large 3D tissues and organs (Fig. 4C) (Bancroft *et al.*, 2002; Glowacki *et al.*, 1998; Griffith *et al.*, 1997; Kim *et al.*, 1998). The cell–polymer constructs are maintained in a continuous-flow condition. The culture medium is pumped from a reservoir through an oxygenator and the cell–polymer constructs, and recirculated back to the reservoir. The flow rate

for cell survival is adjusted based on cell mass. The entire perfusion unit is maintained in normal sterile culture conditions. Compared to static culture, medium perfusion has been shown to significantly enhance cell viability and matrix production (Glowacki *et al.*, 1998). Additionally, the medium flow rate was found to influence ECM deposition and the timing of osteogenic differentiation when marrow stromal cells were cultured on three-dimensional scaffolds in a perfusion bioreactor (Bancroft *et al.*, 2002). These systems are useful for the development of complex tissue structures as well as the study of the effects of mechanical stimulation on cell viability, differentiation, and ECM production.

Other Culture Conditions

Ideally the culture conditions should provide all necessary signals that the cells normally experience *in vivo* for optimal tissue regeneration. For instance, mechanical stimulation plays an important role in the differentiation of mesenchymal tissues (Chiquet *et al.*, 1996; Goodman and Aspenberg, 1993). Application of well-controlled loads may stimulate bone growth into porous scaffolds. The degradation of the scaffolds can be affected by applied strain (Miller and Williams, 1984). Transwell culture systems that allow the use of different culture media for apical or basal sides are often employed to induce and maintain the polarity of epithelial cells. The growth and function of some retinal cells may be regulated by the light–dark cycle. In some cases, a gradient substrate with spatially controlled wettability or other properties may be desired (Ruardy *et al.*, 1995). Some cellular chemotactic responses may require the creation of concentration gradients of growth factors. Temporal presentation of signals is also important. For example, each phase of the differentiation of osteoblasts (proliferation, maturation of ECM, and mineralization) requires different signals (Lian and Stein, 1992; Peter *et al.*, 1998a). Coculture of several types may be preferred for *in vitro* organogenesis including angiogenesis.

CONCLUSIONS

Significant progress has been made to optimize the engineering of tissue and organ analogs. However, many challenges remain in the engineering of 3D tissues and organs for clinical use. Nevertheless, many advances have been made in synthetic polymer chemistry, scaffold processing methods, and tissue-culture techniques. These may eventually allow the generation of long-term functional complex cell–polymer constructs with precisely controlled local environment such as material microstructure, nutrient and growth factor concentration, and mechanical forces.

Practical Aspects of Biomaterials

Implants, Devices, and Biomaterials: Issues Unique to this Field

9.1 INTRODUCTION

Frederick J. Schoen

Chapter 9 addresses some special concerns in the use of surgical implants and medical devices. The themes of this chapter are that implant retrieval and analysis contribute greatly to understanding and ultimately solving problems with implants, both individually and in cohorts, and that the characteristics of biomaterials' surfaces play a critical role in determining the tissue reactions to implants. Moreover, in this respect, sterilization of implants is not only critical to preventing infection, but also this procedure can alter the chemistry of biomaterials' surfaces (and indeed their bulk properties) and thereby inadvertently alter implant performance. A central concept of this chapter is that following contact of biomaterials with tissues, careful, informed and detailed analysis of the implants, the biomaterials that comprise them, and the surrounding tissues can be a powerful tool in understanding the mechanisms and causes of tissue-biomaterials interactions, both desired and adverse.

Implant retrieval and evaluation is an approach that contributes to ensuring the efficacy and safety of medical devices and understanding the mechanisms of interaction of the constituent biomaterials with the surrounding tissues. Implants can be retrieved at either reoperation or necropsy or autopsy of animals or humans, respectively. The literature contains numerous instances where problem-oriented medical implant research has yielded important insights into deficiencies and complications limiting the success of implants (Schoen, 1998). Many specific examples are discussed in Chapter 9.5. Implant research has guided development of new and modification of existing implant designs and materials, assisted in decisions of implant selection and management of patients and permitted *in vivo* study of the mechanisms of biomaterials-tissue interactions, both local and distant from the device.

Preclinical studies of modified designs and materials are crucial to developmental advances. These investigations usually include *in vitro* functional testing (such as fatigue studies at accelerated rates) and implantation of functional devices in the intended location in an appropriate animal model, followed by

noninvasive and invasive monitoring, specimen explantation, and detailed pathological and material analysis. Relative to clinical studies, animal investigation may permit more detailed monitoring of device function and enhanced observation of morphologic detail as well as frequent assay of laboratory parameters, and allow *in situ* observation of fresh implants following elective sacrifice at desired intervals. In addition, specimens from experimental animals can minimize the artifacts that can occur inadvertently under clinical circumstances. Furthermore, advantageous technical adjuncts may be available in animal but not human investigations, such as injection of radiolabeled imaging markers or fixation by pressure perfusion that maintains tissues and cells in their physiological configuration following removal. Animal studies often facilitate observation of specific complications in an accelerated time frame, such as calcification of bioprosthetic valves, in which the equivalent of 5–10 yr in humans is simulated in 4–6 mo in juvenile sheep (Schoen *et al.*, 1985). Moreover, in preclinical animal studies, experimental conditions can generally be held constant among groups of subjects, including nutrition, activity levels, and treatment conditions, and concurrent control implants are often possible. This is clearly not possible in clinical studies.

Nevertheless, clinicopathologic analysis of cohorts of patients who have received a new or modified prosthesis type evaluates device safety and efficacy to an extent beyond that obtainable by either *in vitro* tests of durability and biocompatibility or preclinical investigations of implant configurations in large animals. Moreover, through analysis of rates and modes of failure as well as characterization of the morphology and mechanisms of specific failure modes, retrieval studies can contribute to the development of methods for enhanced clinical recognition of failures. The information gained should serve to guide both future development of improved prosthetic devices to eliminate complications and diagnostic and therapeutic management strategies to reduce the frequency and clinical impact of complications. For individual patients, demonstration of a propensity toward certain complications could impact greatly on further management. Moreover, history has shown that some medical devices demonstrate important

complications only during clinical trials or postmarket surveillance (indeed, complications that were not predicted by animal investigations). Subsequent bench study of clinically important device failure mechanisms may yield prevention strategies; such strategies may then be screened *in-vivo* in animal studies; favorable therapies are then tested in clinical trials. Thus, an important future goal is the effective integrated use of data derived from implant retrieval investigations (along with other clinical and experimental data) to influence both regulatory decisions and device improvements in an ongoing, incremental and iterative fashion throughout the product life-cycle.

Clinical implant retrieval and evaluation can yield several additional benefits. Implant retrieval studies have demonstrated that success of a material or design feature in one application may not necessarily translate to another. Although analysis of implants and medical devices has traditionally concentrated on failed devices, important data can accrue from implants serving the patient well until death or removal for unrelated causes. Indeed, detailed analyses of implant structural features following implantation can yield an understanding of not only predisposition to specific failure modes but also structural correlates of favorable performance. Implant retrieval and evaluation may also provide specimens and data that can be used to educate patients, their families, physicians, residents, students, engineers, and biomaterials scientists, as well as the general public. As a basic research resource, the process of implant retrieval and evaluation yields data that can be used to develop and test hypotheses and to improve protocols and techniques.

For investigation of bioactive materials/devices and potentially tissue engineered medical devices, in which the interactions between the implant and the surrounding tissue are complex, research based on implant retrieval and evaluation continues to be critical. In such instances, novel and innovative approaches must be used in the investigation of *in vivo* tissue compatibility. In such implant types, the scope of the concept of "biocompatibility" is much broader and the approaches employed in implant retrieval and evaluation require identification of the phenotypes and functions of cells and the architecture and remodeling of extracellular matrix (Schwartz and Edelman, 2002; Rabkin *et al.*, 2002). These are circumstances in which individual patient characteristics (for example, genetic polymorphisms in molecules important in matrix remodeling) could have a profound influence on outcome in some patients (Ye, 2000; Jones *et al.*, 2003). This potentially yields a new area of study: "biomateriogenomics," conceptually analogous to the emerging area of pharmacogenomics (Weinshilboum, 2003). Indeed, individuals with genetic defects in coagulation proteins may be unusually susceptible to thrombosis of prosthetic heart valves (Gencbay *et al.*, 1998). Thus, a critical role of implant retrieval will be the identification of tissue characteristics (*biomarkers*) that will be predictive of (i.e., surrogates for) success and failure. A most exciting possibility is that such biomarkers may be used to non-invasively image/monitor the maturation/remodeling of tissue engineered devices *in vivo* in individual patients (Rabkin and Schoen, 2002; Sameni *et al.*, 2003).

9.2 STERILIZATION OF IMPLANTS AND DEVICES

John B. Kowalski and Robert F. Morrissey

Implants and devices (products) introduced transiently or permanently into the body of a human or an animal must be sterile to avoid subsequent infection that can lead to serious illness or death. In this chapter, we discuss the meaning of the term "sterile," give an overview of the development and validation of sterilization processes, and describe the various sterilization methods, including their advantages and disadvantages (Dempsey and Thirucote, 1989). Sterilization process development and validation are discussed from the point of view of compatibility of the implant/device and associated packaging with the sterilization process as well as meeting the requirements for sterility. It is recommended that the biomaterials specialist consider sterilization-related issues early in the developmental process so that the final product can be readily sterilized by the most cost-effective process.

STERILITY AS A CONCEPT

"Sterility" is defined as the absence of all living organisms. This especially includes the realm of microorganisms,

FIG. 1. Sterility tests of an experimental vascular graft illustrating negative (sterile, left) and positive (nonsterile, right) results.

such as bacteria, yeasts, molds, and viruses. The presence of even one viable bacterium on an implant renders it nonsterile. Sterility should not be confused with cleanliness. A polished stainless steel surface may easily be nonsterile (contaminated with numerous unseen microorganisms), whereas a rusty nail can be made sterile after exposure to a sterilization process that was properly developed and validated. It is true that implants and devices that are “microbiologically clean,” having few viable microorganisms present (low bioburden), are more readily sterilized than those that are highly contaminated.

How then is sterility measured or proven? For relatively small numbers of product samples (assuming the product is not too large to test in its entirety), sterility can be determined by immersing each of the product samples into an individual container of sterile liquid microbiological culture medium and incubating the containers under the proper conditions. If the product is sterile, no microbial growth will occur; if it is nonsterile, the culture medium will become turbid as a result of microbial proliferation (Fig. 1). Testing small numbers of samples, however, does not give very meaningful information about the sterility of a large batch of products (often in the thousands of units) that have been processed in an industrial-scale sterilizer. Sterilization process development and validation studies are used to determine what is referred to as a sterility assurance level (SAL). The SAL is the probability that a product will be nonsterile after exposure to a specified sterilization process. The generally accepted maximum SAL for implants is 10^{-6} or a probability of no more than one in one million that the implant will be nonsterile. The process development and validation studies also document the compatibility

of the product and its package with the proposed sterilization process.

STERILIZATION PROCESS DEVELOPMENT AND VALIDATION

Product and Packaging Compatibility

The first concern in sterilization process development and validation is the demonstration that the product is compatible with the process; this also applies to the packaging, which maintains the integrity and sterility of the product on its journey to the medical practitioner and patient. The integrity of the product and the packaging system must be demonstrated shortly after sterilization and also after aging studies (often performed at elevated temperatures) to document the absence of delayed sterilization-related deleterious effects. Such delayed effects are most commonly encountered with radiation sterilization. During the product and packaging compatibility studies, “worst case” processing conditions must be used to ensure that the product and packaging are tested after exposure to the most rigorous conditions that may be encountered. For example, if the sterilization process specification allows a temperature range of 52 to 57°C, such tests must be conducted on samples exposed to a 57°C process. Also, the effect of multiple sterilization exposures must be considered in the event that a product must be exposed to a second sterilization process as a result of a condition that invalidates the initial sterilization such as a sterilizer malfunction.

When sterilizing with gaseous agents, the amount of residual sterilant and any by-product(s) in the medical device and associated packaging must be determined. If required, an aeration regimen must be developed to ensure that the residuals are below safe limits for patient use, and that manufacturing personnel are not exposed to the sterilant and/or by-product(s) that may be released into the workplace atmosphere.

Sterility Assurance Level

Sterilization validation studies must also document that the product attains the required SAL after exposure to the proposed process. By using the techniques of bioburden determination and fractional-run sterilization studies (see later discussion), the ability of the proposed process to consistently deliver an SAL of 10^{-6} or better must be conclusively documented. For these studies to be valid, the product samples must be produced under actual manufacturing conditions and be exposed to the process in their final packaging configuration. Also, the fractional-run sterilization studies must represent the least lethal conditions allowed by the process specification. In the example cited above, where the specified temperature range was 52 to 57°C, the fractional sterilization runs would be performed at the lowest temperature, 52°C, the temperature that would give the slowest rate of microorganism inactivation.

The determination of an SAL begins with the enumeration of the bioburden, the number of viable microorganisms on the product just prior to sterilization (Morrissey, 1981). Bioburden

is usually determined on 10 to 30 product samples and involves washing, shaking, or sonicating the microorganisms from the item into a sterile recovery fluid such as a saline solution. By using conventional microbiological techniques, the number of microorganisms in the recovery fluid can be determined.

Once the bioburden is known, fractional-run sterilization studies can be performed to determine the microbial rate of kill or process lethality. In a fractional sterilization run, product samples (in packages) are exposed to a fraction of the desired sterilization process or dose. For example, if the proposed sterilization process has an exposure time of 2 hours, the fractional runs may have exposure times of 30, 40, and 50 min. Samples from these runs are tested for sterility and the results graphically analyzed to estimate the exposure time required to achieve a 10^{-6} SAL. The results from such a study are shown in Fig. 2. In this example, the average bioburden per sample was 240 colony-forming units. After the 30-, 40-, and 50-min fractional runs, there were, respectively, 28/50, 7/50, and 1/50 samples that remained nonsterile. The estimated time to achieve a 10^{-6} SAL for this hypothetical bioburden and sterilization process is approximately 100 minutes, which is within the proposed 120-min exposure time. Note that when there is less than one surviving organism per product unit, there is not actually 0.01 of an organism on each unit, but a probability of 1 in 100 that any given product unit is nonsterile.

In the example just given, 100 minutes of exposure to the hypothetical sterilization process was the *estimate* of the time required to attain an SAL of 10^{-6} . The actual exposure time used in the routine sterilization process will include a safety factor to ensure that natural variation in the number of microorganisms on product units (and/or differing resistance to sterilization) does not lead to a failure to attain the required 10^{-6} SAL. A good discussion of the various aspects of

FIG. 2. Microbial kill curve based on data from a series of fractional sterilization runs. Time to achieve a 10^{-6} SAL is approximately 100 min.

sterilization process validation is contained in the specific International Standards Organization (ISO) sterilization documents (ISO 11134, 1994; ISO 11135, 1994; ISO 11137, 1995).

OVERVIEW OF STERILIZATION METHODS

The first sterilization method to be used for implants was moist heat or autoclaving, which involves exposure to saturated steam under pressure. Owing to the relatively high temperature of the process (121°C), most nonmetallic implants and packaging materials cannot be sterilized by this method. This limitation led to the development and use of ethylene oxide (EO) gas and ionizing radiation (gamma rays, accelerated electrons) to sterilize medical products (Association for the Advancement of Medical Instrumentation, 1999; Morrissey and Phillips, 1993; Block, 2000). The advances in complexity of medical products from stainless steel surgical instruments to drug-device combinations and biomaterials for tissue scaffolding has led to the further development of sterilization processes to include low-temperature gas plasma and new gaseous agents such as chlorine dioxide.

MOIST HEAT STERILIZATION

The first sterilization method applied to medical products was moist heat sterilization or autoclaving (ISO 11134, 1994).

Process and Mechanism of Action

With this method, sterilization is achieved by exposing the product to saturated steam, usually at 121°C to 125°C . The use of steam at this temperature requires a pressure-rated sterilization chamber; a typical industrial steam sterilizer is shown in Fig. 3. The design of the product must ensure that all surfaces are contacted by the steam, and the packaging must allow steam to penetrate freely. A typical moist heat sterilization process lasts 15 to 30 min *after all surfaces of the product reach a temperature of at least 121°C .*

Moist heat sterilization kills microorganisms by destroying metabolic and structural components essential to their replication. The coagulation of essential enzymes and the disruption of protein and lipid complexes are the main lethal events.

Applications—Advantages and Disadvantages

Currently, the main use of this method occurs in hospitals; it is the method of choice for the sterilization of metallic surgical instruments and heat-resistant surgical supplies (linen drapes, dressings). Hospitals also perform moist heat sterilization of metallic devices such as stainless steel sutures. A specialized form of moist heat sterilization is used for many intravenous solutions.

The advantages of moist heat sterilization are efficacy, speed, process simplicity, and lack of toxic residues. The high temperature and pressure limit the range of compatible products and packaging materials.

FIG. 3. An example of an industrial-scale steam sterilizer.

EO STERILIZATION

Sterilization with EO gas has been exploited as a low-temperature process that is compatible with a wide range of product and packaging materials (ISO 11135, 1994)

Process and Mechanism of Action

Below its boiling point of 11°C, EO is a clear, colorless liquid. It is toxic and considered a human carcinogen. Contact of liquid EO with the skin and eyes and inhalation of the gas should be avoided. EO may be used in the pure form or mixed with N₂, CO₂, or a non-ozone-depleting chlorofluorocarbon (CFC)-like compound. Pure EO and mixtures without a proven inerting compound are flammable and potentially explosive. Because of the negative effects of CFC compounds (CFC-12) on the earth's ozone layer, alternative inerting compounds have been developed.

For EO sterilization, products contained within gas-permeable packaging are loaded into a sterilization vessel, generally fabricated from stainless steel. The vessel is evacuated

to remove air, at a rate and to a final pressure that is compatible with the product and packaging, and then moisture (from steam) is introduced to attain a relative humidity generally between 60 and 80%. The presence of moisture is required for sterilization efficacy with EO gas. The EO gas (or mixture) is then injected to a final concentration of ~600–800 mg/liter. The sterilizer is maintained at the desired gas concentration and temperature (typically 40 to 50°C) for a sufficient time to achieve the required SAL. The chamber is reevacuated to remove the EO, and “air flushes” are performed to reduce the EO levels to below acceptable limits. Often, further aeration outside of the sterilization chamber (in some instances, at elevated temperatures) is required to effectively remove residual EO (and by-products) from the product and packaging materials.

A vessel similar to that shown in Fig. 3 is employed for EO sterilization. It is somewhat more complex than its steam counterpart to allow for evacuation, moisture and gas addition and control, and air flushes. An EO sterilization process typically ranges from 2 to 16 hours in duration, depending on the time required for aeration inside the sterilization vessel. The lethal effect of EO on microorganisms is mainly due to alkylation of amine groups on nucleic acids.

Applications

EO is used to sterilize a wide range of medical products, including surgical sutures, intraocular lenses, ligament and tendon repair devices, absorbable and nonabsorbable meshes, neurosurgery devices, absorbable bone-repair devices, heart valves, vascular grafts, and stents coated with bioactive compounds.

EO Residuals Issues

Because of potential toxicity/carcinogenicity, residual EO and its by-product, ethylene chlorohydrin (EC) are of concern in medical products and packaging materials. Also, release of EO into the air in poststerilization manufacturing and storage areas is a concern due to the potential for personnel exposure. The maximum allowable limits for EO and EC are no longer expressed as parts-per-million (ppm) in a medical product but rather as a maximum allowable dose delivered to a patient (ISO 10993-7, 1995) (Table 1). Limits are given for devices categorized as "permanent contact," "prolonged exposure," "limited exposure," and "special situations." Current Occupational Health and Safety (OSHA) regulations dictate that a worker may not be exposed to more than 1 ppm of EO during an 8-hour time-weighted average work day.

Advantages and Disadvantages

The advantages of EO are its efficacy (even at low temperatures), high penetration ability, and compatibility with a wide range of materials. The main disadvantage centers on EO residuals with respect to both the implant and release into the environment.

The impact of CFC compounds on the earth's ozone layer forced facilities using the 12% CFC-12/88% EO mixture to switch to pure EO, a non-CFC gas mixture, or one of the alternative inerting compounds that have been developed. Pure EO and mixtures without an inerting compound require the use of costly explosion-proof equipment and damage-limiting building construction.

TABLE 1 Proposed EO Residue Limits on Medical Devices

Device type	Maximum ppm
Implant:	
Small (<10 g)	250
Medium (10–100 g)	100
Large (>100 g)	25
Intrauterine devices	5
Intraocular lenses	25
Devices contacting:	
Blood (<i>ex vivo</i>)	25
Mucosa	250
Skin	250
Surgical scrub sponges	25

RADIATION STERILIZATION

This method of sterilization utilizes ionizing radiation that involves either gamma rays from a ^{60}Co (cobalt-60) isotope source or machine-generated accelerated electrons. With this method, delivery of a sufficient radiation dose to the entire product will yield the required SAL (ISO 11137, 1995).

^{60}Co Sterilization

Of the radiation sterilization methods, exposure to ^{60}Co gamma rays is by far the most popular and widespread method. Gamma rays are highly penetrating, and the typical doses used for the sterilization of medical products are readily delivered and measured.

Process and Mechanism of Action

A schematic top view of a typical industrial ^{60}Co irradiator is shown in Fig. 4. The ^{60}Co isotope is contained in sealed stainless steel "pencils" ($\sim 1 \times 45$ cm) held in a planar array within a metal source rack. When the irradiator is not in use, the source rack is lowered into a water-filled pool (~ 25 feet deep).

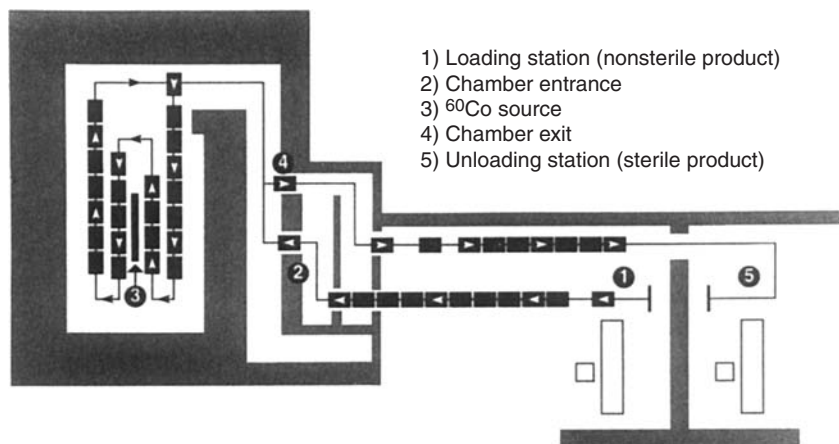

FIG. 4. A schematic top view of a typical industrial ^{60}Co irradiator.

At this depth, the radiation cannot reach the surface, and it is then safe for personnel to enter the radiation cell. The outside walls and ceiling of the cell are constructed of thick, reinforced concrete for radiation shielding.

In use, materials to be sterilized are moved around the raised source rack by a conveyor system to ensure that the desired dose is uniformly delivered. Radiation measuring devices called dosimeters are placed along with the materials to be sterilized to document that the minimum dose required for sterilization was delivered and that the maximum dose for product and package integrity was not exceeded. The maximum dose divided by the minimum dose is referred to as the "overdose ratio." Irradiators are designed and product-loading patterns are configured to minimize this ratio. The most commonly validated dose used to sterilize medical products is 25 kGy.

The radioactive decay of ^{60}Co (5.3-year half-life) results in the formation of ^{60}Ni , the ejection of an electron, and the release of gamma rays. The gamma rays cause ionization of key cellular components, especially nucleic acids, which results in the death of microorganisms (Hutchinson, 1961). The ejected electron does not have sufficient energy to penetrate the wall of the pencil and therefore does not participate in the sterilization process.

Applications—Advantages and Disadvantages

^{60}Co radiation sterilization is widely used for medical products, such as surgical sutures and drapes, metallic bone implants, knee and hip prostheses, syringes, and neurosurgery devices. A wide range of materials are compatible with radiation sterilization, including polyethylene, polyesters, polystyrene, polysulfones, and polycarbonate. The fluoropolymer polytetrafluoroethylene (PTFE) is not compatible with this sterilization method because of its extreme radiation sensitivity. Undesirable material effects with radiation sterilization are generally due to molecular-chain scission and/or cross-linking.

^{60}Co radiation sterilization approaches being the ideal sterilization method. It is a simple process that is rapid and effective, and it is readily measured and controlled through straightforward dosimetry methods. The main disadvantages are the very high capital costs associated with establishing an in-house sterilization operation and the incompatibility of some materials with this method. Another disadvantage is the continual decay of the isotope (even when the irradiator is idle), which results in longer processing times and ultimately the need for additional isotope to be added to the irradiator. Recently, a validation approach has been introduced for radiation and electron beam sterilization that is less labor intensive and requires considerably fewer product samples (AAMI TIR 27, 2001; Kowalski and Tallentire, 2003).

Electron Beam Sterilization

Medical products may also be sterilized with accelerated electrons (Cleland *et al.*, 1993). With this method, radioactive isotopes are not involved because the electron beam is machine-generated using an accelerator. The accelerator is also located within a concrete room to contain "stray electrons" but, in

this case, when the accelerator is turned off, no radiation or radioactive material is present and therefore a water-filled pool is unnecessary.

Process and Mechanism of Action

With this method, articles to be sterilized are passed under the electron beam for a time that is sufficient to accumulate the desired dose (again, often 25 kGy). As with gamma rays, the lethality against microorganisms is related to ionization of key cellular components. In contrast to gamma rays, however, accelerated electrons have considerably less penetrating ability, making this method unsuitable for thick or densely packaged products.

Applications—Advantages and Disadvantages

Electron beam sterilization has the same potential range of applications and material compatibility characteristics as the ^{60}Co process. However, because of the issue of penetration distance, its use is much more limited; the availability of higher energy/higher power machines is lessening this limitation. A unique application for this method is the in-line sterilization of thin products immediately following primary packaging.

OTHER STERILIZATION PROCESSES

Traditional Methods

Because of the extreme temperatures involved ($>140^\circ\text{C}$), dry heat sterilization is rarely if ever used for medical products. Occasionally, products are sterilized in hospitals by immersion in an aqueous glutaraldehyde solution (Block, 2000). This procedure is used only in special circumstances where the product is sensitive to heat and the aeration time after EO sterilization is not acceptable. Achieving an acceptable SAL with this method requires meticulous attention to detail and relatively long immersion times.

New Technologies

Several new technologies have emerged that have potential utility for the sterilization of medical products. These include low-temperature gas plasma, gaseous chlorine dioxide, ozone, vapor-phase hydrogen peroxide, and machine-generated X-rays (Block, 2000). The first four methods are being examined as potential alternatives to EO. Machine-generated X-rays have the advantage of machine generation (nonisotopic source) and penetrating power similar to gamma rays.

A hydrogen peroxide gas plasma system has been developed for the sterilization of heat- and moisture-sensitive devices (Favero, 2000). The process operates at $<50^\circ\text{C}$ and is very rapid; the total process time is less than 75 min. This system was initially developed for hospital use with a key benefit being no requirement for poststerilization aeration. Instruments and devices processed in this system are ready for immediate use

since aeration is not required to remove residual hydrogen peroxide in contrast to EO sterilization where the aeration period can be quite lengthy. The use of this technology has broadened to medical products manufacturers where a rapid process and the lack of a requirement for aeration offer operational advantages.

Gaseous chlorine dioxide has been shown to be effective for the sterilization of medical products (implants as well as other devices), pharmaceutical components, and barrier isolation systems (Kowalski *et al.*, 1988; Kowalski, 1998). The process is relatively rapid, generally 1.5 to 3 hours in duration, and there is little or no need for poststerilization aeration because of the low level of sterilant residuals with most materials. The design of the gas generation system allows for a wide range of sterilizer sizes and configurations. The green color of this gas allows for spectrophotometric measurement of gas concentration inside the sterilization chamber. The ability to readily monitor and control gas concentration is a significant benefit in sterilization process development and validation studies. Because chlorine dioxide (and also hydrogen peroxide) are oxidizing agents, it is important to carry out the product and package compatibility testing described earlier that must be a part of all sterilization process development and validation studies.

CHALLENGE TO THE BIOMATERIALS SPECIALIST

The challenge to the future biomaterials specialist will be to develop materials and products that have the desired biological and mechanical properties and that can be sterilized by cost-effective methods having minimum potential effects upon the patient, manufacturing personnel, and environment. Biomaterials specialists developing the next generation of implants and devices must consider sterilization issues and requirements at the earliest stages of the product development process. Failure to do so often results in a product “defaulting” to a less desirable sterilization process from a cost and/or fit into manufacturing point of view. Reliance upon EO will diminish somewhat in favor of radiation sterilization and some of the newly emerging technologies. The hydrogen peroxide gas plasma and gaseous chlorine dioxide sterilization processes offer operational benefits and these sterilants have a more favorable toxicity profile. New sterilization technologies that pose less risk to people and the environment should be exploited whenever possible (Jorkasky, 1987).

9.3 IMPLANT AND DEVICE FAILURE

Frederick J. Schoen and Allan S. Hoffman

Although the majority of clinical implants and other medical devices serve their patients well, often for extended intervals, some fail. Irrespective of implant site or desired function of the device, the overwhelming majority of clinical complications produced by medical devices fall into several well-defined categories that are summarized in Table 1. Determination of the cause(s) and contributory mechanism(s) of implant or other device failure is usually done by a process called implant retrieval and evaluation (see Chapter 9.5). The results of this analysis have several potential implications. They may, for example:

- Alter patient management, leading to a choice of a different type of prosthesis, and/or a change in the type or dose of drug therapy such as anticoagulation, and/or closer monitoring of a patient by a non-invasive therapy such as echocardiography for a heart valve or X-ray or bone scan to monitor a hip joint.
- Reveal a vulnerability of a specific prosthesis type to a particular mode or mechanism of failure, leading to

TABLE 2 Potential Contributory Causes of Implant or Device Failure

Inadequate materials properties
Inadequate materials testing
Design flaw
Inadequate preclinical animal test models
Components missized/mismatched during fabrication
Defects introduced during manufacturing, packaging, shipping, and storage
Damage or contamination during sterilization
Damage or contamination during implantation
Technical error during implantation
Poor patient–prosthesis matching
Unavoidable, physiologic patient–prosthesis interactions
Inadequate patient management
Unusual/abnormal patient response

action by regulatory agencies such as withdrawal from use, and/or closer scrutiny of a group of patients with such a device and/or a change in design, materials selection, processing, or fabrication.

- Influence product liability litigation, either in an individual case or in a class-action situation involving multiple patients.

The purpose of this chapter is to define a conceptual approach to determination of the factors responsible for device or implant failure and to identify the variety of potential causes of failure of an extracorporeal device or an implant. Analysis relates to considerations that relate to either the development and testing process, and thereby potentially affect all devices in a cohort, or conditions germane primarily to the failed device and the patient who had it.

For example:

- Was there a design flaw, or a poor choice of materials using an appropriate design?
- Did failure arise because the preclinical testing of the device did not reveal some defect of design or materials that only became apparent following large-scale clinical utilization?
- Was the implant damaged during fabrication or implantation?
- Did the patient have an abnormal physiologic response to the implant, e.g., hypersensitivity or a tendency toward blood clotting?

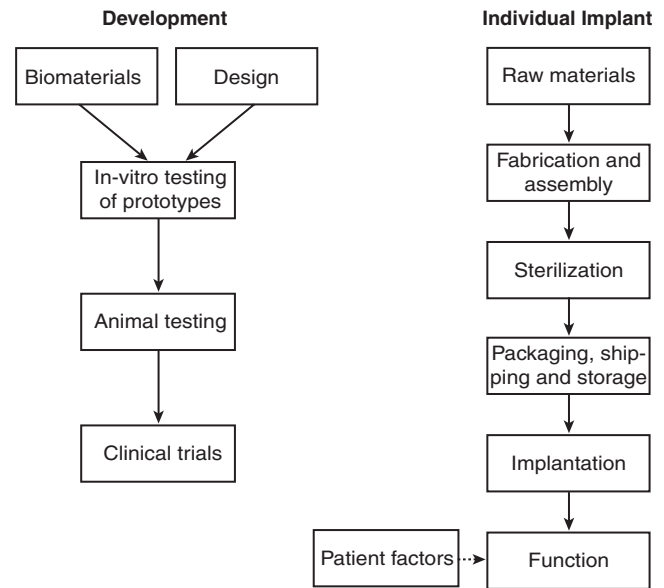

FIG. 1. Potential causes of implant or device failure.

The array of potential causes is summarized in Table 2 and conceptualized in Fig. 1. As we will see, failure of a device in the clinical setting often involves multiple contributing factors. This chapter is not meant to describe the detailed mechanisms of either deterioration or biological responses of materials (see Chapter 6.2). Moreover, although this chapter focuses on selected examples (primarily cardiovascular), the approach and investigative pathways are broadly applicable to other systems

(e.g., orthopaedic and dental) which is covered in other chapters (see Jacobs, Brown, Cranin, etc.)

BIOMATERIALS SELECTION

Materials are often implicated as the major cause of a device failure. The wide range of different material “breakdown” mechanisms that can cause an implant or device to fail is summarized in Table 3. If the wrong material is selected for a particular application, a device or implant can fail simply because the components do not have the requisite physical, chemical, or biological properties. For example, the poor resistance of polytetrafluoroethylene (PTFE or Teflon®-like) polymers to abrasive wear and its unsuitability for use in both hip-joint prostheses (Charnley *et al.*, 1969) and artificial heart valves (Silver and Wilson, 1977) were appreciated following extensive clinical use. Similarly, the inadequate durability of a carbon-reinforced Teflon carbon-reinforced Teflon®-like composites in temporomandibular joint replacement was encountered in clinical usage (Trumpy *et al.*, 1996). In addition, the earliest silicone ball poppets in the Starr–Edwards caged-ball heart valves frequently absorbed lipids from blood during function, and consequently swelled and became brittle and sometimes fractured (Chin *et al.*, 1971). “Ball variance,” as this complication was known, frequently led to abnormal poppet motion with slowly developing dysfunction or fracture-related catastrophic loss of parts of or the entire poppet from the cage. This sometimes caused blockage of blood vessels downstream from the heart due to the shedding of small fragments. This problem stimulated development of an improved curing protocol for medical silicone elastomers, and “ball variance” was thereby eliminated. Interestingly and conversely, a material used to form the femoral stem of a hip-joint prosthesis is too stiff, can cause “stress shielding,” leading to structurally poor surrounding bone and consequent loosening (Huiskes, 1998).

<ul style="list-style-type: none"> • Corrosion

DESIGN

Device design is critical. Design of the femoral stems of hip-joint prostheses has evolved from clinical experience with fractured stems in human implants to computer-aided design and manufacturing techniques. In addition, the design of a heart valve affects the pattern of blood flow and associated platelet damage and/or presence of regions of blood stasis, both of which can lead to thrombosis (Yoganathan *et al.*, 1978, 1981).

When a widely used tilting-disk heart valve was redesigned to allow more complete opening and thereby enhance its hemodynamic function as well as reduce the incidence of thrombosis, a large number of mechanical failures occurred (Walker *et al.*, 1995). Nearly all had similar characteristics: they resulted from metal fatigue fracture of the welds anchoring metallic struts (which confine and guide the motion of the disk) to the housing, with consequent separation of the strut and escape of the disk. Pathology studies revealed that the underlying problem was metal fatigue resulting from design-related high-velocity overrotation of the disk during closure, excessively stressing the welds, potentially coupled with intrinsic flaws in the welded regions (Schoen *et al.*, 1992). Interestingly, many such failures occurred in young patients during exercise, when cardiac forces and thereby valve closing velocities are enhanced. Another example was a specific design of a bileaflet tilting-disk heart valve which developed fractures that were initiated in various locations along the contacts of the disks with the housing. In this case the likely cause was a design flaw that led to cavitation bubbles as the disk moved away from the housing during the earliest phases of valve opening. The working hypothesis is that implosion of these bubbles initiated microscopic cracks in the pyrolytic carbon components that then precipitated gross fractures.

TESTING OF MATERIALS/DESIGN CONFIGURATIONS

In some cases, the *in vitro* or *in vivo* evaluation tests that were carried out on the material itself, or on the design and device prototype, did not adequately simulate conditions that are encountered in actual clinical use. In the case of a new bileaflet tilting-disk heart valve design that suffered clinical failures due to thrombosis initiated at the points where the hemidisks contacted and pivoted in the housing, the testing of implants in sheep failed to reveal a tendency toward thrombosis (Gross *et al.*, 1996). Furthermore, appropriate tests are not available for some physiologic responses. For example, the potential for a significant immunological response, such as has been suggested but not proven in some patients with silicone gel breast implants, is not possible to evaluate in preclinical studies. It is also possible for available tests to have been overlooked because the specific problems that occurred later were not anticipated.

A particularly illustrative example that points out the need for improved preclinical testing regimes was the failure after 1 or more years of function of bioprosthetic heart valves fabricated from photooxidized bovine pericardium by

abrasion-induced tearing of the pericardial tissue against the cloth that covered a portion of the stent (Schoen, 1998). The problem in this case was that photooxidized pericardium has a higher compliance than the glutaraldehyde-preserved pericardium used in an identical design that has been clinically successful. Higher compliance leads to greater excursion of the cuspal material during valve closing. The greater tissue movement of the more compliant material caused the tissue to contact and thereby abrade against the cloth. However, this problem occurred despite extensive preimplantation *in vitro* bench fatigue testing that did not reveal this problem, most likely owing to the markedly accelerated rate of *in vitro* testing in the system that limits tissue movements used (generally approximately 20 times or more actual). Moreover, animal testing done in sheep was not (and is typically not) extended more than approximately 5 months, except in a few specimens that in this case did not exhibit gross failure.

BIOLOGICAL TESTING OF IMPLANTS

After prototype devices have been designed and fabricated, biologic tests in animals are normally used to gain more information for eventual regulatory approval and introduction of such a device into the clinic. However, as with the *in vitro* tests on the materials or designs, *in vivo* tests on the final device or implant could be poorly chosen, key tests could be overlooked, and/or the animal model selected or permitted may not be the most appropriate one available. For example, there have been continuing arguments over the past 20 or more years among biomaterials scientists as to whether the dog is an appropriate animal model for evaluating blood-surface interactions, especially since dog platelets are much more adherent to foreign surfaces than are human platelets. Further, there is no adequate animal model to study the intense inflammatory reaction to wear debris and other particulates that can accumulate adjacent to a hip joint.

An interesting lesson was learned with respect to differences in healing in some animal models vs. humans with a caged-ball mechanical prosthetic heart valve type that had a ball fabricated from silicone and cloth-covered cage struts (Schoen *et al.*, 1984). This design was intended to encourage anchoring and organization of thrombus in the fabric and thereby decrease thromboembolism. Preclinical studies of this valve concept utilized mitral implants in pigs, sheep, and calves; in such models the cloth-covered struts were rapidly healed by endothelium-coated fibrous tissue. However, subsequent clinical implantation of these valves was complicated by cloth wear and embolization. This vivid "case history" illustrates and reinforces the concept that human implantation may reveal important problems not predicted by preclinical animal testing. The more vigorous healing that occurred in the preclinical implants in this case is typical in animals compared to humans; this sometimes makes prediction of such problems very difficult. This is the major rationale for closely monitored clinical trials during introduction of a new implant type, and continued surveillance following widespread general availability and implication thereafter.

Another area in which animal models must be used thoughtfully is in the study of calcification of tissue valves (Schoen and Levy, 1999). Two models are generally used: (a) subcutaneous implants of valve materials in weanling (approximately 3 weeks old) rats, which achieve clinical levels of calcification in 8 weeks or less, and (b) mitral valve replacements in juvenile sheep, which calcify extensively in 3–5 months. However, when older animals are used, calcification is vastly diminished. Use of inadequately severe models could lead to overestimation of the efficacy of an anticalcification strategy.

RAW MATERIALS, FABRICATION, AND STERILIZATION

In unusual circumstances, a batch of raw material is defective or damaged. The fabrication process used to manufacture a device can introduce defects or contaminants that can lead to failure of a device whose materials and design and their combination are well-matched and appropriate for the application, and otherwise intact at the start of device assembly. The weld fracture in the tilting-disk heart valve mentioned above illustrates well the introduction of defects during the fabrication process that can contribute to a tendency toward failure.

Ultra High Molecular Weight PolyEthylene (UHMW-PE) has been utilized for more than 40 years as a standard component for articulating load transferring prostheses. Much has been published about the influence(s) of processing on basic biomechanical and *in vivo* functional properties. More than two decades past, sterilization by low dose gamma radiation was tested and accepted as a regular production cycle. Within the past decade, retrieval and analysis studies showed alterations in structural and tribology properties for some UHMW-PE components that were correlated with gamma radiation and shelf storage in air, near surface oxidation, structural and property changes and altered stabilities during *in vivo* function. The background and various changes introduced within the profession, related to this situation, have been described in detail within two books based on conferences and edited by Wright and Goodman (1996, 2001). Readers are referred to these books for additional information. Most interestingly, one result of "corrective measures" has been to introduce new generations of enhanced cross-linked and other polyethylene biomaterial products.

With some methods, incomplete sterilization or damage to the material by the sterilization process can occur. Certain materials place serious limitations on sterilization conditions. For example, sterilization of poly(methyl methacrylate) (PMMA) intraocular lenses may lead to discoloration. Moreover, such devices cannot be heat sterilized because the shape (and thereby optics) of the rigid PMMA lens would change above the glass transition temperature of the PMMA (100°C). Sterilization by ethylene oxide gas cannot be used with some biomaterials because of solubility within and/or reactivity with the biomaterial. These limitations are sometimes so severe that a sterilization protocol is used that is inadequate to sterilize the device.

Incomplete sterilization, of course, can lead to infection, as exemplified by a cohort of porcine tissue valves that were contaminated with *Myobacterium chelonae*, an organism related to that causing human tuberculosis (Rumisek *et al.*, 1985). It was later appreciated that the antibacterial and antifungal efficacy of low concentrations of glutaraldehyde (with which this tissue was treated) is poor. The use of combined sterilization agents (e.g., alcoholic glutaraldehyde solutions) solved this problem without causing damage to the valve tissue.

PACKAGING, SHIPPING, AND STORAGE

Contamination or degradation not only can occur during fabrication and sterilization of devices, but also can be introduced during packaging and shipping. In all medical devices and implants, inadequate packaging or improper storage can contribute to limited shelf life. Transdermal drug-delivery patches have to be carefully protected so that the drug does not leak out of the device. Tissue-derived heart valves and other devices may be degraded by excessive heat or freezing, and so are packaged with temperature indicators. Packaging and storage are also critical issues for condoms, usually made from natural rubber; this material is sensitive to oxidation, which can degrade the condom during storage on the shelf.

CLINICAL HANDLING AND SURGICAL PROCEDURE

Given an implant made of appropriate materials, properly designed, fabricated, sterilized, tested, manufactured, packaged, shipped, and stored, the “moment of truth” occurs at the instant when the package is opened and the device is handled and implanted or contacted extracorporeally with the patient’s “biosystem.” The most important issues here relate to the possibility of infection due to preimplantation contamination or mechanical damage caused by improper handling by surgical personnel and/or their instruments. Other examples are the exposure of devices to solutions/light-especially UV, contact with towels, starch on gloves, etc.

An example of a technical “error” is the implantation with kinking of a tubular vascular graft, thereby impeding its flow and possibly inducing thrombus.

THE PATIENT/USER

Every device or implant will have a certain “failure rate” based on normal population statistics, even if each one is identical to every other one. Nevertheless, such events can be very unfortunate for the rare patient who encounters such unexpected responses.

Factors related to the particular recipient may cause some failures. A patient can abuse or misuse an implant, or can exhibit an unexpected “abnormal” physiologic response. For example, a hip implant recipient who overexercises before adequate healing has occurred could cause implant loosening. Improper handling of a condom could precipitate a rip or pinhole.

Patients must be matched to their prostheses. For example, since young patients exhibit accelerated calcification of tissue heart valves, such devices are rarely used in them. Moreover, it would not be appropriate to use a mechanical valve (which requires anticoagulation therapy) in a patient with a known bleeding problem, such as a stomach ulcer.

Abnormal responses may be related to hypersensitivity or infection. For example, some patients are allergic (i.e., exhibit hypersensitivity) to nickel or other elements or compounds. Cases are reported in which patients with implants containing nickel had hypersensitive reactions that necessitated removal. Another example is that of implant recipients such as immunosuppressed individuals with cancer or organ transplants who are particularly vulnerable to infection at any site; they may be at high risk to develop implant-related infections. Moreover, “abnormal” or “skewed” physiologic responses may also occur in any large population of patients. For example, some patients have genetic or acquired abnormalities of coagulation that render them particularly vulnerable to thrombosis. They are at heightened thrombotic risk for cardiovascular implant or device therapies (De Stefano, 1996; Girling and de Swiet, 1997).

Failure can also be related to use, independent of patient factors. Interposition grafts linking artery to vein in the arm are often used for the access to the vasculature required by hemodialysis. Use requires frequent puncture by needles. Repetitive puncture can lead to coalescent holes, graft fragmentation, and extensive local hemorrhage.

CONCLUSION

In this chapter, we have described the wide range and diversity of factors that can contribute to the failure of a medical device or implant. It is important to emphasize that inadequate properties or behavior of the biomaterials or designs are not always responsible for failure. “Unexpected,” abnormal physiological responses of a patient due to an implant or treatment with a therapeutic device can be expected. It is up to the biomaterial scientists and engineers to alert and educate the public and their representatives to these possibilities. In this way, the materials scientist or engineer can play a major role in ensuring the success of medical devices and implants.

9.4 CORRELATION, SURFACES AND BIOMATERIALS SCIENCE

Buddy D. Ratner

INTRODUCTION

Physical or chemical measurements that can reliably predict *in vivo* biocompatibility are unavailable for most biomaterials. It would be ideal, when considering a new material for medical applications, to use a spectroscopic technique to measure the properties, and, from that physical measurement, to predict how well the material will work in a particular application. Animal experiments are expensive, are of questionable value for predicting performance in humans, and raise ethical issues (see Chapter 5.5). Human clinical trials are very expensive and also raise ethical issues (Chapter 10.4). Can we predict or prescreen *in vivo* or *in vitro* performance from measurements of surface and other properties? This chapter, addressing correlation, will examine this question, and offer suggestions for future exploration.

Correlations can take many forms. For biomaterials, three possibilities are:

1. Measure specific surface physicochemical properties (for example, contact angle) and correlate that with a biointeraction response such as protein adsorption or blood cell interaction
2. Measure protein adsorption or cell adhesion and predict *in vivo* performance
3. Measure an animal response to materials (for example, blood platelet consumption by the material) and predict clinical performance

This chapter will primarily focus on those correlations that fit within type (1), but the comments made will have relevance to many correlations that can be envisioned for biomaterials.

BIOCOMPATIBILITY AND MEDICAL DEVICE PERFORMANCE

A reexamination of the definition of biocompatibility, briefly presented in the Introduction chapter (i) of this textbook, is appropriate at this point.

Biocompatibility is the ability of a material to perform with an appropriate host response in a specific application (Williams, 1987).

The “biocompatibility” of a medical device can be defined in terms of the success of that device in fulfilling its intended function. Thus, the blood filtration module of a hemodialysis system might be defined by its ability to appropriately fractionate soluble blood components, its robustness over its intended lifetime, and its nondamaging interaction with the patient’s blood. Alternatively, we can define a “blood compatibility” for the membrane, a “blood compatibility” for the silicone rubber header, a “blood compatibility” for the tubing, and a “blood and soft-tissue compatibility” for the percutaneous connection between the apparatus and the patient’s bloodstream. Similarly, for a hip-joint prosthesis, we can discuss the fatigue resistance of the device, the corrosion resistance of the device, the distribution of stresses transferred to the bone by the device, the solid angle of mobility provided, and the overall success of the device in restoring a patient to an ambulatory state. Again, the hip-joint prosthesis performance might also be couched in terms of the tissue reaction to the bone cement, the tissue reaction to an uncemented titanium prosthesis stem, and the tissue reaction to the acetabular cup. In both of these examples, two cases are offered: in the first case, a whole system (device) performance is assessed, and in the second case, the biological reaction to specific components of the device (the biomaterials) is examined. The difference between the consideration of the whole device and the materials that compose it is a critically important point. In certain contexts, only the performance of the complete device is defined as biocompatibility. This definition can be inferred from the U.S. Food and Drug Administration policy that only complete devices, and never materials, receive “approval.” The performance of the individual materials is referred to sometimes as “biocompatibility” and sometimes as “bioreaction” or “bioresponse.”

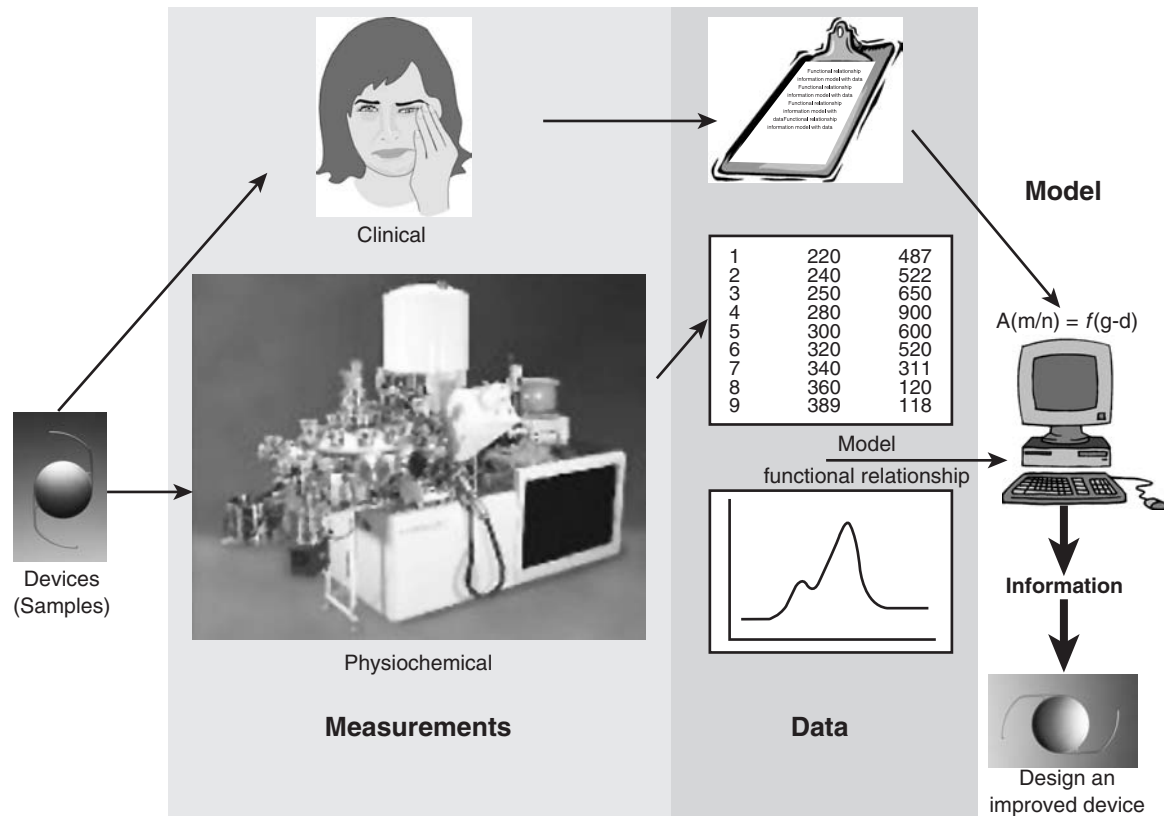

FIG. 1. Clinical and physicochemical data are converted to useful information to optimize the performance of an implant device.

This is a textbook on biomaterials, so it would be appropriate to focus on the materials. “Bioreaction” is a much simpler word than “biocompatible,” and this term will largely be used here. Bioreaction will be discussed here and defined by example.

Toxicology assays, often inappropriately referred to as biocompatibility assessment, were presented in Chapter 5.2. These assays deal with measurement of substances that leach from materials, most of which will induce some cell or tissue reaction. Such assays will be discussed here because the published correlations are clear, interpretable, and measurable. If we concentrate on bioreactions to implanted materials that do not intentionally leach substances (i.e., most biomaterials), the surface properties immediately assume a high profile as the prime candidate to control bioreaction. However, hardness, porosity, shape, movement, and specific implant site are also important. These issues will be addressed in working through important concepts in correlating material properties to bioreaction.

DATA, INFORMATION, AND STATISTICS

Laboratory experiments lead to the acquisition of data from the testing of the properties (biological and physical) of implant materials. Frequently we are presented with a column of numbers or a plot. Staring at these numbers or plots is often unhelpful in understanding the system under study. What we really desire is not *data*, but *information*, about our system.

This idea is illustrated in Fig. 1, proposing how clinical performance data and physicochemical measurement data might lead to the development of an improved implant device. Correlation is one way to process data so that it yields information.

Correlation is a tool in a class of methods called statistics that are useful for analyzing data so as to appreciate its variance, significance, and interrelationships. A general introduction to statistics is not presented here, but every student of biomaterials science should be versed in these mathematical tools. A few useful, general books on statistics as applied to scientific problems are Bevington and Robinson (2002), Mosteller and Tukey (1977), and Anderson and Sclove (1986). A book that can be useful in interpreting the meaning of statistics is Huck (2000). A search of Amazon.com found more than 4500 books on statistics and probability.

CORRELATION

Correlation is a relationship between two or more variables. Correlation does not necessarily mean cause and effect. For example, most people walking with open umbrellas will have wet feet. But, in this situation, it is obvious that umbrellas do not cause wet feet. We have a high correlation, but it misses the controlling factor (causative factor) in this example—the rain. Thus, we can propose that A (the umbrella) causes B (wet feet), B causes A, they cause each other, or they are

both caused by C (the rain). We cannot prove causation, but it can be strongly suggested. Often, where correlations are observed, the causative factor is obscured, and so we have data but little useful information. Where relationships are established between a dependent variable and an independent (or explanatory) variable, this is referred to as regression analysis.

It may be more productive to look at this problem in terms of calibration and prediction. Calibration in a practical (e.g., analytical) sense has been defined by Martens and Naes as the use of empirical data and prior knowledge for determining how to predict unknown quantitative information Y from available measurements X, via some mathematical transfer function (Martens and Naes, 1989). This could be as simple as plotting Y versus X and using a least-squares fit to deal with modest levels of random noise, or as complex as a multivariate calibration model to accommodate noisy data, interferences, multiple causes, nonlinearities, and outliers. Multivariate methods will be elaborated upon toward the end of this chapter.

ASPECTS OF THE BIOREACTION TO BIOMATERIALS

Bioreaction, a process related to, but more general than, “biocompatibility,” can have many manifestations. Some of these are listed in Table 1. A bioreaction is most simply defined as an observed response upon interaction of a material with a biological system or system containing biomolecules. Can simple measured physical properties of materials be correlated with bioreactions? There are many examples where this is indeed the case. Table 2 lists some of the surface physical measurements for materials that one might hypothesize as influencing bioreaction or biocompatibility.

THE CASE FOR CORRELATION—A BRIEF REVIEW OF THE LITERATURE

In the 1970s and 1980s there was great enthusiasm about using correlation to predict biomaterial performance. The lessons learned have provided insights and also tempered that

TABLE 1 Some Bioreactions

Protein adsorption	Macrophage adhesion
Protein retention	Neutrophil attachment
Lipid adsorption	Cell spreading
Bacterial adhesion	Phagocytosis
Platelet adhesion	Biodegradation
Hemolysis	Angiogenesis
Platelet activation	Apoptosis
Expression of genes	m-RNA production
Cytokine release	Fibrous encapsulation

Note: these reactions are commonly observed with implant materials. However, their relationship to “biocompatibility” is not direct.

TABLE 2 Physical Parameters of Biomaterial Surfaces That Might Correlate with Bioreactivity

Wettability	Subsurface features
Hydrophilic/hydrophobic	Distribution of functional groups
Polar/dispersive	Receptor sites
Surface chemistry	Modulus
Specific functional groups	Hydrogel (swelling) character
Surface electrical properties	Mobility
Roughness/porosity	Adventitious contamination
Domains (patterns) of chemistry	Trace levels of functional groups

enthusiasm. Still, papers continue to explore correlation and few modern efforts will be described here.

An early and influential paper demonstrating that physical measurements might be correlated with observed reactions to biomaterials concerned extractable from biomaterials (Homsy, 1970). Many biomaterials were examined in this study. Each was extracted in a pseudoextracellular fluid. The extract was examined by infrared absorbance spectroscopy for hydrocarbon bands that are indicative of organic compounds. A strong, positive correlation was observed between the strength of the IR absorbances and the reaction of the materials with a primary tissue culture of newborn mouse heart cells. This paper was important in scientifically justifying *in vitro* cell culture analysis for screening the toxicology of biomaterials, and for developing the principle that biomaterials should not unintentionally leach substances.

In the late 1960s, Robert Baier and colleagues offered an intriguing hypothesis concerning surface properties and bioreaction that continues to stimulate new experiments (Baier, 1972). This hypothesis is based upon interfacial energetics of surfaces as approximated from contact-angle measurements and suggests that materials with critical surface tensions (see Chapter 1.4) of approximately 22 dyn/cm would exhibit minimum bioreactivity (Fig. 2). Support for this hypothesis has been

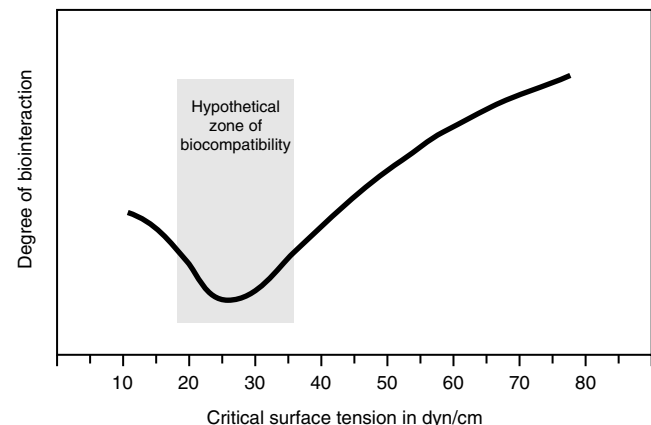

FIG. 2. A hypothesis for a minimum biointeraction for surfaces with critical surface tensions around 22 dyn/cm.

generated in a number of experiments spanning many different types of biointeractions (Baier *et al.*, 1985; Dexter, 1979). However, in a larger number of cases, this minimum has not been observed raising questions about the generality of this concept (Neumann *et al.*, 1979; Yasuda *et al.*, 1978; Mohandas *et al.*, 1974; Lyman *et al.*, 1970; Chang *et al.*, 1977).

Some of the clearest biointeraction correlations have been observed in simple, nonproteinaceous media. Linear trends of cell (mammalian and bacterial) adhesion versus various measures of surface energy have been noted (Chang *et al.*, 1977; Neumann *et al.*, 1979; Yasuda *et al.*, 1978; Mohandas *et al.*, 1974). For example, Chang and co-workers (1977) found that the adhesion of washed pig platelets to solid substrates increased with increasing water contact angle, a parameter that generally correlates well with solid surface tension. It is interesting that these simple linear trends often vanish or diminish if protein is present in the attachment medium (Neumann *et al.*, 1979; Chang *et al.*, 1977; van der Valk *et al.*, 1983). More complex surface energetic parameters have also been explored to correlate biointeraction to surface properties (Kaelble and Moacanin, 1977).

Correlations between material properties and long-term events upon implantation are less frequently seen in the literature. However, some important examples have been published. The baboon A-V shunt model of arterial thrombosis has yielded a number of intriguing correlations (Harker and Hanson, 1979). Using an *ex vivo* femoral-femoral shunt, this model measures a first-order rate constant of platelet destruction induced by the shunt material (the units are platelets destroyed/cm²·day). The values for this surface reactivity parameter are independent of flow rate (after the flow rate is sufficiently high to ensure kinetically limited reaction), length of time that the reaction is observed, blood platelet count, and surface area of the material in contact with the blood. In one experiment, a series of hydrogels grafted to the luminal surfaces of 0.25-cm i.d. tubes was studied (Hanson *et al.*, 1980). The platelet consumption (see Chapter 5.4) was found to increase in a simple, linear fashion with the equilibrium water content of the hydrogels. This correlation, illustrated in Fig. 3, is particularly intriguing because the hydrogel materials studied were amide-, carboxylic acid-, and hydroxyl-based.

FIG. 3. A correlation between baboon platelet consumption as measured in an *ex vivo* shunt system and hydrogel water content. (From Hanson *et al.*, 1980.)

The only clear, correlating parameter was equilibrium water content. In another study, the platelet consumption of a series of polyurethanes was observed to decrease in a linear fashion as the fraction of the polyurethane C1s ESCA surface spectrum that was indicative of hydrocarbon moieties increased (Hanson *et al.*, 1982).

There have been many attempts to correlate specific protein adsorption with biological reaction. A 1975 study showed that the number of platelets adsorbed to polyurethanes correlated inversely with the amount of albumin adsorbed in competition with fibrinogen and IgG (Lyman *et al.*, 1975). For a series of polyurethanes, platelet attachment was shown to correlate with the amount of fibrinogen adsorbed (Chinn *et al.*, 1991). However, two surprising outlier points could not be explained—two materials that adsorbed high fibrinogen levels adhered low levels of platelets. Bailly *et al.* (1996) used a direct ELISA method to measure adsorbed fibrinogen on catheters and found that *in vitro* platelet adhesion and *in vivo* catheter thrombogenicity correlated with amount of adsorbed fibrinogen. Hu *et al.* (2001) have isolated specific domains within fibrinogen that help to explain their observation that the level of adsorbed fibrinogen correlates with the magnitude of the foreign body reaction at short (~3 day) implantation times. These studies all implicate levels of adsorbed fibrinogen with complex biological reactions.

A material parameter that lends itself to correlation is roughness or surface texture. Roughness is readily measured using a scanning electron microscope, a profilometer, or an atomic force microscope (see Chapter 1.4). Relationships between roughness and blood hemolysis (Wielogorski *et al.*, 1976) or thrombogenicity (Hecker and Scandrett, 1985) were reported. Textures and roughness are also extremely important to the fixation of materials into hard tissue and to the nature of the foreign-body response observed (Brauker *et al.*, 1992; Thomas and Cook, 1985; Schmidt and von Recum, 1991) (see Chapter 2.15). A complication in the use of the roughness parameters is differentiation between porosity and roughness, and also an appreciation of the difference between the average feature amplitude (often called R_a) and the nature of the roughness (e.g., are rolling hills and jagged rocks of the same height also the same roughness? See Fig. 4).

Clinical results correlated with material properties are rare, in part because materials used in clinical studies are generally not characterized to measure the parameters appropriate to make such correlations. However, a few such studies have been published. In the 1970s, a contact-angle measurement criterion was established for qualifying the clinical success of processed umbilical cord vascular grafts (Shapiro *et al.*, 1978). In another, example, rigid gas-permeable contact lens wettability was correlated with subject discomfort and a predictive trend was noted (Bourassa and Benjamin, 1989). Catheters that are used in humans were evaluated in a test system closely simulating clinical application (Wilner *et al.*, 1978). Catheters were classified into three groups related to their probable success, but clear relationships to surface properties were not discerned. Studies by Bailly *et al.* (1996) were more successful at establishing relationships between catheter properties and *in vivo* thrombogenicity. The complications in performing control studies, the difficulties in assembling a sufficiently large experimental

FIG. 4. Four very different surfaces with similar average roughnesses (R_a).

population, and the complexity of the materials (devices) and the human biology make clinical correlation challenging.

ISSUES COMPLICATING SIMPLE CORRELATION

Correlations should allow us to take many readily measured physical properties and use that information in the design of improved biomaterials. Though many studies suggesting interesting possibilities are cited here, this textbook does not present these correlations as rules that can be used in biomaterials design. It should be clear by now that, although many correlations have been noted, there is considerable contradictory evidence about what the correlating factors are, and the nature of the correlations. Also, in many systems, no obvious correlations have been noted.

The most widely used correlating factor has been surface energetics, possibly because contact angles can be readily measured in any laboratory. Surface energetic parameters all relate back to the second law of thermodynamics and it is well established that the interactions of simple colloid particles can be modeled using thermodynamic and electrostatic arguments. If living cells are treated as simple colloid particles with fixed mass, charge density, polar forces, and hydrophobic interactions, thermodynamic (energetic) modeling may be appropriate (Gerson and Scheer, 1980; Fletcher and Pringle, 1985). However, living cells most often cannot be viewed as “hard, charged spheres.” Living cells can change their surface characteristics in response to surfaces and other stimuli. Also, specific (e.g., receptor) interactions do not lend themselves to this simple thermodynamic modeling. For example, two surfaces with similar (but not the same) immobilized oligopeptides, and hence essentially the same surface energy, may interact very differently with cells, if one of the oligopeptides represents a minimal recognized sequence for the cell surface receptor. This was observed with fibroblast cell attachment where an immobilized peptide containing an RGD unit (arginine-glycine-aspartic acid) and a closely related immobilized peptide containing an RGE segment (where the E indicates

glutamic acid) were compared (Massia and Hubbell, 1990). The RGD peptide was highly active in inducing cell spreading while the RGE peptide was not (see Chapter 2.16 for details on this experiment). Finally, the nature of the correlations may be multivariate rather than univariate. This concept will now be discussed.

MULTIVARIATE CORRELATION

We are trained throughout our science education to appreciate cause-and-effect correlations. For example, if the temperature of a solution is increased, the reaction rate of two reactants in the solution will increase in some relatively simple manner. Unfortunately, many systems, particularly multicomponent systems such as are so often found in biomaterials science, have competing reactions that are dependent upon each other (e.g., the product of one reaction may influence the rate of another reaction). Thus, we do not see a simple relationship, but rather, many things changing simultaneously. Our eye cannot discriminate the key trend(s) in this “stew” of changing numeric values. Multivariate statistics is a class of statistical methods that looks for trends, patterns, and relationships among many variables. Also, where contemporary analytical instrumentation produces large amounts of complex (e.g. spectral) data, multivariate statistics can assist in examining the data for similarities, differences, and trends. Where large data sets overload our ability to discern relationships, multivariate methods thrive on large amounts of data and, in fact, become more accurate and useful. This class of statistical methods has come into its own only with the introduction of powerful computers since the methods are computation-intensive. Many general introductions to multivariate statistics are available (Martens and Naes, 1989; Sharaf *et al.*, 1986; Brereton, 2003; Massart *et al.*, 1988, Wickens, 1995). Multivariate statistics applied to problems involving chemistry is often referred to as “chemometrics.”

An important general principle in multivariate analysis is dimensionality reduction. A plot of x versus y requires us to

think in two dimension. A "3D" plot of x , y , and z can still be easily visualized. Where we have w , x , y , and z as the axes, we lose the ability to absorb the information in graphical form and assign trends to the data. However, if we take our 3D example, we can visualize a projection (shadow) of the 3D data cluster in two dimensions. We have reduced the dimensionality from 3 to 2. Similarly, our 4D data set can be projected (by a computer) into a 3D space. Thus we have a data representation we can visualize in order to look for trends. This dimensionality reduction is readily performed by computers using standard linear algebra methods. The number of dimensions that the computer can work with is, for all practical purposes, unlimited.

There are many multivariate statistical algorithms useful for analyzing data. They are sometimes divided into classification methods (also called cluster analysis methods) and factor analysis methods (Mellinger, 1987). Classification methods find similarities in groups of data points and arrange them accordingly. Factor analysis methods take data and transform them into new "factors" that are linear combinations of the original data. In this way the dimensionality of the problem is reduced. Factor analysis methods useful for multivariate correlation with data sets such as are acquired in biomaterials research include principal component analysis (PCA) (Wold *et al.*, 1987) and partial least squares (PLS) regression (Geladi and Kowalski, 1986). Two important points about these methods are that they do not require a hard model (rarely do we have such a quantitative model) and that they make use of all the data (i.e., we do not have to choose which data we want to put into the correlation model). Examples of the application of these methods to biomaterials research are increasing (Perez-Luna *et al.*, 1994; Wojciechowski and Brash, 1993). The power of these statistical methods is being recognized, and they will become standard data analysis tools. This is because they make efficient use of all data, thrive on large amounts of data produced by modern instruments, are objective in that we do not have to choose which data to use, are congruent with biomaterials studies that typically have many interrelated variables, and reduce the influence of noise and irrelevant variables thereby effectively increasing the signal-to-noise ratio.

Multivariate statistical methods can be a great boon to data analysis, but they will not solve all problems in biomaterials science. They should be considered as powerful hypothesis generators. The correlations and trends noted using such analysis represent a new view of the significance of data that we cannot appreciate by staring at spectra or tables. New hypotheses about the importance of materials variables can be formulated, and then they must be tested. Multivariate statistical methods also provide powerful tools for experimental design, but these will not be discussed here.

CONCLUSIONS

Perhaps the reader expected this chapter to provide instruction on the importance of wettability, or roughness, or carboxyl group concentration for biological reaction? Unfortunately, biomaterials science is not yet at the state where we can assemble a handbook of design data about the relationships between surface structures and biological reactions. We do not yet

understand the controlling variables from the biology or even the materials science sufficiently well to generalize many of our observations. What this chapter does do is to suggest that such relationships probably exist, and to point out that there are powerful mathematical methods that have the potential to help us generalize our data into correlations and trends useful in biomaterials and medical device design.

9.5 IMPLANT RETRIEVAL AND EVALUATION

James M. Anderson, Frederick J. Schoen, Stanley A. Brown, and Katharine Merritt

Implant retrieval and evaluation offers the opportunity to investigate and study the intended use of biomaterials *in vivo*. Implant retrieval and evaluation programs, in general, are designed to determine the efficacy and safety or biocompatibility of biomaterials, prostheses, and medical devices. The goal of safety testing is to determine if a biomaterial presents potential harm to the patient; it evaluates the interaction of the biomaterial with the *in vivo* environment and determines the effect of the host on the implant. Biocompatibility assessment is the determination of the ability of a biomaterial to perform with an appropriate host response in a specific application. In the *in vivo* environment, biocompatibility assessment is considered to be a measure of the degree and extent of adverse alteration(s) in homeostatic mechanism(s).

In this chapter, implant retrieval and evaluation are considered from the perspective of ultimate human clinical use. Therefore, this chapter draws upon many important perspectives presented in chapters dealing with materials science and engineering, biology, biochemistry, and medicine, host reactions and their evaluation, the testing of biomaterials, the degradation of materials in the biological environment, the application of materials in medicine and dentistry, the surgical perspective of implantation, the correlation of material surface properties with biological responses of biomaterials, and failure analysis. Although this chapter focuses on implant retrieval and evaluation in the clinical environment, many of the goals and perspectives presented are important to preclinical (i.e., animal) investigation. Emphasis will be on the rationale and overall contributions of hypothesis-driven explant analysis applicable to failed as well as nonfailed and, in some situations, unimplanted devices. In this chapter, implants are considered to be composed of one or more biomaterials that are part of

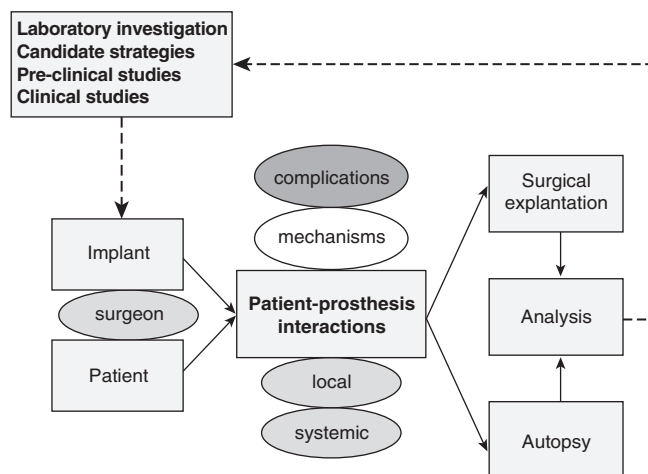

FIG. 1. Role of implant retrieval and evaluation in the development and use of clinical devices.

a specific design for a specific application. For these purposes, implants are prostheses, medical devices, or artificial organs.

GOALS

The general concept of implant retrieval that will guide our further discussion is presented in Fig. 1. An implant is placed in a patient by a surgeon. The potential impact of the surgeon (device selection, implantation technique, and implant manipulation, for example) on success or failure has major implications and constitutes a key difference between drugs and devices. All implants have interaction of the constituent biomaterials with the surrounding tissues. These interactions may be local at the site of implantation or distant from the device, and their mechanisms may be elucidated by careful and appropriate study. Clinically important deleterious biomaterials–tissue interactions manifest as *complications*. Implants are retrieved after successful function or failure by either surgical removal (at reoperation) or autopsy (by permission obtained after the patient's death). The information derived from implant retrieval and evaluation is frequently used to guide development of new and modification of existing implant designs and materials, to assist in decisions of implant selection, and to otherwise alter the management of patients (such as anticoagulation drug regimens for prosthetic heart valves, or activity limitations for patients with prosthetic joints).

The general goals of retrieved implant evaluation are presented in Table 1. While many implant failures can be characterized as implant- or material-dependent or clinically or biologically dependent, many modes and mechanisms of failure are dependent on both implant and biological factors. To appropriately appreciate the dynamics and temporal variations of tissue–materials and blood–materials interactions of implants, a fundamental understanding of these interactions is important. An implant retrieval and evaluation program should elucidate materials, design, and biological factors in implant performance and enhance design criteria for future development. Finally, implant retrieval and evaluation should

TABLE 1 General Goals of Implant Retrieval and Evaluation

Determine rates, modes, and mechanisms of implant failure
Identify effects of patient and prosthesis factors on performance
Establish factors that promote implant success
Determine dynamics, temporal variations, and mechanisms of tissue–materials and blood–materials interactions
Develop design criteria for future implants
Determine adequacy and appropriateness of animal models

offer the opportunity to determine the adequacy and appropriateness of animal models used in preclinical testing of implants and biomaterials. Thus, the strengths and weaknesses as well as the advantages and disadvantages of animal models can be evaluated.

The goals of routine hospital surgical pathology or autopsy examination of a prosthetic device are generally restricted to documentation of the removal of a specific device at reoperation or that the patient has died with, and diagnosis of a clinical abnormality that required therapeutic intervention. Detailed correlation of morphologic features with clinical signs, symptoms, and dysfunctional physiology is usually not performed. However, directed and informed pathological examination of prostheses retrieved during preclinical animal studies or at reoperation or autopsy of human patients can provide valuable additional information. First, preclinical studies of modified designs and materials are crucial to developmental advances. These investigations usually include implantation of functional devices in the intended location in an appropriate animal model, followed by noninvasive and invasive monitoring, followed by specimen explantation, and detailed pathological and material analysis. Second, for individual patients, demonstration of a propensity toward certain complications could have great impact on further management. Third, clinicopathologic analysis of cohorts of patients who have received a new or modified prosthesis type evaluates device safety and efficacy to an extent beyond that obtainable by either *in vitro* tests of durability and biocompatibility or preclinical investigations of implant configurations in large animals. Moreover, through analysis of rates and modes of failure as well as characterization of the morphology and mechanisms of specific failure modes in patients with implanted medical devices, retrieval studies can contribute to the development of methods for enhanced clinical recognition of failures. The information gained should serve to guide both future development of improved prosthetic devices to eliminate complications and diagnostic and therapeutic management strategies to reduce the frequency and clinical impact of complications. Emphasis is usually directed toward failed implants; however, careful and sophisticated analysis of removed prostheses that are functioning properly is also needed. Indeed, detailed analyses of implant structural features prior to and their evolution following implantation can yield an understanding of structural correlates of favorable performance and identify predisposition to specific failure modes, which can be extremely valuable.

Device retrieval analysis has an important regulatory role, as specified in the Safe Medical Devices Act of 1990 (PL101-629), the first major amendment to the Federal Food, Drug and Cosmetics Act since the Medical Device Amendments of 1976. The user requirements of the 1990 legislation require health-care personnel and hospitals to report (within 10 days) to the Food and Drug Administration (FDA) or manufacturers or both (depending on the nature of the occurrence) all prosthesis-associated complications that cause death, serious illness, or injury. Such incidents are often discovered during a pathologist's diagnostic evaluation of an implant in the autopsy suite or the surgical pathology laboratory.

Implant retrieval and evaluation programs may also provide specimens and data that serve as a teaching or research resource. The information gained can be used to educate patients, their families, physicians, residents, students, engineers, and materials scientists, as well as the general public. As a research resource, implant retrieval and evaluation yields data that can be used to develop and test hypotheses and to improve protocols and techniques.

COMPONENTS OF IMPLANT RETRIEVAL AND EVALUATION

Implant retrieval and evaluation is an interdisciplinary effort by scientists with expertise in materials science, materials engineering, biomechanics, biology, pathology, microbiology, radiology, medicine, and surgery. Table 2 lists the important components of such a program. Given these components, the importance of an interdisciplinary or team perspective is apparent.

The first component is the appropriate accessioning, cataloging, and identification of retrieved implants. Patient anonymity is required in any implant retrieval and evaluation program and this can be achieved through appropriate accessioning cataloging, coding of demographic information, and restriction of access. As is typical at many institutions, retrieval at University Hospitals of Cleveland/Case Western Reserve

TABLE 2 Important Components and Features of an Implant Retrieval and Evaluation Program

Entire activity is hypothesis-driven
Specimens are appropriately accessioned, cataloged, and identified
Known and potential failure modes are considered
Patient's medical history and laboratory results are reviewed
Data are collected on well-designed, study-specific forms
Careful gross examination, photography, and other basic analyses are always done
Advanced analytical techniques done by specialists are considered
Analytical protocols and techniques for assessing host and implant responses are rigorously followed
Correlations and cause-and-effect relationships among material, design, mechanical, manufacturing, clinical, and biological variables are sought
Quantitative data are collected wherever possible and appropriate
Statistical and multivariate analyses are used

University is carried out through the Surgical Pathology and Autopsy Divisions of the Institute of Pathology (see Table 3).

This program uses the general accessioning and cataloging scheme for surgical pathology specimens. Gross and microscopic diagnoses in a standardized format are provided for patients' charts, for the appropriate clinicians and surgeons, and for the database for Implant Retrieval and Evaluation Program. The Department of Surgery provides specimens to the Division of Surgical Pathology, with the patient's name and hospital identification number, clinical diagnoses, and notes on the patient and/or implant history.

As can be seen from Table 3, the number of types of implants retrieved is large and covers the orthopedic, cardiovascular, gynecological, and soft-tissue areas. Second, the number of

retrieved implants of each type has increased over the past decade. Several factors are responsible for this. They include increased recognition by surgeons of the importance of implant retrieval and evaluation as well as the increased numbers of implants.

An in-depth evaluation of a retrieved implant requires a review of the patient's medical history and radiographs, where pertinent. Table 4 provides a partial list of conditions that may influence the failure or success of orthopedic and cardiovascular implants. The identification of acute and chronic problems presented by the patient will provide guidance on how the evaluation of a specific implant should be carried out. For example, a clinical diagnosis of infection necessitates that certain techniques should be used in the evaluation. In addition, gross examination and photography play an important role and must be carried out before specific techniques are used to evaluate implants.

It is critical to use a strategy that will allow optimal information yield using appropriate analytical protocols and techniques to assess host and implant responses. This strategy is directed toward developing correlative and cause-and-effect relationships among material, design, mechanical, manufacturing, clinical, and biological variables. Finally, whenever possible, analytical protocols and techniques should produce quantitative information that can be analyzed statistically. These analyses may also include clinical information.

Procedures used to evaluate devices and prostheses after function in animals and humans are largely the same. However, subject to humane treatment considerations, enumerated in institutional and National Institutes of Health (NIH) guidelines that enforce the Federal Animal Welfare Act of 1992, animal studies permit more detailed monitoring of device function and enhanced observation of morphologic detail (including blood-tissue-biomaterials interaction), as well as frequent assay of laboratory parameters (such as indices of platelet function or coagulation), and allow *in situ* observation of fresh implants following elective sacrifice at desired intervals. In addition,

specimens from experimental animals can often be obtained rapidly, thereby minimizing the autolytic changes that occur when tissues are removed from their blood supply. Furthermore, advantageous technical adjuncts may be available in animal but not human investigations, including *in vivo* studies, such as injection of radiolabeled ligands for imaging platelet deposition, fixation by pressure perfusion that maintains tissues and cells in their physiological configuration following removal, and injection of various substances that serve as informative markers during analysis (such as indicators of endothelial barrier integrity). Animal studies often facilitate observation of specific complications in an accelerated time frame, such as calcification of bioprosthetic valves, in which the equivalent of 5–10 years in humans is simulated in 4–6 months in sheep. Moreover, in preclinical studies, experimental conditions can be held constant among groups of subjects, including nutrition, activity levels, and treatment conditions. Consequently, concurrent control implants, in which only a single critical parameter varies, are often available in animal but not human studies.

Most implant retrieval involves examination of failed implants that have been surgically removed from patients or have been encountered at autopsy. Nevertheless, critical information can accrue from examination of "successful" implants removed after either fulfilling their function (e.g., a bone fixation device) or death of the patient resulting from an unrelated cause (e.g., a heart valve prosthesis in a patient who dies of cancer). However, such studies may present difficulties, including but not limited to access to the anatomic site, timing of the explantation following excessive postmortem interval, and family permission (Jacobs *et al.*, 1999).

APPROACH TO ASSESSMENT OF HOST AND IMPLANT RESPONSES

Evaluation of the implant without attention to the tissue will produce an incomplete evaluation and no understanding of the host response. Table 5 provides a partial list of techniques for evaluating implants and tissues. We anticipate that novel implants and materials may dictate further techniques to be used in evaluating host-biomaterials interactions and new analytical techniques will likely be developed.

In general, analytical protocols and techniques for assessing host and implant responses can be divided into two categories: nondestructive and destructive testing procedures. Only after appropriate accessioning, cataloging and identification, and complete review of the patient's medical history and radiography can the analytical protocols and techniques for implant evaluation be specified.

It should be noted that the techniques for implant evaluation are most commonly destructive techniques, that is, the implant or portions of the implant must be destroyed or altered to obtain the desired information on the properties of the implant or material. The availability of the implant and tissue specimens will dictate the choice of technique.

Detailed analysis of the implant-tissue interface often necessitates that both a piece of tissue and a piece of the implant which it contacts be sectioned and examined in continuity

(i.e., as one unit). This generally precludes any other analysis of that specimen. Similarly, chemical analysis of a piece of tissue for metal ion concentration requires acid digestion and thus precludes morphological analysis. Thus, consideration must be given to either selection of multiple specimens or division of a specimen before processing in order to permit part to be used for morphological and part for chemical analyses. Each of these portions may need to be further subdivided to be processed according to the requirements of specific tests. Moreover, since many of the procedures include cutting or sectioning a portion of the retrieved device, one must consider the legal aspects of device ownership and destruction of what may become evidence in a court of law. Strict institutional guidelines need to be adhered to, and permission for use of destructive methods may be necessary. For clinicopathologic correlation studies that involve utilization of both patient data and pathological findings, approval of the local institutional review board (IRB) is required. This is largely to ensure that the confidentiality and other interests of the patients from whom the implants were removed will be maintained, especially for purposes of publication or other dissemination of information.

Special Technical Problems of Bone and Calcified Tissue

Evaluation of an implant and the surrounding host tissue when the implant was placed into bone, bone has formed around it, local tissue has calcified, or teeth presently pose unique problems. Dental implants and orthopedic implants are usually associated with hard tissue, but other implants may have contact with calcified tissue. Material containing calcified tissue, bone, or teeth should be identified before the laboratory begins processing it or there may be harm to some of the equipment used for sectioning soft tissue. In addition some consensus standards, such as ASTM F561 and ISO/FDIS 12891-1 have been developed that address the special issues. Bone is a dynamic tissue and analysis of bone formation and bone resorption may be a critical part of the study. Selection of techniques for evaluation must be undertaken carefully. Consideration needs to be given to what questions are being addressed before anything is cut or any harsh solutions are used.

If the implant and tissue are handled correctly, the techniques listed in Table 5 are applicable to the study of hard tissue and associated implants. As stated earlier, some techniques are mutually exclusive. For example, histologic analysis of particle size and quantity and chemical digestion and analysis for metal ions cannot be done on the same sample.

Following routine fixation to preserve cellular detail, either of two generic approaches may be taken with implants adjacent to hard tissue: preparation of undecalcified sections or decalcification prior to embedding. Fully decalcified bone can be embedded and sectioned using methods common to soft-tissue pathology. To prepare undecalcified sections, hard tissue and the associated implant component or section are dehydrated and embedded in a hard plastic (usually methyl methacrylate)

TABLE 5 Techniques for Implant Evaluation

Implant	Tissue

and thick (approximately 500 μm) sections are cut with a diamond saw and ground down to form the final thin section (approximately 50 μm). The advantage of undecalcified sections is that areas of mineralization and newly formed bone can be clearly distinguished from soft tissue. Specimen X-rays can also be taken to identify sites and extent of mineralization. Assistance with techniques for evaluation of specimens containing bone is available from the Society of Histotechnology (Callis and Sterchi, 1998; McNeil *et al.*, 1997; Sanderson and Bachus, 1997).

Other Special Issues

Because implant retrieval programs may obtain data that will be used in regulatory or litigation procedures, it is important to document the disposition and appearance of the tissue and of the implant at each stage in the evaluation. Ample use of photography will greatly help in the description of the tissue and implant condition at each step of analysis. Careful labeling that is recorded during photography is helpful in later review of the evaluation procedure.

Concerns relative to the safety of laboratory personnel arise in the examination of retrieved materials. If the device and/or tissues arrive in the laboratory without having been adequately disinfected or treated, special precautions need to be observed with the use of barrier clothing and gloves and the use of biosafety cabinets. All safety regulations of the institution need to be known and followed. Procedures for disposal of hazardous chemicals also need to be carefully observed. If untreated devices or tissues are to be packaged and shipped from the clinical setting to the laboratory, care must be taken to follow the rules and regulations of the shipping agency and the Department of Transportation for transportation of biohazardous material.

An additional and very complex matter relates to implant ownership (Beyleveld *et al.*, 1995). Several parties may have (and claim) rights to possession of a removed device under various circumstances: the patient, the surgeon, the pathologist, the hospital, an entity such as an insurance company, and attorneys representing both the plaintiff and the defendant in product liability or malpractice litigation. Moreover, ownership may not automatically entail the right to test. These issues are both controversial and unresolved.

The Multilevel Strategy to Implant Evaluation

Implant retrieval and analysis protocols often utilize a multilevel approach along the spectrum of essential documentation to the use of sophisticated research tools. Some investigators have advocated a basic two-level approach (Table 6). Level I studies include routine evaluation modalities capable of being

TABLE 6 Study Prioritization

Level I studies
Gross dissection
Photographic documentation
Microbiologic cultures
Radiography
Light microscopic histopathology
Level II studies
Scanning electron microscopy
Transmission electron microscopy
Energy dispersive X-ray microanalysis (EDXA)
Analysis of adsorbed and absorbed proteins
Mechanical properties measurement
Materials surface analysis
Leukocyte immunophenotypic studies
Molecular analyses for cellular gene expression

done in virtually any laboratory, and that characterize the overall safety and efficacy of a device. Level II studies comprise well-defined and meaningful test methods that are difficult, time-consuming, or expensive to perform, require special expertise, or yield more investigative or esoteric data. Since some level II analyses may be mutually exclusive, some material might routinely need to be accessioned, set aside (during level I analyses) and prepared for more specialized level II studies, in the event that they should be indicated later. Level II evaluation is usually undertaken with specific investigative objectives directed toward a focused research question or project. Prioritized, practical approaches using these guidelines have been described for heart valves, cardiac assist devices and artificial hearts, and other cardiovascular devices (Schoen *et al.*, 1990; Schoen, 1995; Borovetz, 1995; Schoen, 2001; Schwartz *et al.*, 2002).

Both ASTM and ISO implant retrieval standards (F561 and ISO 12891, respectively) have utilized a three-stage approach to implant analysis. Stage I analysis consists of routine device identification and description. Stage II is more detailed, time-consuming, and expensive and includes photography and non-destructive failure analysis. Since stage I and II protocols are the same for all material types, they are combined in F561. Stage III protocols include destructive analytical techniques, many of which are specific to particular material types, and thus separate guidelines are provided for metallic, polymeric, and ceramic materials. Combinations of these protocols provide guidelines for analysis of the various components of composites and tissue engineered materials.

THE ROLE OF IMPLANT RETRIEVAL IN DEVICE DEVELOPMENT

For implants placed into many anatomic sites, prosthesis-associated pathology is a major determinant of quality of life and prognosis of patients. Implant retrieval and evaluation plays a critical role in the evolution of medical devices through development and clinical use (Fig. 1). Implants are examined as (1) fabricated but unimplanted prototypes, to reveal changes in device components induced by the fabrication process that can predict (or lead to an understanding of) failure modes observed subsequently; (2) specimens that have been subjected to *in vitro* tests of biocompatibility or durability; (3) specimens removed from animal models following *in vivo* function, usually as actual devices; (4) specimens that accrue in carefully controlled clinical trials; and (5) failed or functioning specimens that are explanted in the course of ongoing surveillance of general clinical use of a device. In each case, implant retrieval is concerned with the documentation of device safety and efficacy and problems that dictate modification of design, materials, or use of the implants in patients (e.g., patient-device matching or patient management). Devices are explanted and analyzed with attention directed toward all complications, but especially those that may be considered special vulnerabilities engendered by the device type. Efforts are made to retrieve and evaluate as many such implants as possible, both failed and nonfailed. Evaluation of retrieved animal implants plays a special role in the documentation for the FDA-Investigational Device Exemption (IDE) required for a clinical trial and for the FDA-Pre-market

Approval (PMA) required for general marketing. The literature contains numerous instances where problem-oriented implant evaluation studies have yielded important insights into the deficiencies and complications that have limited the success of various implants. Implant retrieval has also contributed to the assessment of the safety and efficacy of implant modifications intended to be improvements. The conceptual approach to the analysis of a failed implant is explored in Chapter 9.3.

WHAT CLINICALLY USEFUL INFORMATION HAS BEEN LEARNED FROM IMPLANT RETRIEVAL AND ANALYSIS?

Cardiovascular Implants

Cardiovascular implants commonly involve both blood and soft-tissue interactions with materials. The complications most commonly found with these implants, i.e., heart valve

TABLE 7 Complications of Heart Valve Substitutes, Vascular Grafts and Cardiac Assist/Replacement Devices

Infection

prostheses, vascular grafts, cardiac assist devices/artificial hearts, and vascular stents are listed in Tables 7 and 8. Perspectives, approaches, and techniques for evaluating cardiovascular implants have been described (Schoen, 1990; Schoen, 1995; Borovetz, 1995; Schoen, 2001; Schwartz *et al.*, 2002). Specific examples from the field of cardiovascular prostheses are summarized next and in Table 9 to illustrate the scope and utility of this activity.

Experience with caged-ball mechanical prosthetic heart valves in the 1960s demonstrated both thrombus and degradation as complications. Degradation of silicone due to lipid absorption (called ball variance) was virtually eliminated by improved curing of silicone poppets (Hylet *et al.*, 1972). Subsequently, a cloth-covered caged-ball mechanical prosthetic heart valve that had a ball fabricated from silicone and a metallic cage covered by polypropylene mesh was introduced. The cloth-covered cage struts were designed to encourage tissue ingrowth and thereby decrease thromboembolism. Preclinical studies in pigs, sheep, and calves demonstrated rapid healing by fibrous tissue of the cloth-covered struts. However, subsequent clinical studies of these valves showed abundant cloth wear in some patients, sufficient to cause escape of the ball through the spaces between the cage struts, a circumstance that was rapidly fatal without emergency surgery (Schoen *et al.*, 1984). This analysis demonstrated the general concept that valve prostheses used in humans may have important complications that were not predicted by animal investigations, in this case because the vigorous healing that occurred in animals but not in humans obscured the potential problem.

Modification of a tilting-disk valve design intended to permit enhanced opening and thereby reduce thromboembolism also led to an unfortunate clinical problem. The design change necessitated a manufacturing change in the manner in which metallic struts were welded to the housing. An unusually large cluster of clinical implants of these valves failed by fracture of the welds anchoring one of the two metallic struts that guided and restricted disk motion (Walker *et al.*, 1995). This led to separation of a strut from the housing and consequent disk escape with acute valve failure, which was frequently fatal. Detailed materials analysis of retrieved implants that had failed revealed that the underlying problem was metal fatigue at the strut-housing junction resulting from overrotation of the disk during valve closure. This caused an abnormally hard strike of the disk on the strut, and consequent excessive bending stresses near the weld, which coupled with the intrinsic porosity and resultant vulnerability of welded joints induced fatigue failure (Schoen *et al.*, 1992).

Multiple coordinated studies of retrieved experimental and clinical implants have characterized and facilitated therapeutic approaches toward elimination of calcification-induced failure modes in bioprosthetic tissue heart-valve replacement (Schoen and Levy, 1999). Such studies have identified the causes and morphology of failure, patterns of mineral deposition, nature of the mineral phase, and early events in the mechanisms of calcification. Calcification of valve tissue in both circulatory and subcutaneous animal models exhibits morphological features similar to that observed in clinical specimens, but calcification is markedly accelerated in the experimental explants. Such studies have provided the means to test approaches to inhibit bioprosthetic valve calcification by modifying host, implant,

TABLE 9 Clinical Utility of Retrieval Studies—Heart Valve Substitutes

Implant type	Knowledge gained/lessons learned
Caged ball valves	<ul style="list-style-type: none"> • Poppets fabricated from industrial silicone absorbed blood lipids and became swollen and brittle • Fragments of degraded heart valve material may embolize to other organs • Thrombosis can occur at stasis points downstream of the ball
Cloth-covered caged ball valves	<ul style="list-style-type: none"> • Cloth wear can cause hemolysis and cloth emboli • Cloth wear accompanied by silicone poppet wear can precipitate poppet escape • Healing of fabric may be more vigorous in animals than in humans • Quantitation of data (e.g., polymeric poppet weight and dimensions) may facilitate the understanding of a failure mode
Caged disk valves	<ul style="list-style-type: none"> • Teflon has poor wear resistance as a valve occluder • Poor design features may potentiate thrombosis
Tilting-disk valves	<ul style="list-style-type: none"> • Thrombosis may initiate downstream to the edge of a partially open disk at a region of stasis • A “minor” change in valve design can result in a new propensity toward failure • Animal implants instrumented with strain gauges can be used to test a hypothetical mechanical failure mechanism • Understanding a failure mode can lead to both new methods for noninvasive diagnosis (e.g., X-ray and acoustic) and modified patient management strategies (e.g., drugs to depress cardiac contractility)
Bileaflet tilting-disk valves	<ul style="list-style-type: none"> • Cavitation may cause critical materials damage in some valve designs • Thrombosis may be initiated in regions of microstasis at component junctions • Microscopic areas of stasis may be predicted by computer-assisted computation • Animal implant models may fail to predict vulnerability to thrombosis in humans
Bioprosthetic heart valves	<ul style="list-style-type: none"> • Tissue calcification is a major failure mode • Calcification is most pronounced in areas of leaflet flexion, where deformations are maximal • Calcification is accelerated in young recipients, especially children • Heart valve calcification can be studied outside of the circulation (e.g., subcutaneous implants in rats) • Calcification is initiated principally at cell remnants deep in the tissue
Cryopreserved allograft valves	<ul style="list-style-type: none"> • These valves are not viable and cannot grow • Failure is not immunologically mediated and, therefore, immunosuppression is inappropriate
Substitution of new materials	<ul style="list-style-type: none"> • Pyrolytic carbon has favorable clinical durability • Detailed examination of functional (not failed) prostheses may yield worthwhile data

and mechanical influences. These studies serve to emphasize that biological as well as mechanical failure mechanisms can be understood using specifically chosen and controlled animal model investigations, guided by and correlated with the results of careful studies of retrieved clinical specimens. Furthermore, they show how implant retrieval studies can be used as a critical component of a program to assure efficacy and safety of potential therapeutic modifications.

An additional use of retrieval studies is exemplified by a case in which a change in biomaterials was shown to be beneficial. Implant retrieval studies of a low-profile disk valve composed of a disk and cage fabricated from Teflon demonstrated poor wear properties of the disk. After a new model of the valve with disk and struts fabricated from pyrolytic carbon was introduced, clinical experience suggested that the use of carbon contributed to a major advancement in the durability of prosthetic heart valves. Retrieval studies of carbon valves recovered at autopsy or surgery and analyzed by surface scanning electron microscopy and surface profilometry indicated that compared with valves composed of Teflon, carbon valves exhibited minimal abrasive wear (Schoen *et al.*, 1982). This study revealed that although analysis of implants and medical devices has traditionally concentrated on those devices that

failed in service, important data can accrue from implants serving the patient until death or removal for unrelated causes. Thus, detailed examination of the properly functioning prostheses removed from patients after long duration of implantation may yield worthwhile data, provided that a focused question is asked of the material.

Other retrieval studies have revealed (1) the cause of excessive thrombosis of a new bileaflet tilting-disk design (Gross *et al.*, 1996); (2) the cause of mechanical failure of a new pericardial bioprosthesis fabricated from photofixed bovine pericardium that had different mechanical properties than conventional glutaraldehyde-fixed tissue (Schoen, 1998a); and (3) the cause of failure and characteristic changes that occur in cryopreserved allograft aortic heart valves transplanted from one individual to another (Mitchell *et al.*, 1998). Studies of ventricular assist devices have demonstrated the importance of valves or biomaterial junctions in initiating thrombosis (Fyfe and Schoen, 1993; Wagner *et al.*, 1993), and several studies have described the failure modes of specific types of vascular grafts in different locations (Canizales *et al.*, 1982; Downs *et al.*, 1991; Guidoin *et al.*, 1993) and the morphology of vascular stents (Anderson *et al.*, 1992; van Beusekom *et al.*, 1993; Farb *et al.*, 1999).

Orthopedic and Dental Implants

Complications most commonly found with orthopedic and dental implants are presented in Table 10 and Table 11, respectively. The clinical utility of hard-tissue (orthopedic and dental) implant retrieval and evaluation is summarized in Table 12.

Early studies were concerned primarily with metallic devices used for internal fixation of fractures. Examination of some early designs showed failure at regions of poor metallurgy or weak areas due to poor design (Cahoon and Paxton, 1968). Other studies (Cook *et al.*, 1985; Wright *et al.*, 1982) reinforce the importance of material and design, such as the pitfall of stamping the manufacturer's name in the middle of the plate where stresses are high. Modern total hip replacements have also had fatigue fractures initiated at labels etched at high-stress regions (Woolson *et al.*, 1997). Galvanic corrosion due to mixed metal alloys was also demonstrated in early retrieval studies (Scales *et al.*, 1959). Analyses of fixation devices have shown a correlation between corrosion and biological reactions such as allergic reactions to metallic elements in the implants (Brown and Merritt, 1981; Cook *et al.*, 1988; Merritt and Rodrigo, 1996).

The development of the low-friction total hip arthroplasty by Charnley is a classical example of how implant retrieval can yield important clinical information which impacts implant materials and design (Charnley *et al.*, 1969). The initial choice for the low-friction polymeric cup (replacing the acetabulum) was a Teflon-like PTFE. As in the heart valves described above, this relatively soft material had a very high wear rate and within a few years, many hip replacements had been removed due to severe wear and intense inflammatory reactions. The analysis

TABLE 12 Clinical Utility of Retrieval Studies: Hard-Tissue Implants

Implant type	Knowledge gained/lessons learned
Plates, screws, and rods used for fracture fixation	<ul style="list-style-type: none"> Do not mix metal alloys in same device Match the hardness (degree of cold work) and stiffness with the application Metallic implant wear and corrosion may lead to problems associated with allergic reactions
Tooth root implants	<ul style="list-style-type: none"> Careful surgical technique avoids thermal tissue necrosis of the implant-tissue interface Implant surface finish is a critical determinant of outcome
Femoral stems of total hip replacements (fracture analysis)	<ul style="list-style-type: none"> Cobalt alloys require high-quality casting High-strength superalloys may be advantageous Welded regions may fail in tensile-loaded locations Part numbers should not be etched in tensile-loaded locations
Femoral stem, modular interface	<ul style="list-style-type: none"> Corrosion at an interface is dependent on metallurgical and mechanical design factors
Polymeric component to total joint replacements (excluding one-piece flex hinge joints like finger)	<ul style="list-style-type: none"> Teflon performs poorly in wear applications Reinforcement of UHMWPE with chopped carbon fiber is ineffective Laboratory simulation should be done using clinically realistic implant wear motion and loading patterns Mechanical designs that produce high localized stresses may cause delamination Radiation sterilization to produce cross-linking is useful but can lead to molecular-chain scission, oxidation, and aging
Analysis of tissues surrounding total joint replacements	<ul style="list-style-type: none"> Wear particles derived from breakdown of the implant-bone interface or wear of the articulation (bearing) material cause inflammation and loosening.
Titanium and titanium-alloy implants	<ul style="list-style-type: none"> A good material in one implant application may not necessarily be good in another Commercially pure titanium is appropriate for tooth root implant or fracture fixation devices Titanium alloys may yield severe wear in some total joint applications

of the retrievals has also demonstrated the relationships between large head diameter and the wear debris and excessive wear that have served as the basis for our understanding of joint bearing design. Clinical and retrieval studies are now examining the performance of metal-on-metal total hip bearing couples (Doorn *et al.*, 1996).

Teflon was replaced by ultrahigh-molecular-weight polyethylene (UHMWPE) as the acetabular cup bearing surfaces, and retrieval studies have continuously stimulated changes in the methods of processing UHMWPE. Retrieval studies have demonstrated that reinforcing UHMWPE with carbon fibers did not sufficiently improve its strength (Wright *et al.*, 1988). Heat pressing to improve surface hardness was not effective with some total knee designs (Bloebaum *et al.*, 1991; Wright *et al.*, 1992). Work was also directed toward assessing the effects of radiation sterilization on the polymer (Sutula *et al.*, 1995).

Implant retrieval and analysis has provided critical information toward understanding the anchoring of implants in bone. Branemark and associates demonstrated that direct bone-metal osseointegration of titanium tooth-root implants was possible with carefully controlled surgical technique and implant surface preparation (Albrektsson *et al.*, 1982). Porous coatings may be applied to implants to facilitate bony ingrowth; relationships between pore size and bony ingrowth have come from retrieval studies (Cook *et al.*, 1988).

Examination of the interface between the bone and the acrylic bone cement in long-term implant recipients examined at autopsy demonstrated the presence of inflammation with macrophages, thus providing the initial description of bone resorption due to particulate debris (Charnley, 1970). The relationship between the amount of particulate wear debris generated and bone resorption due to inflammation was graphically demonstrated by the retrieval and tissue studies of Willert and Semlitsch (1977). Extensive research has been conducted over the years looking at "particle disease" and characterization of the polymeric debris, as correlated with implant type and design (Schmalzied *et al.*, 1997). Studies on tissue reactions to particulates and wear debris require special histologic evaluation as described by Wright and Goodman (1996), in the various consensus standards, in other references cited earlier, and in many other studies readily available in the orthopedic or histotechnology literature.

Implant retrieval studies have demonstrated that success of a material in one application may not necessarily translate to another. For example, titanium does well as a bone-implant interface, but it may be subject to severe wear as a bearing surface (Agins *et al.*, 1988). An alternative approach in the hip was to use titanium alloy stems with a modular press-fit heads made of a more wear-resistant cobalt alloy. However, some of these designs demonstrated significant corrosion, which was first attributed to use of mixed metals (Collier *et al.*, 1991), and later to microgalvanic corrosion of the cast heads (Mathiasen *et al.*, 1991) and to micromotion and fretting corrosion between components (Brown *et al.*, 1995).

As with orthopedic devices, complications of dental implants may be related to the mechanical-biomechanical aspects of force transfer, or the chemical-biochemical aspects of elements transferred across biomaterial and tissue interfaces,

or both. The complex synergism that exists between tissue and biomaterial responses presents a significant challenge in the identification of the failure mechanisms of dental implants. Since many dental devices are percutaneous, in that they contact bone but are also exposed to the oral cavity, the problems of infection are also significant (Moore, 1987; Sussman and Moss, 1993).

Lemons (1988) and others have provided appropriate perspectives to be taken in the evaluation of dental implants.

CONCLUSIONS

Although the focus of this chapter has been on retrieval and evaluation of implants in humans, the perspectives, approaches, techniques, and methods may also apply to evaluation of new material, preclinical testing for biocompatibility, and premarket clinical evaluation. Each type of *in vivo* or clinical setting has its unique implant-host interactions and therefore requires the development of a unique strategy for retrieval and evaluation.

Indeed, for investigation of bioactive materials and tissue-engineered medical devices, in which interactions between the implant and the surrounding tissue are complex, novel and innovative approaches must be used in the investigation of *in vivo* tissue compatibility. In such cases, the scope of the concept of "biocompatibility" is much broader and the approaches of implant retrieval and evaluation require measures of the phenotypes and functions of cells and the architecture and remodeling of extracellular matrix and the vasculature (Rabkin *et al.*, 2002; Rabkin and Schoen, 2002; Peters *et al.*, 2002; Mizuno *et al.*, 2002). Moreover, a critical role of implant retrieval will be the identification of tissue characteristics (biomarkers) that will be predictive of (i.e., surrogates for) success and failure. A most exciting possibility is that such biomarkers may be used to noninvasively image/monitor the maturation/remodeling of tissue-engineered devices *in vivo* in individual patients.

New Products and Standards

ELAINE DUNCAN, JACK E. LEMONS, JAY P. MAYESH,
PAMELA SAHA, SUBRATA SAHA, MARY F. SCRANTON

10.1 INTRODUCTION

Jack E. Lemons

A very dynamic situation continues to exist related to the development and introduction of new surgical implant devices. This, in part, relates to product and business competition. Significant amounts of proprietary research and development in conducted annually throughout the industrial sector, often first seen in product-related throughout or within regulatory submissions that become public domain.

Surgical implant biomaterial standards within the United States are based on consensus organizations with the American Society for Testing and Materials Committee F-4 (ASTM F-4) representing most implant devices. These standards are published annually in Volume 13.01 from the ASTM. Those interested in biomaterials and surgical implant devices should refer to the various national and international sources of product literature and standards as a key source of information. The section components of Chapter 10 will provide related references and sources for obtaining the industrial and standard related literature.

10.2 VOLUNTARY CONSENSUS STANDARDS

Jack E. Lemons

WHAT ARE STANDARDS?

Consensus standards are documents that have been developed by committees to represent a consensus opinion on test methods, materials, devices, or procedures. Most standards organizations review their documents within 5 years to ensure that they are up to date. The mechanisms by which they are developed are described in subsequent sections. Development of standards is an ongoing process and the latest publications should be consulted for new standards.

A test method standard describes the test specimen to be used, the conditions under which it is to be tested, how many

specimens and what controls are to be tested, and how the data are to be analyzed. Many methods are validated by “round robin testing,” meaning that several laboratories have followed the method and their results are analyzed to determine the degree to which they agree and to a specified degree of precision and accuracy. Once a test method has been standardized, it can be used in any other laboratory; the details are sufficient to ensure that different facilities will obtain similar results for the same samples. Stating that a test was “conducted in accordance with . . .” ensures that the results can be duplicated. Some representative test methods are listed in Table 1.

A material or specification standard describes the chemical, mechanical, physical and electrical properties of the material. Any test method standards cited are to be used to ensure that a significant sample meets the requirements of the standard. Some representative material standards are listed in Table 2.

For implant materials, there is also a requirement that the materials meet general biocompatibility test criteria. There are two formats for the biocompatibility language in the material standards of the American Society for Testing and Materials (ASTM). For materials that can be well characterized by chemical, mechanical, and physical tests and have demonstrated a well-characterized biological response, reference to the published biological testing data and clinical experience is often sufficient. For materials that are not well characterized, for example, the wide class of materials called epoxy resins, biological test methods are cited, and each particular formulation must be tested independently. This area is evolving for combination biological and synthetic (tissue-engineered) products.

A device standard describes the device and its laboratory-based performance. General design aspects, dimensions, and dimensional tolerances are given using schematic drawings. The materials to be used are described by reference to materials standards. Methods for testing the device are also cited. Since test methods only describe how to do a test, it is in the device-related standards that performance is addressed. For example, the fatigue life requirements or biocompatibility requirements of the device and its materials would be stated in a device standard. Some representative device standards are listed in Table 3.

TABLE 1 Some Representative ASTM Standard Test Methods

A. Mechanical testing standards
ASTM D412 Test methods for rubber properties in tension
ASTM D638 Test method for tensile properties of plastics
ASTM D695 Test method for compressive properties of rigid plastics
ASTM D790 Test methods for flexural properties of unreinforced and reinforced plastics and electrical insulating materials
B. Metallographic methods
ASTM E3 Preparation of metallographic specimens
ASTM E7 Terminology relating to metallography
ASTM E45 Determining the inclusion content of steel
ASTM E112 Determining the average grain size
C. Corrosion testing
ASTM G3 Conventions applicable to electrochemical measurements in corrosion testing
ASTM G5 Reference test method for making potentiostatic and potentiodynamic anodic polarization measurements
ASTM G59 Conducting potentiodynamic polarization resistance measurements
ASTM F746 Pitting and crevice corrosion of surgical alloys
ASTM F897 Fretting corrosion of osteosynthesis plates and screws
ASTM F1875 Practice for Fretting Corrosion Testing of Modular Implant Interfaces: Hip Femoral Head-Bore and Cone Taper Interface.
F2129 Conducting Cyclic Potentiodynamic Polarization Measurements to determine the Corrosion susceptibility of small implant devices.
D. Polymer testing
D2238 Test methods form absorbance of polyethylene due to methyl groups at 1378 cm ⁻¹⁴
D3124 Test method for vinylidene unsaturation in polyethylene by infrared spectrophotometry

TABLE 2 Some Typical ASTM Materials Standards (4)

ASTM F75 Cast cobalt–chromium–molybdenum alloy for surgical implant applications
ASTM F139 Stainless steel sheet and strip for surgical implants (special quality)
ASTM F451 Acrylic bone cements
ASTM F603 High-purity dense aluminum oxide for surgical implant applications
ASTM F604 Silicone elastomers used in medical applications
ASTM F641 Implantable epoxy electronic encapsulants

A procedure or guidance standard describes how to do something that would not be considered a test. Examples include standards for surface preparation and standardized procedures for sterilizing implants. Table 4 lists some typical procedure standards.

TABLE 3 Some Representative AAMI and ASTM Device Standards

AAMI CVP3 Cardiac valve prostheses
AAMI VP20 Vascular graft prostheses
AAMI RD17 Hemodialyzer blood tubing
AAMI ST8 Hospital steam sterilizers
E667 Clinical thermometers (maximum self-registering, mercury-in-glass)
ASTM F367 Holes and slots with spherical contour for metric cortical bone screws
ASTM F703 Implantable breast prostheses
ASTM F623 Foley catheters

TABLE 4 Some Representative AAMI (1) and ASTM (4) Procedure Standards

AAMI ROH-1986 Reuse of hemodialyzers
AAMI ST19 Biological indicators for saturated steam sterilization processes in health care facilities
AAMI ST21 Biological indicators for ethylene oxide sterilization processes in health care facilities
ASTM F86 Surface preparation and marking of metallic surgical implants
ASTM F561 Retrieval and analysis of implanted medical devices and associated tissues
ASTM F565 Care and handling of orthopedic implants and instruments
ASTM F983 Permanent marking of orthopedic implant components

WHO USES STANDARDS?

The term “voluntary standards” implies that the documents are not mandatory; anyone can use them. This terminology also refers to the way that standards are developed. Standards are used by manufacturers, users, test laboratories, and, in many instances, college professors and their students. One’s use or compliance with a standard is voluntary. Using them is often to everyone’s advantage. At this time, standards can also be utilized as a part of the regulatory (FDA) approval process (1997 FDA MA).

Manufacturers often use standards as guidelines in making and testing their materials and devices. Manufacturers also cite standards in their sales literature as a concise way of describing their product. Stating that a device is made from cast cobalt–chromium–molybdenum alloy in accordance with ASTM F75 tells the user precisely what the material is. Conformance to standards is also a way to expedite device review by FDA, as is described in Chapter 10.3.

On a more personal level, for example, after purchasing a piece of plastic pipe at the hardware store labeled with “ASTM D1784,” one could go to ASTM Volume 8.02 and find that this is a specification for rigid poly(vinyl chloride) compounds. If you have “DIN” stamped on the bottom of your ski boots, you know they conform to the standards of the Deutsches Institut für Normung, and the ski shop will have standards for adjusting your bindings.

As an example of why one would want device standards used for medical devices, consider screws for fixing bone fractures. There are device standards for bone screws, plates, taps, and screwdrivers. The physician can purchase a screw and a screwdriver and be confident that the components will fit as intended. A surgeon about to remove a plate implanted at another hospital can evaluate radiographs and see that the device has 4.5-mm bone screws of a specific design. Knowing this, a standard 4.5-mm screwdriver can be used to remove the screws.

Standardized test methods should simplify life. For example, one of the authors taught two laboratory sessions as part of an undergraduate biomedical engineering course. One was on mechanical testing, the other on metallography and implant analysis. In the mechanical testing laboratory, several ASTM standard test methods for mechanical testing, such as D790, “Flexural properties of plastics and electrical insulating materials,” were used. This method describes the samples, test apparatus, test speeds, and equations used to calculate the results. During the lab session the students followed the test directions. In writing the methods section of their reports, all they had to write is that “the test was done according to D790.”

WHO WRITES STANDARDS?

In the United States, voluntary consensus standards are developed by a number of organizations. In the medical electronics, sterilization, vascular prosthesis, and cardiac valve areas, most standards are developed by committees within the Association for the Advancement of Medical Instrumentation (AAMI). In the implant materials and implants area, most standards are set by ASTM Committee F-04 on Medical and Surgical Materials and Devices. These documents may then be reviewed and accepted by the American National Standards Institute (ANSI). ANSI is the official U.S. organization that interacts with other national organizations in developing international standards within the International Standards Organization (ISO), such as TC 150 on Medical Materials and Devices and TC 194 on Biological Evaluation of Medical Devices. The USP provides information on minimal biocompatibility testing for materials intended to be used in medical devices.

Dental material standards are written by the American Dental Association (ADA). Similar committees exist in other countries: the Canadian Standards Association (CSA), the British Standards Institute (BSI), the Association Française de Normalisation (AFNOR) in France, and the Deutsches Institut für Normung (DIN) in Germany, which is a voluntary organization.

The initiation, development, and process for the completion of national ASTM F04 consensus standards for medical and surgical materials and devices has evolved significantly within recent years. In part, this has been a result of multiple interactions amongst those involved with the basic sciences, applied research and development, business marketing and sales, clinical applications, regulatory agencies, professional societies, legal and insurance professions, device recipients, and associated advocacy groups. To establish consensus opinions satisfactory to all of these interest groups is far from a simple process.

History and Current Structure of ASTM F04

The ASTM was organized in 1898, whereas Committee F04 on Medical Devices and Surgical Materials and Devices was founded in 1962. The committee has grown to include a current membership of approximately 500 individuals representing a variety of disciplines and interests. The ASTM F04 Committee has more than 100 active standards and is structured into more than 30 technical subcommittees. The overview structure includes five divisions divided according to responsibilities specific to organizational activities (process) or the development of specific types of standard document (e.g., full consensus standards include six types (1) classification, (2) guide, (3) practice, (4) specification, (5) terminology, and (6) test methods, plus a provisional status). The divisions are (I) resources, (II) orthopedic devices, (III) medical/surgical devices, (IV) tissue engineered products, and (V) Administration. Each division is subdivided into subcommittees and task groups according to areas of interest and activities. This structure is intended to be flexible and can be rearranged to suit new or more efficient operations at any scheduled meeting of the executive committee. The divisions, subcommittees, and task groups have an appointed chair and vice-chair, whereas the executive is nominated and elected on a 2-year cycle.

Standards Development Process

After a request for a new standard is received by a member or group (task group or subcommittee) and accepted by the executive committee, a task group activity is initiated. An appropriate chair is recommended and approved by the administrative committees and the process is started. Consensus standards developments follows a reference document for content, form, and structure. An assignment of an appropriate document number is made for record purposes and a staff manager confirms that the committee and subcommittee representation associated with this activity is classified and balanced with respect to producers and nonproducers. A first draft of the proposed document is reviewed (usually three to five times) before the task force reaches a consensus.

Critical to these proceedings is the necessity that adequate information is available within the public domain in order to substantiate the requirements listed within the final standard. If data are limited or unknown, round-robin tests or new test methods must be developed, and then confirmed to be applicable and valid. Sometimes, documents are held until basic

(necessary) information for the standard is developed. Again, a standard must be based on known results and documents are not intended to represent areas of new research.

As a part of the process, once a draft document has been circulated within the task group and consensus is reached, the task group chair may recommend initial voting at the task group level. At this time, the opinions gained could lead to further improvements and no formal voting rules are required within the task group interactions. At the next stages, the sub and main committees of ASTM F04 must ensure a balance among the various voting interests with adequate representation from the general-interest, user, consumer, and producer segments of the membership. The total of the user, consumer, and general-interest votes must equal or exceed the number of producer votes. To prevent domination by any one interest group, only one vote per voting interest is permitted. The ASTM staff confirms the numerical status (adequate response and balance) for each formal vote and all members are permitted to vote on any ballot within their committee of membership. If approved or approved with editorial (no substantive) changes at the subcommittee level, the document proceeds to main committee ballot and society review. If, however, a negative vote is received during formal voting, the task group and subcommittee chairs must resolve the negative to the satisfaction of the negative voter or must provide a rationale and justification to find the negative voter nonpersuasive. This opinion must be accepted by the task force and approved at the subcommittee and main committee levels by a formal recorded vote based on written documentation and associated discussions. The staff manager works with the committee to confirm the validity of the vote and to document the action.

The general experience has been that it requires 3 to 5 years (six to ten meetings) to go from a first draft to a full standard accepted at the main committee level. Several procedural steps are also required in the process, including approval of a rationale statement, use of standardized units (SI) and terminology, and acceptance by the editorial and precision and bias subcommittees. At the stage of society acceptance, the final document is reviewed by the Committee on Standards prior to publication by ASTM.

After approval, a given standard may remain "active as published" for up to 5 years. At 5 years, that standard must be reaffirmed or revised to suit the information available at that time. For record purposes, the date of last formal approval is included as a part of the standards designation.

BIOCOMPATIBILITY STANDARDS

There is a wide range of tests that may be used to determine the biological response to materials. Short-term uses require only short-term tests. Long-term uses require tests applicable to the particular device and tissue type. Since not all tests are necessary for all applications, national and international standards organizations have developed matrix documents that indicate what methods are appropriate for specific applications. These documents can be used as guidelines in preparing a submission to the U.S. Food and Drug Administration (FDA), the

EC, and other national regulatory agencies for approval of a new material or device. Similar matrix documents have been standardized by the CSA, BSI, and ISO. Test method documents have also been developed by the National Institutes of Health (NIH) and the U.S. Pharmacopeia (USP). Guidelines for dental materials have also been developed by the ADA and ISO.

Much of the standards activity is now associated with the International Standards Organization (ISO) with biological evaluation of medical devices under the consideration of TC 194 and presented in the developing documents of ISO 10993. There are various parts to this document. Part 1 is definitions and the guidance on selection of evaluation test categories that should be done. The other parts of 10993 give more discussion and detail on the selection of individual tests that should be done for a particular biological interaction or biological effect (e.g., contact with blood, systemic toxicity, genotoxicity). Often, the details of test methods are not given in the ISO documents and reference is made to other documents such as ASTM and USP standards for procedures and methodology.

Material selection and evaluation of biological risk are integral components of the design process for medical devices being considered by TC 194. This evaluation is a component of the risk management plan in line with ISO/IEC 14971—Application of Risk Management to Medical Devices, encompassing identification of all hazards and the estimation of their associated risks. Criteria to define the acceptable biological (toxicological) risk must be established at the start of the risk assessment and design management processes. The biological safety evaluation must be designed and performed to demonstrate the achievement of the specified criteria for safety. Adequate risk assessment requires characterization of toxicological hazards and exposures. Following the risk management structure described in ISO 14971, a major component in hazard identification is material characterization.

In the following section we review some of the steps taken to establish the biocompatibility of a new material for a specific application, in this case a long-term orthopedic implant. We use ASTM standard F748 "Practice for Selecting Generic Biological Test Methods for Materials and Devices" as a guideline. The standard test methods described are those used within ASTM.

In Vitro Tests

F619. Practice for Extraction of Medical Plastics. A method for extraction of medical plastics in liquids that simulate body fluids. The extraction vehicle is then used for chemical or biological tests. Extraction fluids include saline, vegetable oil (sesame or cottonseed), and water.

F813. Practice for Direct Contact Cell Culture Evaluation of Materials for Medical Devices. A cell culture test using American Type Culture Collection (ATCC) L929 mouse connective tissue cells. This method or this type of cell culture method can be used as the first stage of biological testing. It is also used for quality control in a production setting. There are other ASTM standard cell

culture methods, and others not standardized by ASTM that could also be used.

F756. Assessment of Hemolytic Properties of Materials.

An *in vitro* test to evaluate the hemolytic properties of materials intended for use in contact with blood. Procedure A is static; procedure B is done under dynamic conditions.

Short-Term in Vivo Testing

F719. Testing Biomaterials in Rabbits for Primary Skin Irritation. A procedure to assess the irritancy of a biomaterial in contact with intact or abraded skin. This test would be indicated for surgical glove material or skin dressings.

F720. Practice for Testing Guinea Pigs for Contact Allergens: Guinea Pig Maximization Test. A two-stage induction procedure employing Freund's complete adjuvant and sodium lauryl sulfate, followed 2 weeks later by a challenge with the extract material. Ten animals per test material.

F749. Practice for Evaluating Material Extracts by Intracutaneous Injection in the Rabbit. Extraction vehicles (as per F619) of saline and vegetable oil are injected intracutaneously and the skin reaction graded for erythema, edema, and necrosis. Two rabbits per extraction vehicle.

F750. Practice for Evaluating Material Extracts by Systemic Injection in the Mouse. Intravenous injection of saline extracts and intraperitoneal injection of oil extracts. Animals are observed for evidence of toxicity. Five mice per extract and five mice per extract vehicle controls.

F763. Practice for Short-Term Screening of Implant Materials. This method provides for several implant types and sites for short term screening *in vivo*. This method is essentially the first stage of animal testing of solid pieces of the implant material.

F1983. Assessment of Compatibility of Absorbable/Resorbable Biomaterials for Implant Applications. This material type presents unique features for tissue evaluation, in that the materials are not inert, and a chronic inflammatory reaction may be observed during the degradation period. The time periods at which reactions are examined are based on the anticipated rates of degradation of the test materials.

Additional tests for special issues are also included in ASTM standards such as examination and reactions to particles, immunotoxicity, and retrieval and analysis of implants and tissues.

There are additional *in vitro* tests that have not yet been standardized by ASTM:

Thrombogenicity. Tests for the propensity for materials to cause blood coagulation have not been standardized. Guidelines for such tests have been developed by the NIH Heart Lung and Blood Institute.

Mutagenicity. There are a number of *in vitro* and *in vivo* tests to determine if chemicals cause cell mutations.

Although not specifically developed for implants, guidelines do exist as part of the OECD guidelines for testing of chemicals, and within ASTM, e.g., E1262, Guide for the Performance of the Chinese Hamster Ovary Cell/Hypoxanthine Guanine Phosphoribosyl Transferase Gene Mutation Assay; E1263 Guide for Conduct of Micronucleus Assays in Mammalian Bone Marrow Erythrocytes; E1280, Guide for Performing the Mouse Lymphoma Assay for Mammalian Cell Mutagenicity; E1397, Practices for the *in Vitro* Rat Hepatocyte DNA Repair Assay; and E1398, Practices for the *in Vivo* Rat Hepatocyte DNA Repair Assay, which are in Vol 11.05 of the Annual book of Standards.

Pyrogenicity. A pyrogen is a chemical that causes fever. The USP rabbit test is a standard *in vivo* test. One can also test for bacterial endotoxins, which are pyrogenic, using the Limulus amoebocyte lysate (LAL) test. The oxygen-carrying cell (amebocyte) of the horseshoe crab, *Limulus polyphemus*, lyses when exposed to endotoxin.

Long-Term Testing in Vivo

There are two aspects to the long-term testing issue. One is the response of tissue to the material; the other is the response of the material (degradation) to implantation.

F981. Practice for Assessment of Compatibility of Biomaterials for Surgical Implants with Respect to Effects of Materials on Muscle and Bone. Long-term implantation of test materials in the muscle and bone of rats, rabbits, and dogs. Two species are recommended. For rabbit muscle implants: the standard calls for four rabbits per sacrifice period, with one control and two test materials placed in the paravertebral muscles on each side of the spine. For bone implants in rabbits: the standard calls for three implants per femur.

A general necropsy is performed at the time of sacrifice. Muscle and bone implant sites are removed at sacrifice and the implants left *in situ* until the tissue has been fixed in formalin. Implants may be removed prior to embedding and sectioning.

No standards have been established for any long-term testing of devices. However, for a device intended for a particular application, it is essential to conduct a functional device test. For a fracture fixation plate, it could be proposed to use plates to fix femoral osteotomies in dogs. This study would consider the effects of the implant on the tissues, as well as the effect of implantation on the properties of the device, i.e., material degradation.

The methodology for long-term carcinogenicity testing of implants also has not yet been standardized by the ASTM, although F1439 (Standard Guide for Performance of Lifetime Bioassay for the Tumorigenic Potential of Implant Materials) does provide guidelines for test selection. This is normally a life survival and tumor production test, typically in rats. ISO 10993-3 provides considerations for genotoxicity, carcinogenicity, and reproductive toxicity testing with reference to some test methods.

SUMMARY

Standard test methods allow results to be reproduced or verified by other researchers. In the biomaterials field, standards can be used for physical, mechanical, chemical, electrical, and biological testing of materials. By using materials that conform to standards, a manufacturer can tell the user what is in the material and what to expect from it in terms of properties.

10.3 DEVELOPMENT AND REGULATION OF MEDICAL PRODUCTS USING BIOMATERIALS

Elaine Duncan

INTRODUCTION

What we now call the “Food, Drug & Cosmetic Act” was amended in 1976 to broaden the powers of the U.S. Food and Drug Administration (FDA) over medical devices. Subsequent amendments have continued steadily to refine and broaden the powers of the agency to control veterinary drugs, biologics, and combination products. Narrowly crafted definitions in the 1976 amendment attempted to segregate the authority between the divisions of the agency, maintaining drugs under the Center for Drug Evaluation and Research (known as CDER). The portion of the agency now known as the Center for Devices and Radiological Health (CDRH) maintains authority over medical devices. Major amendments occurred again in 1990, 1997, and 2002. Regardless of these many amendments, the agency has never been granted the authority to specifically regulate biomaterials. Rather, the regulatory constraints on biomaterials are indirect and according to the intended use of the device, drug, biologic, or combination product.

Combination Products

Through the years, the distinctions among drugs, biologics, and devices have blurred. Combination products are products that are recognized to have device, biologics, or drugs in combination. The premarket review jurisdiction of such combination products is predetermined by interagency agreement. In October 2002, Congress passed the Medical Device User Fee and Modernization Act of 2002 that established the Office of Combination Products. The Office has not yet issued formal operational instructions to the medical device industry as this chapter goes to press, but it is expected that the mode of action of the product will continue to be the primary consideration for determination of review and compliance authority. However, historical precedence can be a factor.

Manufacturers may request FDA to make a determination of the review authority in advance if the manufacturers feel that the review authority is uncertain. FDA has pledged to make public certain determinations of authority, but for reasons of confidentiality the Agency cannot do this until the product under review has cleared the approval process. For combination products, joint review is commonly required and more than one type of premarket application may be necessary. As biomaterials become hybrids of or are developed in combination with tissue-derived molecules, polymers, and pharmaceutical agents, the medical device and biomaterials developer will increasingly encounter this type of regulatory environment.

Global Regulatory Strategy and Intended Use

Biomaterials may be incorporated into drug delivery systems, used as carriers within packages for biologics, and incorporated into key components of medical devices in broad applications from disposable tubing and syringes to implantable devices sustaining life or restoring organ or limb function. In all of these various applications, the biomaterials within or without are regulated indirectly by the intended use of the final product. Therefore, the regulation of the biomaterial depends primarily on the risk associated with the intended use of the product. Aside from drug delivery systems, most applications for conventional biomaterials are in the medical device field, so the focus of this section of the chapter will be on the regulatory constraints on product development of new devices using biomaterials.

The application of biomaterials to medical device technology in nearly every industrialized country is regulated according to the intended use of the product incorporating the material and the relative risk of the use of the materials. These regulations may be as a result of direct laws or regulations and usually take the form of requirements to comply with voluntary or mandatory certifications to recognized standards or norms. After a new product has cleared the requirements (which restrict marketing until complete), continuing compliance requirements attempt to ensure quality of the finished device.

Changes to an existing product (such as a change to a biomaterial) or a new product (with either a well-characterized material or a new biomaterial) may be subject to regulatory

approval or review prior to market introduction, or companies may be required to document that the changes do not affect the safety and efficacy of the device. In general, all regulations that govern medical devices place the burden of proof upon the manufacturer to document the quality of the biomaterials from which the medical devices may be fabricated.

Typical biomaterial regulatory control follows one or more of the following types:

1. Guidance documents or device specific requirements
2. Adoption by reference to international standards for materials and test requirements
3. Requirements for validation and verification of material performance within the device
4. Manufacturing and purchasing controls to ensure continued quality and performance.

Regulations and requirements for biomaterials in medical devices typically focus on concerns for the safety and efficacy of biomaterials when the medical device is used as intended. The potential harm derived by the use of an unsafe material is viewed in the context of the device application. Therefore, more stringent testing of material safety and efficacy is required for devices with longer exposure, those used in life-supporting or life-sustaining devices, or where repeated exposure to the biomaterial component could engender greater risk.

Medical device manufacturers should also consider their global regulatory requirements prior to embarking on the development of a new product. These requirements should be a part of the tasks required in any initial design phase plan. Medical device manufacturers need to determine the compliance requirements on the products based on the market applications, historic precedence, and applicable standards. The U.S. FDA and European requirements, although setting the norm for many countries, are not necessarily the same as those that may be required in Brazil or in Japan. The Canadian and Australian systems have undergone significant changes in recent years and are similar but not identical to the European regulatory system. Most global regulatory strategies now follow the system of essential requirements. Harmonization committees and organizations are striving to make the safety and efficacy of medical devices a global requirement. A well-constructed technical file (a.k.a. Device Master Record or technical dossier) will go a long way in satisfying the regulatory requirements of most countries. Documentation of conformity to international standards and essential requirements will become an increasingly important function for all medical device developers. Harmonization efforts may soon do away with the historic “me too” practice of the 510(k) submission, which requires companies to compare the properties and performance of the product to a previously cleared device. Instead, an FDA submission for a low, or medium-risk device will certify conformity to standards or FDA published guidance documents and equivalence analysis may be less crucial.

Adoption of International Standards for Quality

In the years since the first edition of *Biomaterials Science: An Introduction to Materials in Medicine*, a shift in perspective

to a worldwide harmonized quality system has been adopted within the medical device community. This was less by design and more by rational mandate, as the European Union adopted the Medical Device Directives (MDD) and the Active Implantable Medical Device Directive (AIMDD). The general construction of these directives builds on recognized international standards and Essential Requirements. The Essential Requirements specifically require that the chemical, physical, and biological properties guarantee characteristics and performance of the product. Demonstration of conformance to the essential requirements is directly tied to demonstration of meeting a recognized European or international-level standard.

Beyond specific standards for biomaterial testing to demonstrate compliance (which are discussed later), additional requirements for total quality systems have become an international norm. The U.S. FDA Good Manufacturing Practices were modified to harmonize with globally recognized standards known as ISO 9000 (ISO is the abbreviation for International Standards Organization). The revised regulation, known as the Quality System Regulation (QSR), includes the general principles of Design Control and Review and Risk Analysis. The ISO 13485 standard for “Quality Management Systems—Medical Devices—System Requirements for Regulatory Purposes” is now recognized by Canada. Conformity is required in order to sell any new products in Canada; for those products sold prior to December 31, 2001, 1 year grace was allowed to establish conformity. ISO 13485–2003 has now issued as a “stand-alone” standard for medical device manufacturers, independent of ISO 9000–2000, and harmonizes with the FDA Quality System Regulation.

Product-specific international standards for product quality and evaluation have become an integral part of many regulatory programs around the world. FDA has issued a list of standards for conformity acceptance, and even those not recognized officially by FDA can be useful for communicating safety and performance as part of the review dossier. Some of the more commonly applied standards are for electrical safety and the ISO 10993 series, discussed in detail on the following pages. Up-to-date lists of recognized standards are discussed in detail on page 790.

Design Control and Risk Analysis

Design control and review, coupled with risk analysis, form the foundation of the testing and development requirements for any Class II or Class III medical product. (For details on FDA product classifications, go to www.fda.gov/cdrh). Customer “inputs” and design outputs (specifications) are to be reviewed throughout the design plan. A design plan is reviewed at the beginning of the product development cycle, and again as the program evolves. Typical design stages that trigger design review are the concept phase (usually prior to initiation of major external resources), development phase (often includes animal and bench testing), clinical evaluation phase (often includes investigational trials on human subjects), and the market introduction phase (includes scale-up and transfer to manufacturing).

As they are enforced differently, regulatory requirements between countries can represent different degrees of difficulty for the new medical device. Most countries will require demonstration that the device has been shown to be safe and effective for the intended use and meets certain essential requirements for safety. Risk analysis represents one method medical device manufacturers have of communicating to regulators how the safety of the product has been assured. International standards have been recognized that provide guidance on conducting risk analysis (ISO 14971, EN 1441, IEC 1025). The risk analysis process has become a standardized procedure used to determine the type of controls and mitigations that are needed to ensure product safety and human factors for most new medical devices under development. Transferring design to manufacturing also uses risk analysis methods to assess the most critical process steps for quality performance.

Premarket Approval, Clearance, or “CE Mark”

For Europe, once a developer of a medical device has demonstrated conformance with the Essential Requirements of either the MDD or AIMDD, the company may file a Certificate of Conformance or request that a Notified Body conduct an examination to ensure conformance. The route to conformity assessment is spelled out in the directives and is determined by the classification of the device and the applicable rule, which is primarily a risk-based stratagem. The CE Mark must be applied, based upon assessment of conformance, prior to the sale of any medical device in a country within the European Union and in other countries that have voluntarily adopted the recognition of the CE Mark.

U.S. FDA requires that the manufacturer demonstrate safety and efficacy of the product (Pre-Market Approval Application, or PMA), unless the device can be shown to be substantially equivalent to a predicate product that is legally marketed in the United States [510(k)]. For most new products, those without predicates, and certain high-risk products (typically Class III), a PMA (or its equivalent Product Development Protocol, PDP) is required. Certain Class I and exempted Class II medical devices are permitted to be marketed without FDA's prior authorization, although manufacturing (Quality System Regulations) and/or documentation controls may still apply.

Premarket approval applications for medical devices containing biomaterials may take a variety of regulatory pathways, but for most new or innovative biomaterial-based, implantable devices, the formal Premarket Approval Application (PMA) is commonly required. [FDA has continued to permit certain Class II and Class III devices to enter the market after clearance of the 510(k)]. The specific regulations and classifications for medical products changes frequently, and the list is far too exhaustive to include in a textbook chapter. For the latest regulatory status of any type of medical product using biomaterials, contact the U.S. Food and Drug Administration at their Web site (www.fda.gov).

For companies undergoing the PMA process, a critical step is often the final review by the clinical advisory panel. This panel of medical experts makes recommendations to the FDA on the acceptance of a new medical device, but most

particularly on whether, in their opinion, the clinical evaluation of the product has demonstrated efficacy. Proof of efficacy is highly dependent upon statistical analysis of prospective data collected under tightly controlled clinical evaluation protocols. The FDA has sought to take some of the long-range risk out of the approval process by offering manufacturers alternative approval routes. PMAs can now be reviewed in modules. The modular PMA is finding favor with medical device companies because they can submit sections of testing as completed. This does not, however, eliminate the risk for final rejection of the clinical testing conducted under Investigational Device Exemption regulations by the clinical panel.

The Product Development Protocol (PDP) offers an alternative route to market approval. The PDP allows the manufacturer to present a plan to the FDA and the clinical panel in advance of initiating the testing. At this time, FDA may restrict the application of any PDP to those devices for which FDA feels a model can be developed from prior regulatory experience.

Manufacturing Controls

In most regulatory schemes, manufacturing to acceptable practices is a standard requirement, although the specific obligations and criteria required are different from country to country. The U.S. FDA has developed a tiered system for continued inspection of manufacturing locations based on a risk-based strategy. There are typically limitations imposed on the variety and scope of changes that can be made by the manufacturer to a Class III product after market introduction without prior reapproval by FDA. The FDA has regulations concerning recalls, product removals, and corrections and heavily stresses the importance of corrective and preventive action (CAPA) programs for marketed products.

Compliance to regulations governing the sale and distribution of a medical device after the product has been approved typically requires that standard manufacturing practices be followed. Postapproval limitations to the distribution of the medical device typically include restrictions to be placed on the claims for the product and on the content of labeling. Some “off-label use” is tolerated, but promotion of new claims typically triggers a new application to support a different indication for use or claims of performance not previously reviewed by FDA.

Most regulatory schemes also require the reporting of adverse effects. The degree of hazard that must be reported to the governing agency will vary from country to country. Tracking of implantable or life-supporting devices is limited but still a common regulatory constraint for high-risk implantable devices, such as defibrillators.

Clinical Trials of Unapproved Devices

Basic requirements for the conduct of human clinical trials continue to be harmonized internationally, although significant differences remain. Barriers to initiating a clinical trial still differ between countries, but once the trial is underway, a similar

level of patient rights and investigator obligations is expected. European concerns for patient privacy preceded U.S. adoption of strict patient privacy regulations, although privacy has always been a concern for the human subjects committees reviewing protocols.

Clinical evaluations for significant-risk devices containing biomaterials are typically cleared for study in human patients by FDA under an Investigational Device Exemption. A protocol or study plan is required, and with a few minor exceptions, informed consent from the patient must be documented prior to testing the device or material in an unproven device on a human subject. Investigators must be trained on the use of the product and sign an agreement in order to conduct the study. Investigators must now disclose certain financial aspects. Approval by an Institutional Review Board (IRB), also known as the human subjects committee or ethics committee, is required by the FDA prior to conducting studies funded by the National Institute of Health, and for most international regulatory agencies. Case report forms and data collection methods must be carefully crafted in order to document data required to support the claims for the product under study. All of these same requirements are stipulated in European medical device directives, but individual countries are responsible for their implementation and compliance.

Clinical trials for medical devices containing biomaterials must develop objective evidence of safety of the device, and indirectly the safety of the biomaterial as applied in the device. Any safety problem encountered with the use of a biomaterial during the study needs to be reported as a part of the adverse effects of the clinical trial. Any special performance claim attributed to the biomaterial, such as tissue ingrowth, needs to be evaluated both as a part of a preclinical animal study, and if possible, in the clinical study. In the United States, only claims for biomaterial performance supported with statistically valid evidence will be permitted in the device labeling. For this reason, many performance claims for biomaterials are embedded within the performance claims of the device, or never presented at all.

Often, the indirect or noninvasive measurements, such as X-rays, prove inadequate to demonstrate biomaterial performance criteria, so biomaterial performance claims may also depend upon high-quality animal studies to demonstrate interfacial characteristics, such as tissue ingrowth and biocompatibility. Animal studies must have some basis for prediction of performance in the human application, which can prove difficult given the differences in animal anatomy and healing characteristics when compared to humans. Increasingly these studies are conducted under the Good Laboratory Practices Regulations (CFR Part 58), which establish the quality standards for the research data that may be used in support of an FDA application.

ISO Standard for Biocompatibility Testing

Typical biocompatibility screens, such as those described by ISO 10993, are conducted prior to clinical evaluation of the device or clearance to market the product. Implementation of ISO 10993 varies, based on the risk associated with the use of

the product. The ISO 10993-1 references standardized biocompatibility screens, which are primarily focused on the chemical toxicity of leachable components or degradation by-products. Although ISO 10993-1 admonishes regulators to consider the material from a global suitability perspective, most commonly regulators use the table of tests for consideration as a requirements checklist. Application reviewers tend to give more credence to laboratory test reports. The exposure-based categories and duration segments have, through the years (the chart was adapted from the original Tripartite Agreement of 1987), been seen as a logical, although awkward, structure for determination of testing levels.

Fault does not lie in the standard as much as with its implementation. The standard, evolved from guidance, admonishes regulators that these tests do not substitute for an understanding of the biomaterial performance as a component of the device and the interaction of the body with the device and material. For example, these screens generally do not evaluate the long-term effects of the structural forces at work on the biomaterial when incorporated into an implant. Developers must recognize the need for animal studies designed to evaluate the function and potential failure of the implant in the intended use. Although beneficial as a standardized series of tests, the scope and intent of the ISO 10993 cannot incorporate all concerns for implant performance. Rather these test schemes should be viewed as a toxicological analysis with limited value in predicating the overall performance of a material in an implanted device.

Many of the biological screens that comprise the remaining parts of ISO 10993 are designed to evaluate specific aspects of biocompatibility, and therefore are not required for all medical devices. Part 3 briefly describes genotoxicity, carcinogenicity, and reproductive toxicity testing, but these descriptions do not constitute protocols. Detailed protocols must still be the role of the contract laboratory. Tests for blood interaction are listed in Part 4 with general requirements for the conduct of the tests, but again, specific protocols are beyond its scope. Cytotoxicity is described in Part 5 and evaluations for local effects after implantation are described in Part 6. Although this is meant to elaborate on evaluation of implanted materials, the scope of the evaluations listed specifically excludes implantation studies where the implant is subject to mechanical (functional) loading.

Part 7 describes the evaluation of medical devices for ethylene oxide residues and Part 9 is a technical report and considered still under development. It is intended to facilitate test procedures to evaluate biological responses to degradation products released from medical devices. Part 10 is a more fully developed standard providing specific protocol and acceptance criteria for the evaluation of irritation and sensitization. Sensitization testing has become one of the most expensive and time-consuming screens applied to even short-duration (less than 30 days) devices. Systemic toxicity is described in Part 11. Part 12 describes the preparation of samples and reference materials and provides recommendations for thickness or size of the sample proportional to the extraction ratio for testing. Part 13D could be viewed as a companion to Part 9, as Part 13 describes how to conduct an accelerated degradation test to determine if materials are prone to degradation and what the

by-products are likely to be. Unfortunately, such accelerated procedures can introduce conditions within the materials that are not mimicked in actual application. Part 15 describes the identification and quantification of degradation products from metals and alloys and refers to induced electrochemical degradation that may or may not be appropriate for the application of the device. Part 16 describes toxicokinetic studies that should be considered if the device is designed to be bioresorbable or if leachables might be expected to migrate from the device. Since the standard states that leachables from metals, alloys, and ceramics are usually too low to justify such studies, it is apparent that the standard is meant to apply to polymeric biomaterials.

FDA and international regulatory agencies expect medical device manufacturers to provide a clear analysis of the risks associated with the use of the product. This frequently requires a full understanding of the hazards inherent with the biomaterials employed in the manufacture of the product. The basic performance requirements of these materials within the device must be fully characterized by the device manufacturer. Risk analysis forms the basis of the testing of new products through verification and validation and includes, where necessary, all *in vitro* and bench trials, animal studies, and clinical trials. It is apparent that risk-based rationale for device evaluation will continue to develop as the backbone for regulatory oversight. ISO 14538—Method for the Establishment of Allowable Limits for Residues in Medical Devices using Health Based Risk Assessment is yet another example of this trend. The FDA issued a guidance in May 1999 titled “Immunotoxicity Testing Guidance” that refers to the ISO 10993 but sets forth a flow chart and yet another table to serve as a guide for whether or not immunotoxicity testing is required.

In conducting the risk assessment, regulatory authorities outside the United States recognize the “prior art” use of a medical material and give more credibility to literature studies in assessing risk. In the United States, despite statements that consideration will be given for prior use, the practical reality is that between manufacturers there is limited cooperation to share the information for prior use of a material in the same intended use. Even if this information can be determined from literature or predicate devices, it is seldom available at a level specific to formulation or sterilization method. As a result, for even mundane applications, the FDA may require extensive, costly, and time-consuming testing of medical polymers in acute toxicity screens despite years of empirical knowledge.

Where polymeric materials or metallic and ceramic materials are combined with growth factors (or with other biological agents) or pharmaceutical products, extensive testing is warranted. New concerns for the safety of biomaterials derived from human or animal products are increasing the regulations associated with medical products. The FDA has issued guidance for the use of animal materials used in medical devices. The guidance titled “Medical Devices Containing Materials Derived from Animal Sources (Except for *in Vitro* Diagnostic Devices”) has provided details on FDA’s concerns and how the FDA expects manufacturers will control the sources of the materials.

Shelf-Life and Aging

Physical property characterization and durability testing of the biomaterial in its intended use are critical parameters to establish. If failures begin to occur in the field, differences from baseline parameters can be crucial evidence to assist in establishing the cause. Shelf-life aging of medical device materials has become a required practice. This area will take on increasing concern as medical device manufacturers incorporate drugs and biologics as surface treatments to devices. Sterilization of the product prior to use can frequently affect the performance of the biomaterial and some sterilization effects are not readily apparent. The FDA requires that performance testing for the materials, as well as safety testing of the device, be conducted after the same sterilization cycle that will be applied to the finished product.

Changes to Regulated Medical Devices

Once a medical device product is on the market, a change to a biomaterial can trigger a new 510(k) or a modification of a 510(k) application. The FDA now allows for abbreviated 510(k)s, special 510(k)s, and third-party reviews. Alternative 510(k) submissions are a relatively new process and have not received broad implementation to date. As medical device manufacturers become more accustomed to the use of design control and review and the incorporation of international standards as a part of their input requirements to product design, it is expected that such abbreviated or special 510(k)s will be more commonly applied. For more information, the FDA has developed guidance: “Alternative Approaches to Demonstrating Substantial Equivalence in Premarket Notifications.” The FDA has provided a checklist for the modification of 510(k) devices in the guidance: “Deciding When to Submit a 510(k) for a Change to an Existing Device.” These helpful guides can assist manufacturers in determining whether or not a 510(k) would be expected by the FDA and the optimum way to present the information. In lieu of a 510(k) medical device manufacturers will need to document why the change to a biomaterial did not require a new 510(k).

Companies with Investigational Device Exemption (IDE) clinical studies, whether or not the studies are “significant risk” or non-significant risk, need to have a strategy for determining whether or not a change to a biomaterial triggers either a full IDE supplement, an IDE 5-Day Report, an Annual Report notation, or documentation to the file. In the circumstance of the “non-significant risk study,” there is no IDE, so typically the FDA would not be notified. Nevertheless, it is prudent to alert the Institutional Review Board about any modification to a material, if there is any reasonable doubt of the safety and risk to the patient. (In most circumstances, a non-significant risk study does not involve a biomaterial that could put a patient at risk.) Changes to materials should be reviewed using a decision tree and according to standard operating procedures within the company. Hazard analysis and risk assessment should be reviewed again to determine whether the change in the biomaterial has affected the safety of the product. Any change to a biomaterial should go through the design review and documentation system set up by the company. When in doubt, the

agency should be contacted, because the change to the material could require the study to be conducted under an IDE.

If changes are made to a marketed product as a result of a death or serious injury report or undertaken to prevent such injuries, the change could be subject to review by the U.S. Food and Drug Administration; particularly if existing products are removed from the market by way of “corrections or recalls.” Consult a regulatory consultant or attorney before making changes under these circumstances.

SUMMARY

Medical device regulations and recognized practices for applying biomaterials to new medical products change faster than chapters can be updated. Although this is a broad outline of the current regulations, consult the FDA for the most up-to-date requirements. At the time of publication, the FDA Web site is www.fda.gov.

10.4 ETHICAL ISSUES IN THE DEVELOPMENT OF NEW BIOMATERIALS

Subrata Saha and Pamela Saha

This chapter presents a brief review of ethical questions raised by ethicists and scientists in the course of development of new biomaterials. Engineers, scientists, and physicians need to become familiar with these issues to take part in this debate and they should play an active role in directing the standards of professionalism in the field of biomaterials.

INTRODUCTION

The field of biomaterials science has changed dramatically since its beginning a half century ago. We are no longer confined to improvement of metal alloys, plastics, and ceramics for use in the human body. Actual grown tissue (tissue engineering), even the cloning of human cells and organs, is within our reach. As more is possible, new questions and ethical concerns are raised. Should science set limits on itself? For example, if human beings can one day be cloned, should this be considered off limits for ethical reasons? The environment in which research is being conducted is changing. We see this in the intense competitiveness for recognition. Other factors involve financial and economic opportunities, as well as conflicts of interest in conducting objective research. The fields of science and ethics are themselves changing with increased awareness of the need for appropriate treatment of animal and human subjects in research pitted against the demand for more rigorous unbiased test results. This chapter briefly examines concerns associated with clinical trials, animal experimentation, industrial support of research, authorship, regulation, and patents.

CLINICAL TRIALS

A biomaterials engineer faces significant challenges in planning a study involving the use of patients. This step takes the engineer out of the traditional laboratory more dramatically than any other previous stage in the development of a new implant. A human subjects review committee at all institutions performing experiments on human subjects closely oversees this planning process to ensure strict adherence to ethical standards. At this point we examine some contrasts between the practice of medicine and the engineering and science professions (Gifford, 1986; Kopelman, 1983). A timely overview of the surgeon's ethical considerations in clinical treatment and research has been published (Angelos *et al.*, 2003).

In engineering and science, there is the obligation to objectively test one's theories, applications, and products, and to reasonably anticipate all hazards and potential for misuse or accident. A confidence level, a statistically significant level of probability, must be demonstrated within strict standards of accepted research protocol. When engineering studies are submitted for review by peers, the methods, data, and conclusions are scrutinized for possible flaws that may cast doubt on the validity of the findings. This same level of scientific rigor is, of course, expected for biomedical engineers and biomaterials scientists. The fact that the engineering advances would be applied to patients intensified the rigor of scientific inspection.

The historical roots of research in the practice of medicine was based on methods other than randomization techniques. From the days of Hippocrates, physicians were guided by the experience and observations. Medical journals do publish anecdotal observations. Medical conferences, in the past, consisted in part of presentations of respected physicians relaying their personal opinions based on their individual experiences with patients. Questions from participants follow this exchange of personal epithets in a collegial manner, in contrast to the near-adversarial challenges of claims made by carefully conducted research at scientific conferences.

Whereas the methods of scientists and engineers emphasize the pursuit of knowledge and accuracy of claims, practicing physicians have an additional compelling concern—providing the best care to an individual patient. This is understandable since trust and confidence is placed in the physician who is expected to be the ally of the patient. More recently, evidence-based medicine is rapidly gaining acceptance as the appropriate and justified basis for therapeutic protocols. The debate over randomized double-blind clinical studies, and when and if studies should be discontinued when there appears to be evidence demonstrating substantial advantage or harm, is an attempt to resolve the often conflicting demands of scientific evidence and the obligations of the therapeutic alliance. How and when to obtain informed consent for a study, the design of a termination strategy into a clinical trial to protect the patients, the right of self-determination of individual patients in their medical care, and the need to have accurate assessment for safe and effective care of larger numbers of people are all important considerations in the design of a study (Gifford, 1986; Kopelman, 1983; Rosner, 1987; Saha and Saha, 1988). The evidence suggests

that rigid guidelines cannot be broadly applied and that studies will need to be examined individually in terms of value of the knowledge, available avenues for obtaining it, risks involved to the patient subjects, informed consent problems and their impact on the study, and justifications for violating the therapeutic alliance. Most plans that involve randomization are likely to violate to some degree the therapeutic alliance with an individual patient, if this alliance is viewed in the extreme sense that only what is perceived best should be offered as treatment. However, if it is also true that treatment based on physician experience is not necessarily the optimal care then it can be argued that the traditional perception of a therapeutic alliance requires modification. Thus, some aspects of the practice of medicine and the scientific/engineering professions converge with the infusion of scientific values and acceptance of uncertainty. Also, engineers must appreciate the complex interaction between physician and patient, understand their own role in patient care, and come to share with the physician the obligations of the therapeutic alliance (Fielder, 1992).

ANIMAL EXPERIMENTATION

Another significant change over the post quarter of a century is our perception of animals and their place in research. That a research scientist has a moral obligation to provide a degree of humane treatment to animal subjects is now generally accepted without further debate. Guidelines as to how to comply with current standards for treatment of animals in research were first published in 1963 by the Institute of Laboratory Animal Resources, Commission on Life Sciences, National Research Council. This has been updated six times, most recently in 1996. A new biomaterials implant is likely to require testing in animals prior to testing in human subjects. Familiarity with ethical considerations, regulations, and review boards that oversee animal research is essential to successfully conducting such research.

Although there exists a general consensus in the scientific community that humane animal research is essential, there also is increased public questioning about the ethical appropriateness of all animal research. Militant protests including violence toward researchers and vandalism of research labs have escalated over the past 20 years (Saha and Saha, 1991, 1992). Despite these unacceptable methods of protest by some groups of animal rights activists, new concerns about animal research have entered the debate. A claim has been made that animals have rights and value equal to those of human beings. If this were to become generally accepted, it would certainly place near-insurmountable burdens on research in biomaterials. This would essentially be stating that the health and survival needs of human beings provide no moral justification for inflicting harm or risks on animals. This is the position of animal rights theorist Tom Regan (Whitbeck, 1998). This point of view leads to the inevitable conclusion that human beings are not justified in exploiting animals for human benefits. This would have to extend beyond research to the use of animals as sources of food, clothing, transportation, sport as in hunting and fishing, and beasts of burden. Even though animals can be said to have a moral standing with respect to human beings, perhaps even

a high moral standing, this need not be viewed as standing equal to that of human beings. Various criteria have been used to determine grounds for assigning degrees of moral standing, such as intelligence, ability to feel pain and pleasure, social interaction in a given species, resemblance to humans, position on the evolutionary ladder, and whether particular animals have been pets or even belong to a species commonly used as pets. All these factors present a case against which to weigh the benefits of a given study, and the possibility of achieving the same or acceptable goals by any other means. This has led to an increased interest in alternative models, i.e., computer models and the use of tissue culture. This may help reduce the use of animals but will not likely completely eliminate the need for some animal experimentation. Current knowledge of the biology of whole systems is far too limited to suggest that all pertinent factors could be programmed into a computer or that isolated cell colonies could provide an environment completely comparable to *in vivo* studies. While animal studies are essential for the advancement of the health and welfare of human beings as well as animals, and while exploitation of animals for this purpose may be justifiable, certainly every effort should be made to minimize the use of animal subjects, to provide for humane handling of animal subjects, and to restrict the use of mammals and other higher species.

INDUSTRIAL SUPPORT FOR RESEARCH

Not surprisingly, the successes stemming from biomedical research have brought about tremendous growth in the field. Demand and intensified activity have not only led to an increased need for funds for research, but an opening up of nontraditional sources of research support. As government funding can no longer meet the needs of academic researchers, industry has stepped in bringing with it ethical issues for the biomedical engineer (Saha and Saha, 1998). Justifiable concern over the influence of business interests and its impact on scientific integrity has been expressed. Controversy over conflict of interest issues raised by corporate sponsorship has recently led to editorial requirements to disclose funding sources on publications (Schulman *et al.*, 1994). This requirement has been extended by some journals to include revealing any other associated financial interests and additional bias, i.e., religion or even sexual orientation (Rothman, 1993).

This editorial position on disclosure of funding sources raises still other issues of fairness to authors as some authors protest that this disparages the research despite high quality content (Rothman, 1993). Still, useful guidelines must be developed for interactions between corporations and researchers that leave the integrity of the research intact.

The fact that business imposes problems as well as benefits for their scientist partners is exemplified in the story of Joan Sabaté, a Loma Linda University researcher who theorized that a diet high in nuts and low in fat could cut cholesterol (Stolberg, 1993). He felt that it would not be worthwhile to wade through the long, laborious and likely fruitless process of seeking government support. He therefore turned to industry and found support from the California Walnut Commission. The funding helped Sabaté obtain results that he published in

The New England Journal of Medicine. However, the study was only about walnuts, a modification of the original hypothesis that applied to all nuts. There is a clear suggestion here that the source of funding influenced the published outcome of the study, in spite of the undeniable value of the work.

More serious than the preceding example is the case of an engineer being asked by management to suppress data on a product that may delay or prevent FDA approval. Although the engineer has a duty to protect public safety that supersedes company loyalty, he should weigh and consider possible solutions to the problem that may best meet his responsibilities to all affected parties. Ethics is not just about judging behaviors as moral or immoral. It also has to do with determining the best course of action in a given case (Whitbeck, 1998). This implies that there is not just one possible right answer. There clearly are wrong answers, but the challenge is more than to simply reject these. In the case just offered, an engineer has been asked to do something that violates his responsibility to scientific integrity and to public safety. It is also illegal. What must the engineer do? One possible answer may be to inform the manager in question about the legal and ethical concerns raised by his order to suppress data. This would give the manager an opportunity to retract the order, thus possibly satisfying all allegiances. If the order was not retracted, there still could be other options before the engineer directly “blows the whistle” on the company: for example, going through the channels of the organization. The approach to ethical problem solving is to treat the situation as a practical matter that requires a solution. The goal would be to determine a plan that best addresses all conflicting loyalties and obligations. That is why discussions about these issues help honest and moral individuals learn new ways to solve ethical problems. Although there is little debate about judging certain specific acts of clearly unethical conduct such as fraud, the best right answer often takes serious contemplation and consideration.

AUTHORSHIP

Issues of credit, recognition, adequate as well as appropriate referencing, and plagiarism seem more pronounced today than they have in the past. This is due to several factors. There is what may be a disproportionate emphasis on quantity of publication for gaining tenure, for example. Despite the discussion of this topic in some recent publications, debate over how to assign credit and to protect claims to contributions in a field is an old matter. One need only read about the rivalry between Isaac Newton (1642–1727) and Leibniz (1646–1716) to understand the extent to which recognition is an important need among scientists and how such competition could lead to some destructive practices. One of the first efforts to address this problem among scientists was by the Royal Society in Great Britain, which established the convention of giving credit to the researcher who is first to publish or submit for publication a discovery (Whitbeck, 1998). Unfortunately little has been done today to establish conventions of assigning credit and recognition in a variety of contexts.

The one important question to answer about authorship is, who merits authorship of a particular work? After that,

how should the authors be listed? Conventions concerning authorship vary internationally as well as within disciplines and universities. Many of these are unspoken and efforts to discuss such matters openly may be met with some resistance. Caroline Whitbeck described such reluctance on the part of senior researchers and department heads: “One of the molecular biologists . . . said forcefully that he would refuse to discuss his criteria and practices with any student or post-doc, and tell that person if he wanted to work with him, he would just have to trust him” (Whitbeck, 1998). However, it is precisely this lack of open discussion that leads to misunderstanding and the distrust. As authorship concerns the whole community of scientists and is not confined to the needs of a single laboratory, professional organizations may be helpful in directing discussions on this matter to a fruitful end.

Assuming primary authorship over the work of those of lower rank by merit of position rather than contribution needs to be addressed. Department chairs, heads of laboratories, and research program heads may insist on authorship in exchange for financial support or use of a laboratory or equipment, or simply because he or she is the department head and has the power to insist on it. Standards of assigning authorship, referencing, and crediting others who have contributed in other ways need to be further discussed and examined (Armstrong, 1993). This is important to preserve a healthy environment for the production of meaningful biomedical research.

Authorship is not only about credit. It is also about responsibility. An author must be prepared to be accountable for a published work. That means that assignment of authorship can be harmful as well as helpful and so a scientist must consent to authorship. Some journals today require that all authors sign a submission form accepting authorship (Whitbeck, 1998). This practice was in response to some highly publicized cases of alleged fabrication of research that involved some scientists named on work for which they had not been responsible. Recently, *Science* has stated that it will publish short accounts written by each author describing their individual contributions to the published work.

Other problems of authorship include duplication of publications, gift authorship, stealing of ideas not yet published, and plagiarism by reviewers. These are not presented as issues in themselves as much as they point to a lack of redress or means for correction. A fair and effective mechanism for investigating charges of misconduct within the scientific community would be useful. This may help prevent excessive oversight by governmental agencies, which brings with it other problems such as sensationalistic coverage by the press.

REGULATION

Prior to 1976, the regulation of medical devices was limited to adequate labeling and prevention of marketing clearly fraudulent devices (Ratner *et al.*, 1996). When World War II came to an end, wartime advances in materials and engineering found promising use in medicine. Rapid progress in development of remarkable devices for use in the human body transformed the fields of cardiovascular and orthopedic surgery. Not surprisingly, there were failures of devices that caught

public attention. In 1976, this led to the Medical Device Amendment to the 1938 Federal Food, Drug, and Cosmetic Act. This amendment defined a medical device and empowered the FDA to regulate the devices at all stages of their development and use (Ratner *et al.*, 1996). A classification system provided a means for the FDA to impose different controls on devices according to the amount of risk presented. Class I involved products of least risk such as adhesive bandages and manually adjustable hospital beds. Class II products such as oxygen masks, blood-pressure cuffs, and powered wheelchairs were of intermediate risk. Class III are devices of highest risk, artificial heart valves, for example. In 1990 these FDA regulatory controls were expanded still more by the Safe Medical Devices Act.

In addition to governmental regulation, there are other prominent organizations that have developed guidelines for the design and testing of biomaterials. These are the American Society for Testing and Materials (ASTM), the Association for the Advancement of Medical Instrumentation (AAMI), and the American National Standards Institute (ANSI). These organizations form what are referred to as voluntary consensus standards. Conformation to these standards is voluntary. However, this provides engineers, scientists, and manufacturers with direction and tools for the management of compulsory governmental standards. The advantages of self-regulation over that imposed by lawmakers outside the field are evident. This reduces the burden on Congress and the FDA as well. Appropriate use of the voluntary system of standards is important to maintain trust that the field can regulate itself. It would fall into disrepute if standards were made that gave unjustifiable advantages to one industry over another. Engineers serve an important role in the standards process and also advise federal agencies on this subject. Members of governmental bodies tasked with approval for new devices have the difficult tasks of encouraging advancement, setting aside possible loyalties, avoiding conflict of interests, and evaluating a new product for safety and effectiveness (Saha and Saha, 1987).

PATENTS

Issues of credit and intellectual property reach beyond the order of authorship on papers and extend to protection of one's ideas that have potential for earning profit. The law offers some protection through the use of copyright and patent. Copyright is the right to exclusive publication and sale of a work. This protects against another taking the same work and reproducing it without permission of the holder of the copyright. However, as copyright has only to do with the actual expression of a work and not the ideas expressed, this does not protect against another taking the ideas. Ideas themselves cannot be copyrighted. As soon as a work is in some concrete form, that work is considered protected by copyright until 50 years after the death of the author. Copyright can be reassigned or inherited.

A patent is an exclusive right to produce, use, and sell a particular creation and to prevent others from reproducing, using, or selling a design that one has invented. For useful devices the

time limit on patents in the United States is 20 years. Proving a claim is reinforced by notebook keeping and documentation on the progress of an idea. Not all inventions are patentable. To patent a device one must prove it useful and original. Establishing a patent makes the details of an invention plain and in order to be eligible for a patent it must be applied for within 1 year of public disclosure.

Another means of protecting intellectual property is a trade secret. A trade secret is some method or design that gives one an advantage over the competition as long as it remains secret. Courts will protect trade secrets as long as the holder of the secret takes sufficient precautions to keep the secret secure. Confidential information is legally protected from wrongful disclosure. However, reinventing a trade secret or learning it through reverse engineering of a purchased product is acceptable. Although a trade secret has no time limits as a patent does, it does not restrict others from use of an idea if obtained legitimately.

Claims on intellectual property are applied differently in an academic setting as compared to industry. Invention and new product development in industry are rewarded with promotions, bonuses, and salary raises as opposed to ownership or having one's name associated with the work. This is recognized by the National Society of Professional Engineers, which states in its code of ethics that "engineers' designs, data, records, and notes referring exclusively to an employer's work are the employer's property" (Whitbeck, 1998). However, if research is done at a university, there exist an expectation that the work should be publishable. The concepts of confidentiality and trade secrets have greater significance in industry in contrast to the tradition of freely sharing ideas in an academic setting. Profit motive and competitiveness that restrained sharing of discoveries in industry led to copyright and patent protection so that published discoveries could still have protection. However, the conflicts associated with intellectual property are becoming a problem in the academic setting as well. This can lead to secrecy within research groups and laboratories. This might also curtail the benefit of learning from the work of others or even improving upon the work of others. This raises the question as to whether the public has some claim in the discussion about intellectual property rights. When company A holds patent B, only company A can fully develop and market it. If company A fails to make use of the patent or improve upon it, that particular line of advancement is confined internally to company A. Suppose for example that company A is designing a new material that can be grafted onto and integrated into the human circulatory system and can act as lung tissue. Company A has the idea patented broadly in terms of applications so that the material cannot be used by others for any medical purpose. The discovery, if successful, could be a breakthrough for treatment of lung disease and should have other applications in health care. However, company A has limited resources and will have to put the development of its new idea on hold. Another example is more ominous. Suppose there is a test to determine which candidates will respond to a certain kind of treatment against AIDS; let us call it drug X. However, company Y that makes drug X has a patent on the test and has decided not to develop the test and make it available. Does intellectual property right carry with

it some responsibility? Are there overriding moral concerns? While protecting ownership, are we losing sight of a greater duty to public health and welfare? Certainly a system that allows for the suppression of a new and better course of treatment in favor of a more profitable but less effective method of care needs reexamining. A healthy environment where respect for intellectual property can exist along with a sharing of ideas is best facilitated by the professionals who must deal with these issues daily. Openness in discussing these issues will help lead to a consensus among peers. Promotion of values by professional societies fosters the development of an ethically appropriate consensus.

CONCLUSION

We have introduced a few basic issues on the subject of ethics as it relates to biomaterials and medical devices. This is only a start. Change continues to transform our perceptions about what is possible, what we can do but perhaps what we should not do, about limits on research with humans and animals, and about the balance of objectivity and bias. Science and how it is conducted are changing. Medicine and the doctor–patient relationship are changing. The field of ethics has likewise grown. It has matured from what on the surface appeared to be a collection of conflicting principles into a useful basis for finding a resolution of potentially opposing considerations. One author has stated that ethical problems need to be approached in much the same manner as an engineer would approach a difficult problem in design (Whitbeck, 1998). This approach offers fresh insights useful for engineers, scientists, and physicians to address ethical problems.

10.5 LEGAL ASPECTS OF BIOMATERIALS

Jay P. Mayesh and Mary F. Scranton

INTRODUCTION

Students of biomaterials engineering know that no product lasts forever and that implantable medical devices have unwanted side effects. In today's litigious society, these factors often transform patients and device manufacturers into warring parties in always unwelcome and sometimes financially disastrous products liability litigation over the safety of medical devices. Products liability law imposes legal responsibility on manufacturers of products (ladders, cars, and medical devices, to name a few) as well as other companies involved in the “stream of commerce,” such as wholesalers, distributors, and retailers, for injuries incurred by the consumer.

Products liability plaintiffs typically rely on three theories of liability. First, they claim that the manufacturer was negligent, meaning that the manufacturer failed to use reasonable care in designing and manufacturing the product. Second, plaintiffs claim the manufacturer breached legally enforceable promises, called warranties, in that the product did not meet recognized performance expectations or have the expected qualities of products of its type. Finally, plaintiffs sue under strict liability, in which the manufacturer is held responsible for a product that was unreasonably dangerous to the consumer or carried inadequate warnings, regardless of the degree of care exercised, or any promises made, by the manufacturer. Strict liability rests on two assumptions about law and economics. The first of these is that imposing liability on a manufacturer, even without a showing of carelessness on the manufacturer's part, is fair because the manufacturer is best able to discover and correct defects in its products before they cause harm. The second assumption is that, in the event of personal injury attributable to a product, the manufacturer can afford to compensate the injured party, add the cost of the injury to the product, and, if necessary, raise the price to recover the cost. To avoid liability under these legal theories, medical device manufacturers must design, manufacture, and sell products that are reasonably safe, and they must disclose in written warnings to physicians (and sometimes to patients) all risks associated with the products.

Products liability falls within the area of civil law called *torts*. A tort is simply a wrongful act that may give rise to a lawsuit. The most common tort case is the auto negligence lawsuit. Professional malpractice claims against doctors and lawyers are also torts. If the plaintiff is successful, a tort lawsuit results in an award of money, called damages, against the defendant.

This chapter describes “mass tort” products liability litigation involving implantable medical devices—that is, personal injury litigation implicating thousands of individuals making a claim for injury as the result of failure of the same medical device. Although the individual injuries may vary, most if not all claims arise out of the same mode of failure or insufficient warning. Faced with numbers of cases in the tens of thousands and legal costs in the tens of millions of dollars, the parties often attempt to consolidate mass tort claims in order to streamline pretrial procedures and control costs, either by class action (Mayesh *et al.*, 1986) or by consolidated litigation, in which all cases are assigned to one judge. In the federal courts, consolidated litigation is termed “multidistrict” litigation.

Although medical device mass torts raise complicated scientific and medical issues, in the United States legal system, lay jurors, untrained in science, are the arbiters of reasonable safety, adequate disclosure, and causation. The vagaries of the jury system always create a degree of risk and uncertainty for litigants. That risk is compounded in medical device litigation when jurors are asked to discern which of many competing medical and scientific theories is more credible. Outcomes become even more unpredictable in cases involving unsettled or evolving areas of science.

To help illustrate the subtle and complex world of mass tort litigation, the five biggest subjects of medical device litigation are described below, followed by a discussion of some of the obstacles and advantages faced by litigants in prosecuting and defending these claims, including the problems posed by science in the courtroom.

INTRAUTERINE DEVICES

The first mass tort litigation involving a medical device arose out of injuries to women who received intrauterine devices (IUDs). In the early 1970s the IUD was presented to the public as a safe, effective alternative to oral contraceptives. In the following decades serious reproductive health risks associated with IUDs ensued, prompting women to sue the manufacturers.

A. H. Robins, the manufacturer of the Dalkon Shield, bore the brunt of IUD litigation. Because the Dalkon Shield predated the Medical Device Amendments of 1976 (see later discussion), no requirements for premarket testing were in place. As described in the case *Tetuan v. A. H. Robins Co.* (241 Kan. 441 [1987]), A. H. Robins was anxious to make inroads in the market and stave off competitors, and thus began marketing the device in 1971 having performed few safety and efficacy studies. While internal corporate documents reflected A. H. Robins' concerns with the paucity of information on the product, A. H. Robins nevertheless publicly touted the benefits of

the Dalkon Shield, distributing product cards that claimed the Dalkon Shield was superior to other forms of contraception and placing advertisements in popular magazines. These efforts earned the Dalkon Shield a dominant position in the IUD market.

As further detailed in *Tetuan*, shortly after the device came onto the market, the manufacturer began to receive adverse incident reports from doctors about health problems believed to be induced by the Dalkon Shield, including septic abortions and an increased incidence of pelvic inflammatory disease (PID). The Dalkon Shield, like other IUDs, has a string that descends through the cervix from the uterus to allow the user to ensure the device is in place. Before marketing the Dalkon Shield, the manufacturer had knowledge that the string had a “wicking” tendency, meaning it could transport fluid by capillary action into the uterus and introduce bacteria into an otherwise sterile environment. This wicking was alleged to be the cause of the comparatively high rate of infections and injuries in women who used the Dalkon Shield.

By the end of 1975, the lawsuits against A. H. Robins were sufficiently numerous that they were consolidated before a district court in Kansas for pretrial purposes (*In re A. H. Robins Co., Inc. “Dalkon Shield” IUD Products Liability Litigation*, 406 F. Supp. 540 [J.P.M.L. 1975]), and the number of lawsuits continued to multiply. Although A. H. Robins was successful in early suits, once certain damaging corporate documents became public, the tide turned, and plaintiffs began to win large verdicts. In May of 1985, in the pivotal *Tetuan* case, a Kansas jury awarded \$9.25 million in damages. Shortly after the *Tetuan* verdict, A. H. Robins filed for bankruptcy reorganization (Vairo, 1992). Under the reorganization plan, a trust fund of \$2.475 billion was established to pay outstanding claims against the manufacturer. The bulk of the fund came from another health-care company that agreed to make the contribution in order to acquire A. H. Robins (Vairo, 1992).

IUD plaintiffs have claimed injuries such as uterine perforations, infections, ectopic pregnancies, spontaneous abortions, fetal injuries and birth defects, sterility, and hysterectomies (*In re Northern District of California Dalkon Shield IUD Products Liability Litigation*, 693 F.2d 847 [2d Cir. 1982]). The theories asserted include failure to warn, unsafe design, breach of warranty, and fraud. Plaintiffs prevailed at trial and were able to negotiate large settlements because the defenses that manufacturers typically rely on in medical device litigation were less likely to avail the IUD defendants. Sometimes medical device manufacturers argue that their device cannot be linked with the type of injuries suffered by plaintiffs. In IUD cases, causation has been a less defensible issue as compared to other medical device litigation, because medical experts generally agree on the type of injuries IUDs can produce (Vairo, 1992). Although an IUD manufacturer may successfully argue that the plaintiff's injury had another cause, such as a sexually transmitted disease, the general causative correlation between IUDs and certain injuries is not in question.

In light of evidence that they were not sufficiently candid about health problems associated with their devices, IUD manufacturers also had difficulty proving they satisfied their duty to warn physicians of the risks of IUD use.

For instance, in *Nelson v. Dalkon Shield Claimants Trust* (1994 WL 255392 [D.N.H. June 8, 1994]) the court refused to dismiss the plaintiff's claims because the evidence showed that A. H. Robins failed to issue public warnings about the risks associated with the Dalkon Shield's string. Statutes of limitation, which provide an injured party a fixed amount of time to file suit after an injury occurs, frequently have provided IUD manufacturers with their strongest defense. Injuries caused by IUDs may not manifest themselves for many years, and an even greater amount of time may pass before the user becomes aware that the IUD may have caused the injury.

ARTIFICIAL HEART VALVES

Artificial heart valves are composed primarily of metal or carbon alloys and are classified according to their structure as caged-ball, single tilting-disk, or bileaflet tilting-disk valves (Vongpatanasin *et al.*, 1996). All three types have been the subject of products liability litigation.

In the late 1970s, 15 suits were brought against a manufacturer of a caged-ball valve. Plaintiffs claimed that defects in the valve caused it to wear out prematurely, resulting in major embolic complications, premature open heart surgery to replace the valve, and catastrophic poppet-ball escape from the valve cage. The theories of liability included negligence in the design, manufacture, and testing of the valve; breach of express or implied warranties; and strict liability (*In re Cutter Labs, Inc. "Braunwald-Cutter" Aortic Valve Products Liability Litigation*, 465 F. Supp. 1295 [J.P.M.L. 1979]). The manufacturer incurred significant legal expenses yet was only partially successful in defending the lawsuits (*Lindsay v. Cutter Laboratories, Inc.*, 536 F. Supp. 799 [W.D. Wis. 1982]).

Beginning in the mid-1980s, a manufacturer of a tilting-disk valve, implanted in 50,000 to 100,000 patients between 1979 and 1986 (*Bowling v. Pfizer*, 143 F.R.D. 141 [S.D. Ohio 1992]), became the object of numerous lawsuits due to the valve's potential to fracture. The valve in question was developed around the time the Medical Device Amendments of 1976 were passed and was thus one of the first devices to undergo the premarket approval process that the statute established (see later discussion) (House, 1990). Although the valve was subjected to FDA scrutiny, it did not receive the comprehensive evaluation that would be made today, because the FDA had not yet finalized procedures for granting premarket approval (House, 1990).

Even before the valve was marketed, the first instance of valve failure due to "strut fracture" occurred in clinical trials. The valve consists of a disk located inside a metal ring covered by a Teflon sewing ring, which is sutured to the heart. The disk opens and closes rhythmically, allowing blood to pass through the heart. The disk is held in place by two wire holders, the inflow and outflow struts. When the outflow strut fractures, the disk escapes from the ring, causing uncontrolled blood flow through the heart, usually resulting in death. As of 1990, 389 fractures resulting in 248 deaths had been reported (House, 1990).

According to a detailed Congressional report on the valve, based in part on examination of the manufacturer's internal documents, strut fracture was most likely caused or exacerbated by deficiencies in quality control procedures in the manufacturing process. The report contained allegations that the welding process for the valve was "out of control," that inspections were inadequate, and that the manufacturer was not willing to make the financial commitment necessary to correct the lack of oversight in the manufacturing process (House, 1990). By putting adequate manufacturing controls in place, this manufacturer might have at least reduced the potential for strut fracture and also placed itself in a better position to survive public scrutiny if problems with its valve arose in the future.

In addition, the manufacturer was subjected to criticism for its less-than-forthcoming response to the strut fracture problem. The Congressional report alleged that the manufacturer repeatedly provided misleading information to the medical community and the FDA, minimizing the frequency of strut fracture. It further contended that the manufacturer provided unreliable assurances that the strut fracture problem had been eliminated (House, 1990). After the manufacturer became embroiled in litigation, it continued to cloak information about the strut fracture problem, settling every death suit that was brought as a result of fractured valves, and insisting that the settlements be held in confidence (*Bowling v. Pfizer*, 143 F.R.D. 141 [S.D. Ohio 1992]).

Still the number of lawsuits against the manufacturer mounted, and eventually the manufacturer entered a settlement with a class of plaintiffs implanted with its valve who had not yet experienced fracture. Under the terms of the settlement, the manufacturer agreed to establish a \$75 million Patient Benefit Fund for research and heart valve replacement surgery and a Medical Compensation Fund of between \$80 million and \$130 million to provide cash payments to valve recipients. The settlement also guaranteed immediate cash payments in the event of a fracture and provided for contribution of another \$10 million for spouses of class members (*Bowling v. Pfizer*, 143 F.R.D. 141 [S.D. Ohio 1992]). The manufacturer's overall clumsy handling of the fracture problem highlights the mistakes medical device manufacturers should avoid to avert litigation.

The issue of whether a plaintiff whose heart valve has not failed can make a legally valid claim against a manufacturer has been addressed repeatedly. Generally, courts have demonstrated little willingness to entertain lawsuits based on a heart valve recipient's fear of future valve failure because they find that either physical injury or an actual device failure is a prerequisite to imposing liability on a manufacturer. However, exceptions to the general trend can be found. For instance, in a California case, *Kahn v. Shiley, Inc.* (217 Cal. App.3d 848 [1990]), the court allowed a plaintiff to proceed with her fraud claim, because the court reasoned that fraud does not challenge the safety or efficacy of the medical device. Because fraud allegations focus exclusively on the defendant's conduct, the fact that the plaintiff's valve had not failed was immaterial. In another case, *Michael v. Shiley, Inc.* (46 F.3d 1316 [3d Cir. 1995]), a court allowed the plaintiff to proceed to trial because, unlike most plaintiffs asserting fear of future valve failure, she

suffered a tangible injury because she underwent surgery to replace her heart valve.

PACEMAKERS

A pacemaker is a device that uses electrical impulses to reproduce or regulate the rhythms of the heart. Pacemakers have three components—a pulse generator, leads, and electrodes. The pulse generator produces and sends accurately timed electrical impulses to the heart. Then, the lead, an insulated wire, conducts the output of the generator to one or two electrodes located in the heart. Most currently implanted pacemakers are “bipolar,” meaning they have two electrodes, whereas older leads are usually “unipolar” and have only one electrode (Cobbe and Morley-Daves, 1997).

Widely publicized instances of lead-wire fracture in certain pacemaker models sparked mass litigation. The type of lead wire at issue was encased in a polyurethane coating that tended to hold the lead in the proper shape. The lead wire had a potential to break, puncture its coating, and cause serious injury to the heart and blood vessels (Cohen, 1995).

Commonly, plaintiffs have alleged injuries resulting directly from the malfunction, as well as injuries incident to pacemaker replacement surgery. In *Rogerson v. Telectronics, Co.* (1998 WL 559788 [N.D. Ill. Aug. 25, 1998]), the plaintiff sued after she suffered heart failure when her pacemaker malfunctioned and she was subjected to two open-heart surgeries to remove and replace it. In other instances, as in *In re Cordis Corp. Pacemaker Product Liability Litigation* (1992 WL 754061 [S.D. Ohio Dec. 23, 1992]), plaintiffs have filed class actions seeking, among other relief, that manufacturers bear the cost of medical monitoring of patients implanted with a pacemaker model with a known potential to malfunction.

Pacemaker manufacturers have been largely successful in defending products liability suits, and, in several cases, they have succeeded in convincing courts to dismiss plaintiffs' claims before trial. For example, in one case, *Ellis v. Cardiac Pacemakers, Inc.* (1998 WL 401682 [W. D. N. Y. July 17, 1998]), the court dismissed plaintiff's manufacturing defect and design defect claims because the plaintiff failed to present evidence of any error in the manufacturing process or any evidence that a safer design was feasible. The failure-to-warn claim was dismissed under the “learned intermediary” doctrine, which provides that, in the case of most medical devices, a manufacturer has discharged its duty to warn once it has informed the medical community (not the patient) of the risks associated with a medical device.

Despite their record of success in litigation, pacemaker manufacturers in recent years have twice agreed to settlement of class actions brought against them. One manufacturer agreed to create a \$60 million fund to settle 1500 claims brought by recipients of pacemakers with allegedly defective leads (Anonymous, 1996). Another manufacturer agreed to create a \$57.2 million benefit fund for persons who received allegedly defective pacemaker lead models, although under the terms of the settlement, the manufacturer admitted no wrongdoing (Anonymous, 1998a).

PEDICLE SCREWS

Pedicle screws are bone screws that are implanted in the pedicles of the spine and are used to anchor a variety of stabilizing hardware. Litigation involving pedicle screws was sparked by a December 1993 exposé on the ABC news program, 20/20. The story publicized allegations that pedicle screws, which at that time had received FDA approval only for use in the long bones of arms and legs, were being implanted in the pedicles, a procedure associated with a high rate of complications (Brown and Sawicki, 1997). The story spawned a multitude of lawsuits, which were consolidated before a Pennsylvania district court for all pretrial procedures (*In re Orthopedic Bone Screw Products Liability Litigation*, 176 F.R.D. 158 [E.D. Pa. 1997]). Before that court relinquished control of the litigation, 2300 civil actions involving more than 5000 plaintiffs were before it (*In re Orthopedic Bone Screw Products Liability Litigation*, 1998 WL 118060 [E.D. Pa. Jan. 12, 1998]).

Plaintiffs alleged several variants of device failure. They complained that pedicle screws implanted in their spines broke, loosened, corroded, or were malpositioned, causing, among other injuries, pseudarthrosis, neurogenic bladder, and arachnoiditis. In addition to device failure, plaintiffs also alleged that manufacturers committed fraud on the FDA by seeking FDA approval for pedicle screw use only in the long bones of the arms and legs, but then promoting their use in spinal surgery. Plaintiffs have also attempted, unsuccessfully, to impose liability on doctors and medical associations, alleging they conspired with manufacturers to commit fraud by conducting medical seminars that promoted pedicle screws for unapproved uses.

Plaintiffs have argued that manufacturers should be liable for failing to warn of the risks inherent in pedicle screws. As with many pacemaker cases, failure-to-warn claims involving pedicle screws have frequently been dismissed by courts under the “learned intermediary” doctrine, particularly when the implanting surgeon testifies that he was aware of the risks through sources entirely independent of the manufacturer's product literature. In addition, plaintiffs have claimed, usually without success, that the pedicle screws were defective. In *Toll v. Smith & Nephew Richards, Inc.* (1998 WL 398062 [E.D. La. July 14, 1998]), for instance, the court dismissed the case because the plaintiff could not make the required showing that an alternative design capable of preventing the alleged injury existed. Courts have found that lack of FDA approval for use of pedicle screws in the spine does not strengthen plaintiffs' claims of defect, and that “off-label” use of a medical device (that is, use for a purpose other than that for which it is FDA-approved) is not prohibited. Finally, since spinal surgery can have complications regardless of instrumentation used, plaintiffs' claims have frequently failed because they could not show that their injuries were not complications of surgery unrelated to the use of the screws.

As the discussion indicates, many claims against pedicle screw manufacturers have been dismissed by courts prior to trial. However, a handful of cases have reached juries, and the results have been mixed. A Louisiana jury rendered a verdict against one manufacturer in the amount of \$318,000

after finding the pedicle screw was unreasonably dangerous (Anonymous, 1995a), and a Texas jury awarded the plaintiff \$451,000 against one manufacturer for misrepresenting the safe and effective use of its pedicle screws (Anonymous, 1998b). On the other hand, a Pennsylvania jury rendered a verdict for the defendant manufacturer (Anonymous, 1995b), and a Tennessee trial ended with a hung jury (Anonymous, 1998c).

The financial strain of the massive litigation prompted one manufacturer to settle and agree to contribute \$100 million and the proceeds of its insurance policies to a settlement fund. In exchange, the manufacturer, as well as its distributors and physicians and hospitals who used its products, were released from suit under any products liability theory (*In re Orthopedic Bone Screw Products Liability Litigation*, 176 F.R.D. 158 [E.D. Pa. 1997]).

SILICONE BREAST IMPLANTS

Since the early 1960s, an estimated 2 million silicone breast implants have been implanted in women, for both breast augmentation and reconstruction. Silicone breast implants are made out of a polydimethylsiloxane (PDMS) elastomer shell, to which fumed amorphous silica is added, encasing PDMS gel or saline. Some implants have been manufactured with a thin layer of polyurethane foam covering the elastomer shell; this was thought to decrease the formation of capsular contracture (hardening of the scar capsule surrounding the implant with resultant disfigurement), one of the common local complications of breast implants.

Physicians have long recognized that silicone breast implants (including those filled with saline) occasionally cause local complications such as capsular contracture, and that implants can rupture, often necessitating surgery to remove and replace the implants. However, it was not until the early 1990s, spurred by a television exposé and the publication of several case reports of women with implants who developed autoimmune diseases, that breast implants exploded into mass tort litigation. The FDA, having classified silicone breast implants as Class III devices that “present a potential unreasonable risk of illness or injury” in 1988, enforced the requirement that manufacturers collect and provide safety data on silicone breast implants. At this point, no controlled epidemiological studies exploring the relationship between breast implants and systemic disease existed. Citing the lack of safety data, the FDA imposed a moratorium on use of silicone breast implants, except in clinical studies.

Meanwhile, tens of thousands of implant recipients sued the implant and raw material manufacturers, claiming that they had developed autoimmune diseases, such as lupus, scleroderma, and fibromyalgia. To establish that the implants caused illness, plaintiffs’ lawyers relied on uncontrolled case reports of autoimmune disease in women with implants and on anecdotal testimony by treating physicians to persuade juries that the implants caused illness. They also relied on early case reports of autoimmune disease following direct injections of silicone liquid and paraffin into the breasts of Japanese women. Although none of these sources of evidence scientifically established

that breast implants cause autoimmune disease, several early plaintiffs won large verdicts.

After publication of the first well-controlled epidemiological studies refuting an association between implants and recognized autoimmune diseases, many plaintiffs modified their injury claims. They alleged that they had developed “atypical” autoimmune diseases with signs and symptoms that would not have been looked for in the studies that tracked the classic autoimmune diseases.

Plaintiffs premised liability on assertions that manufacturers defectively designed the implants and failed to warn physicians and patients of health risks. A central allegation in plaintiffs’ lawsuits has been that silicone has myriad ill effects on the immune system. Plaintiffs claim that, as a result of rupture of the implants and “gel bleed” of low-molecular-weight PDMS through the elastomer shell, silicone microdroplets migrate to remote organs where the silicone causes a chronic inflammatory response and the development of silicone granulomas (Plaintiffs’ Submission and Proposed Findings, 1997). Moreover, they claim that silicone is an antigen capable of eliciting an immunologic response in the body, and that silicone acts as an adjuvant, heightening the body’s immunologic response to other substances. Plaintiffs claim that silicone, through these mechanisms, exacerbates existing autoimmune diseases and causes classic and atypical autoimmune diseases in exposed women.

In addition to citing gel bleed as a factor in causation, plaintiffs offered several theories that implicate biodegradation of silicone. They alleged that silicone, migrating throughout the body, is picked up by phagocytes and transformed into crystalline silica, which, they claim, is immunogenic and causes connective-tissue disorders. Moreover, they allege that the silicone biodegrades into silanols, relying on *in vivo* NMR spectroscopy studies that purported to identify silicone and its metabolic by-products in the blood and livers of exposed women. Other scientists have been unable to replicate these NMR findings (Macdonald *et al.*, 1995; Mayesh and O’Hea, 1997).

In a medical science atmosphere of case reports and elaborate scientific theories raising questions and uncertainties, even though no epidemiological studies supported causation, the industry was prepared to spend approximately \$4 billion to settle claims globally. The plaintiffs demanded more money, and settlement fell apart. Faced with potential liability and enormous defense costs, Dow Corning, the largest manufacturer of breast implants, was forced into bankruptcy.

Over time, scientific evidence began to mount against causation. Each epidemiology study from leading institutions such as the Mayo Clinic, Harvard Medical School, Johns Hopkins University, the University of Michigan, and the University of California failed to show any association between silicone breast implants and any autoimmune disease or atypical disease. Nonetheless, occasionally manufacturers were still subjected to substantial jury verdicts.

In 1996, the Coordinating Judge before whom all lawsuits filed in federal court were consolidated for pretrial proceedings appointed a National Science Panel of four impartial scientific experts. An immunologist, epidemiologist, toxicologist, and rheumatologist were charged to evaluate the scientific data

on silicone breast implants in relation to connective tissue diseases and immunologic dysfunction (National Science Panel, 1998). These experts were instructed to “review and critique the scientific literature pertaining to the possibility of a causal association between silicone breast implants and connective tissue diseases, related signs and symptoms, and immune system dysfunction.”

On three occasions in 1996 and 1997, the panel heard testimony from medical and scientific experts chosen by the lawyers for plaintiffs and for the manufacturers. The panel received more than 2000 documents from counsel for plaintiffs and manufacturers, and the panel members performed their own literature searches. The panel concluded in November 1998 that available data do not support a connection between silicone breast implants and any of the defined connective tissue diseases or other autoimmune or rheumatic conditions (National Science Panel, 1998).

PREEMPTION

As discussed in the preceding section on regulation of medical devices, medical device manufacturers were not required to seek FDA approval for new medical devices prior to 1976. In that year, a new regulatory scheme was implemented under the Medical Device Amendments of 1976 (MDA). The MDA includes a “preemption” provision, Section 360k(a), which states that “no State . . . may establish . . . any requirement (1) which is different from, or in addition to, any requirement applicable under this chapter, and (2) which relates to the safety or effectiveness of the device. . . .” Manufacturers have frequently argued that the MDA’s preemption provision precludes plaintiffs from bringing lawsuits under the tort law. The preemption defense succeeds if the court finds that Congress intended that the federal MDA scheme govern the question of device safety to the exclusion of the tort law.

In 1996, the Supreme Court addressed preemption in the context of medical device litigation in a case called *Medtronic Inc. v. Lohr* (518 U.S. 470 [1996]). The Court considered the issue of whether state tort law claims against the manufacturer of a pacemaker, approved by the FDA under the abbreviated premarket notification process, were preempted. The Court unanimously determined that the plaintiff’s design defect claim was not preempted because the premarket notification process merely focuses on the “substantial equivalence” of a device, not its safety. The Court also unanimously agreed that the plaintiff’s claims were not preempted to the extent that the plaintiff alleged that the pacemaker manufacturer violated FDA regulations. It found that the preemption provision, and its accompanying regulations, did not preclude claims that imposed requirements mirroring those imposed by federal law. Finally, the Court found that the plaintiff’s manufacturing and labeling claims were not preempted.

Following the *Lohr* decision, the proper interpretation of the MDA’s preemption provision has continued to divide courts. However, certain patterns are discernible. The extent to which tort law claims are preempted has usually been determined by the regulatory status of the medical device in question. When the device was marketed under the premarket

notification process, courts, in accordance with *Lohr*, have found that tort law claims are not preempted. The impact of *Lohr* is highly significant in this respect. As the Supreme Court in *Lohr* pointed out, the FDA has had difficulty keeping up with the Pre Marketing Approval process, and as a result, most new medical devices obtain FDA approval under the “substantial equivalence” exception. Therefore, for manufacturers of the large number of devices marketed after obtaining FDA approval through the premarket notification process, the MDA’s preemption provision will not provide a defense. In contrast, when a device was marketed only after securing FDA approval through the more comprehensive Pre Marketing Approval process, courts have frequently found that most tort law claims are preempted. Similarly, courts have found that claims against manufacturers of devices that have been granted an investigative device exemption are preempted.

It should be noted that no matter what the regulatory status of a particular medical device, under *Lohr* and subsequent judicial decisions, claims that are based on violations of FDA regulations are not preempted. Therefore, no manufacturer can assert preemption as a defense to all potential claims.

SCIENCE IN THE COURTROOM

When medical device lawsuits reach the trial phase, the expert witness assumes a critical role. Whether an allegedly defective medical device caused the plaintiff’s injury is an issue deemed beyond the ken of the average juror, and courts therefore require the litigants to present scientific evidence in the form of expert opinions. The courtroom, however, is a forum ill-suited to discussion of scientific principles, and the scientific evidence communicated to jurors too often fails to meet the standards of reliability our judicial system envisions.

Laypersons who lack schooling in the fundamentals of scientific inquiry are prone to biases. For instance, a layperson would be more inclined to accept coincidence as proof. As Marcia Angell, editor of *The New England Journal of Medicine*, noted, many people might find reasonable the proposition that mere temporal relationship, i.e., that health complications followed breast implantation, is sufficient proof that the implants caused the injuries (Angell, 1996). A scientist, on the other hand, is trained to understand that association is not causation and anecdotal reports are no substitute for scientific data.

The gap between a layperson’s and a scientist’s understanding of cause and effect yawns even wider in the courtroom because both the goals and the methods of science and litigation are at odds (Mayesh and Ried, 1986). Litigation and science employ disparate standards of proof, as well as disparate measures of causation. Science examines causative correlations in the population at large, whereas litigation asks whether a particular device caused a particular plaintiff’s injury. Moreover, litigation and scientific inquiry demand quantitatively different standards of proof. Scientific inquiry seeks to establish causal relationships to a 95% degree of certainty, whereas judicial inquiry requires only a 51% probability of correctness. Under these circumstances, it is easily imaginable that a jury could

determine that a systemic disease was caused by exposure to an implanted device while a scientist would find the same evidence merely sufficient to suggest an interesting hypothesis (Mayesh and Ried, 1986b).

As a practical matter, the judicial system's goal of timely conflict resolution would not be well served by imposing the standards of the scientific community on the courtroom. Lawsuits must be resolved in a few years. Questions of science typically take decades of testing and data accumulation before repeatability can be achieved and the question thereby resolved. To resolve the tension, the judicial system has fashioned a compromise by allowing juries to hear only that scientific evidence deemed by the judge to be reliable and generally accepted within the scientific community.

The saga of DNA identification is an example of how judges serve as the gatekeepers of whether scientific evidence is allowed before the jury. Until DNA typing became generally accepted as reliable, it was not even allowed into the courtroom. Now that it has been established as accepted methodology, DNA proof may be put before the jury although, of course, subject to rigorous dispute over correct methodology. This model, however, does not always prove satisfactory.

Because scientific inquiry is typically characterized by a degree of uncertainty, deft litigants may succeed in casting doubt upon strong scientific proof. On the other side, experts for hire are sometimes allowed to spin unproven theories in order to strengthen the inclination of jurors to assume that anecdotes are the equal of data and association the correlate of cause. At the conclusion of the evidence, 12 laypersons, who have listened to experts express conflicting opinions, vote on which is more persuasive. The opinions themselves need not be held with more than a "reasonable degree" of scientific certainty, which the giver of the opinion may define as "more probable than not." Although the jurors need usually be unanimous, their measure of confidence need only reach "a fair preponderance of the credible evidence," meaning 51%. Little wonder, then, that there is a disconnect between real science and courtroom science.

BIOMATERIALS ACCESS ASSURANCE ACT

Plaintiffs suing the manufacturer of an allegedly defective device sometimes also join as defendants the suppliers of its raw materials and component parts. The incentive to sue a raw material supplier is particularly strong if the supplier has significant financial resources and the medical device manufacturer has limited assets. For instance, DuPont, a supplier of Teflon used in TMJ implants, was named in a succession of lawsuits after the small manufacturer of the implants went bankrupt (Birnbaum and Jackson, 1998; Harper, 1997). Although bulk suppliers have consistently succeeded in having suits against them dismissed, the cost of litigation can nonetheless be substantial. After weighing the risk of becoming embroiled in expensive litigation against the tiny profits derived from the medical device market, bulk suppliers began to deny manufacturers access to their products.

To address the dwindling supply of biomaterials essential for the manufacture of implantable devices, Congress passed the Biomaterials Access Assurance Act of 1998. The act shields suppliers of raw materials and component parts from liability unless the supplier is also the manufacturer or seller of the device, or furnished materials or components that did not comply with contractual requirements or certain other specifications. Under the act, a supplier named in a lawsuit is entitled to move for dismissal immediately. Once the motion to dismiss is filed, the supplier is excused from participation in any "discovery," the expensive and time-consuming process by which litigants seek information from each other before trial. Limited discovery is allowed only to determine whether a supplier failed to comply with contractual requirements or specifications.

After dismissal from the lawsuit, the supplier may still face liability in certain, limited circumstances. After a verdict against the device manufacturer, the plaintiff or the manufacturer can require the supplier to pay part of the judgment if the court determines that the supplier's negligent or intentional conduct was a cause of the plaintiff's injury. The plaintiff may only utilize this procedure if the full amount of damages cannot be recovered from the manufacturer.

LIABILITY OF THE DESIGN ENGINEER

For several reasons, an individual design engineer is an unlikely defendant in medical device cases. First, plaintiffs know that manufacturers are more likely to have the financial resources to compensate them for their injuries. Second, a plaintiff gains a "David and Goliath" tactical advantage by suing only the manufacturer, and not the design engineer. A jury will be more inclined to sympathize with a plaintiff if the case is viewed as a confrontation between a single individual and a corporate giant. However, if sued, a design engineer is theoretically not immune from liability.

The theories available to plaintiffs are less expansive when suing a design engineer as opposed to a manufacturer. Design engineers may be liable under a theory of professional malpractice, which asks whether the design engineer has exercised the degree of care reasonably expected in the profession. Liability will only be imposed if the design engineer is found to be at fault for failing to live up to that standard. In contrast, a medical device manufacturer may be found liable under a strict liability theory, which requires no showing of carelessness.

Courts have generally recognized that the policy objectives underlying strict liability would not be furthered by applying the theory of strict liability to design engineers. Courts have reasoned that design engineers provide a professional service and do not occupy the same superior position that allows manufacturers to discover defects and spread economic losses.

Although the law of strict liability is subject to some flux and uncertainty, the great weight of judicial precedent provides a good deal of assurance that a design engineer who develops a medical device will not be held liable. And, as a practical matter, a design engineer is rarely, if ever, named as a defendant.

DEFENSIVE MANUFACTURING AND MARKETING

Although little can be done to prevent a plaintiff from initiating a lawsuit, the best defense to a products liability suit is having manufactured a safe, well-designed product with legally adequate warnings (Mayesh and Rome, 1992). In virtually every lawsuit alleging injury caused by a medical device, the plaintiff—and eventually jurors—will have access to the manufacturer's internal corporate documents. These include lot histories, manufacturing specifications, results of toxicology and safety tests, quality assurance documents, FDA submissions and compliance reviews, adverse incident reports, and intracorporate memos discussing all of these, whether paper or e-mail. The majority of these documents will have been prepared many years prior to the lawsuit, often by personnel who are no longer employed by the manufacturer at the time of trial.

If the manufacturer makes the proper investment up front in designing, manufacturing, and selling the product, these documents can be the best proof that the manufacturer performed all necessary safety testing, that the product design conformed with all government and industry standards, that no manufacturing defects occurred, that warnings and instructions for use were legally appropriate, and that the manufacturer complied with all regulatory requirements for device approval. Moreover, the documents should establish that the manufacturer took appropriate postmarket actions. This includes documentation that it was responsive to adverse incident notices from doctors and patients, had a method of tracking such complaints as well as resolving them, and when appropriate, took postmarket action, such as product recall and issuing revised warnings.

Perspectives and Possibilities in Biomaterials Science

BUDDY D. RATNER, FREDERICK J. SCHOEN, JACK E. LEMONS, AND ALLAN S. HOFFMAN

The field of biomaterials is a young one with perhaps 50 years of formal history. We have emerged from an era in which biomaterials research and development was driven by surgeon–visionary–entrepreneurs (the “surgeon hero”; see *A History of Biomaterials*) to the beginning of the 21st century where development activities have largely transferred to university, government and industry laboratories. Early 21st-century biomaterials science is characterized by the integration of exciting discoveries from molecular and cell biology, materials science, and clinical medicine. Experiments driven by an immediate need to address a problem with a patient (i.e., make a device and get it into the clinic as quickly as possible) are more and more being supplanted by systematic, hypothesis-driven investigation by teams of engineers, basic scientists and physicians. This new style of research invites the incorporation of recent scientific ideas into the development of biomaterials. In this epilogue to *Biomaterials Science: An Introduction to Materials in Medicine*, the editors offer to those interested in the future of biomaterials a potpourri of representative ideas and perspectives that have the potential to revolutionize the field. This chapter is intended to stimulate vision, dreaming, and planning. Some of the ideas presented in this section are predicated (1) upon molecular engineering (engineering from the molecules up rather than the bulk properties down), (2) on new ideas from physics, and (3) on advanced materials science. The growth in nanotechnology and engineered tissues also contributes to more biospecific and mechanically appropriate materials. Many of these basic ideas have been expanded upon elsewhere (Drexler, 1992; Lehn, 1988, 1995; McGee, 1991; Prime and Whitesides, 1991; Ratner, 1993; Tirrell *et al.*, 1991; Ulman, 1991; Ratner and Ratner, 2003; Fuchs *et al.*, 2001; Griffith, 2000; Griffith and Naughton, 2002; Hench and Pollak, 2002; Hubbell, 1999; Langer, 2000; Langer and Vacanti, 1993; LaVan *et al.*, 2002; Vacanti and Langer, 1999). Other ideas described in this chapter come from the contemporary medical and biomaterials literature.

Our choices for these “capsule reviews” of new ideas hardly present a complete list of exciting frontiers. There are many other new ideas, paradigms, and algorithms that might be

equally influential. The important point is that biomaterial science can freely use many ideas—we, the biomaterials community, have long ago passed beyond the rigid barriers of a small collection of conventional academic disciplines, and we now concentrate on solving problems relating to human health and the interactions of biological systems with materials without concern for these disciplinary silos.

Here are some contemporary areas that offer the possibility to transform aspects of today’s biomaterials science and lead to exciting advances in human health and the quality of life.

BIOMATERIALS AND GLUCOSE SENSING MEET PHOTONICS

The rainbow iridescence characteristic of opals is associated with multilayer diffraction from organized arrays of amorphous silica nanospheres embedded in an amorphous silica matrix. The colors in an opal are dictated by the size of spheres, their spacing, and the refractive index difference between spheres and matrix. Professor Sanford Asher of the University of Pittsburgh has brought this principle to glucose sensing (Alexeev *et al.*, 2003). Dr. Asher’s group assembles monodisperse silica nanospheres into close-packed sphere arrays. In the interstitial space between the spheres he infiltrates a hydrogel monomer and then cross-link–polymerizes the system to a gel. The gel is then soaked in hydrofluoric acid to solubilize the silica spheres leaving hollow cells within the hydrogel (a template fabrication method). The material is seen to have an opal-like appearance. Interestingly, when the gel is swollen (in different solvents, for example), the color shifts distinctly (Fig. 1). By coupling a novel, reversible cross-linking reaction into the gel that causes the gel to swell proportionately to solution glucose concentration, he has created a system that changes colors profoundly in response to glucose concentration over the range from hyperglycemic to normal to hypoglycemic. A strip of this unique gel has been incorporated into a contact lens. Since tear glucose is in equilibrium with blood glucose,

FIG. 1. The principle of a photonic crystal gel whose color changes with gel swelling and glucose concentration (courtesy of Professor Sanford Asher).

when a diabetic's blood sugar rises, the gel strip changes colors. A diabetic wearing this contact lens carries a small mirror with a built-in light source and a color code around the edge. By gently pressing down the lower eyelid to expose the lower portion of the eyelid, the diabetic can directly read his or her glucose level off the color chart. Importantly, tear proteins do not seem to damage or affect the glucose sensing.

This development is deserving of inclusion in this section on Perspectives and Possibilities because it brings the rapidly growing (and glowing) area of photonic materials to biomaterials. The template-synthesized glucose-sensitive gel also freely exploits ideas from materials science, physics, polymer chemistry, biochemistry, medicine, and optics and leads to a new concept that may dramatically improve the quality of life for diabetics, a far cry from the frequent needle sticks required at this time to draw blood.

LACK OF "PURE" AND "SAFE" NATURAL BIOMATERIALS

Nature offers us a wealth of materials that have shown potential for application in biomaterials. Some examples include alginate (from seaweed), chitin (from crab shells), silk (from silkworms) and nacre (from sea shells). Such materials are generally plentiful (hence, in principle, low cost) and can have remarkable functionality and material performance.

However, because of their origins in natural environments, these materials often have substantial contamination levels from bacteria, other living creatures, biosynthesized molecules, and pollutants (sometimes referred to as the "bioburden"). Furthermore, proteins and protein-based materials derived from sources such as cattle offer almost endless possibilities for controlled-release systems, therapeutics, and materials (for example, collagen or fibrin). Yet these proteins can harbor potentially deadly or undesirable agents such as viruses, prions, or bacteria. Furthermore, all these biomaterials and therapeutic agents are difficult (or impossible) to sterilize. There is a pressing need for methodologies to clean, purify, and sterilize biomaterials derived from natural sources. These methodologies must be scalable to permit production at economically reasonable levels. Some progress has been made in removing endotoxin from protein preparations (Dudley *et al.*, 2003). Also, some manufacturers do sell these materials in highly pure forms, but costs are high. Beyond purity and sterilization a larger challenge remains—what remarkable biomaterials might be developed from materials from natural sources if safe, plentiful supplies of such materials were available?

SELF-ASSEMBLED MATERIALS

Physicist Richard Feynman, in his classic address that launched the nanotechnology revolution (Feynman, 1960), proposed the engineering materials from the bottom up—self-assembling the materials from atoms and molecules. Self-assembly is a central principle of nature and can be used for surface modification (Chapter 2.14). Self-assembly can also be used to make three-dimensional materials, probably the most impressive example being life, which self-assembles from molecules that are synthesized when the sperm meets the egg. Materials made by self-assembly have high degrees of order and orientation at various length scales including nanometer, micron, and millimeter. Numerous examples are available of self-assembled structures, typically made with specially synthesized designer molecules that have shown potential for biomaterials applications. Professor Sam Stupp uses an amphiphile approach to synthesize elegant structures (Stupp *et al.*, 1997). These structures have found application for bone repair and nerve regeneration. Professors Robert Langer and Gabor Somjai have used self-assembly to create smart surfaces that switch from hydrophobic to hydrophilic by turning on and off an electrical potential (Lahann, *et al.*, 2003b)(also described later in the sub-section on "novel elastic and 'smart' biopolymers.") DNA nucleotide bases have been noted to self-assemble (Boland and Ratner, 1994), and this assembly process has been implicated in the evolution of life on earth (Sowerby and Heckl, 1998). Nonadhesive, glycolyx-like surfaces have been created using self-assembling oligosaccharide surfactant polymers (Holland *et al.*, 1998). Silk proteins assemble leading to the remarkable physical properties of these fibers (see later discussion). The examples are so numerous that the reader is referred to one of the many reviews and monographs on this subject. Importantly, this self-assembly design principle will lead to precision-engineered, readily manufacturable biomaterials of the future.

DNA TECHNOLOGIES

Nucleic acid polymers (DNA, RNA) are largely thought of as information coding systems. The reading of the 3 billion base pairs making up the human genome was a triumph of technology, biology, perseverance, and politics—there will inevitably be important advances in medicine and human health that will appear as this huge data set is translated into useful information (Lander *et al.*, 2001). However, the wider possibilities for nucleotides have been pointed out by Ronald Breaker in describing the nucleic acid space. With one monomer unit we might have four possible molecules (A, T, G, C). If we consider three monomer units, the possibilities go to 64 (codons in the genetic code). If $N = 85$ we could create 10,000 earth masses of DNA of unique molecules. Nature has not nearly exhausted the possibilities . . . we as engineers can explore this molecular space. What might be done with nucleotide polymers?

Interestingly, the molecular building blocks making up DNA and RNA have shown the potential for sophisticated, designed molecular-structure formation and specialized functionality. DNA is stable, is water soluble, and can be made in forms that are rigid or flexible. Endonucleases and restriction enzymes allow chains to cut in precise molecular positions while ligases permit them to be reconnected. This synthetic flexibility has triggered impressive creativity (Luo, 2003). For example, Professor Ned Seeman uses DNA chains to construct elegant two- and three-dimensional supramolecular structures (Seeman, 1997; see Fig. 2). The data storage abilities of DNA are not of special importance in this nanofabrication technology. The ability to create unique geometries and nanomachines dominates the thinking in creating these supramolecular structures.

SILK AS A BIOMATERIAL

Silk is a strong and tough natural biomaterial fiber spun by insects and spiders. Braided silk is used as a surgical suture

and in woven silk fabrics for consumer use. Spiders produce a variety of silks, and there is a clear link between protein sequence and structure–property relationships (Gosline *et al.*, 1999). There are up to seven different types of silk fiber and each silk is composed of peptide modules that confer distinct mechanical properties (Hinman *et al.*, 2000). An understanding of silk structure and an economical means of production would permit further exploitation of silk for a wide range of new uses, such as oxygen-permeable membranes and biocompatible materials (Altman *et al.*, 2003).

Recent research has led to an understanding of the detail of how silk proteins are assembled in nature (Lazaris, 2002). Biological synthesis and processing of polymers can be used as a route to gain insight into topics such as molecular recognition, self-assembly, and the formation of materials with well-defined architectures (Valluzzi *et al.*, 2002). The potential ability to mimic production of this natural material (a general process called *biomimetics*), the production of high-molecular-weight spider silk by analog proteins encoded by synthetic genes in several microbial systems (Fahnestock *et al.*, 2000), and the demonstration that appropriately transgenic goats can express spider-silk protein in their milk raise the possibility of large-scale biotechnological production of usable silk (Atkins, 2003).

NOVEL ELASTIC AND “SMART” BIOPOLYMERS

Novel polymers with unusual but highly desirable properties continue to be developed for medical devices. Recent examples include the synthesis and characterization of a biodegradable elastomer that has properties resembling those of the extracellular matrix protein elastin, and other polymers with properties that vary in a predictable, controllable manner with environmental conditions. Specifically, a tough, biodegradable elastomer with unique mechanical properties has been synthesized from sebacic acid and glycerol and formulated as a substrate for engineered tissue (Wang *et al.*, 2002b, 2003). Moreover, degradable, thermoplastic polymers that are

FIG. 2. Molecular models of DNA chains spliced into unique supramolecular geometries (images courtesy of Professor Nadrian Seeman).

able to change their shape predictably after an increase in temperature have been synthesized (Lenlein and Langer, 2002). In a particularly useful adjunct to minimally invasive surgical procedures, devices composed of these polymers could be compressed into a compact form that could be implanted into the body through small incisions and would expand at body temperature. Self-tying suture knots may be possible. Finally, another polymer that potentially rapidly and in a controlled manner drastically changes its surface groups and hence chemistry in controlled response to environmental change has been developed (Lahann *et al.*, 2003b). This polymer exhibits dynamic changes in interfacial properties, such as wettability, in response to an electrical potential through conformational transitions between hydrophilic and hydrophobic states. Such a surface design enables translation of molecular-level conformational transitions to macroscopic changes in surface properties without altering the surface's chemical identity. Therapeutic medical devices could be fabricated so that their function could be uniquely and beneficially responsive to the chemical and physical environment. Moreover, surface-immobilized specifically functional molecules can support the self-assembly of cells, proteins, and antibodies to create cell-based bioassays (Lahann *et al.*, 2003b).

NEURONAL ELECTRODE ARRAYS

Electrical stimulation of brain and neuronal tissue via electrodes has been explored since the invention of electricity. Clinically, stimulatory electrodes are used for pacemakers, Parkinson's disease, and the control of bowel function and for pacing numerous other organs (see chapter 7.15). More recently, new applications for arrays containing numerous electrodes have been demonstrated. The electrodes in the arrays are used for either stimulation or recording. These applications typically integrate biomaterials science, electrical engineering, computer processing, and medical science. The cochlear prosthesis is the first electrode array application to find widespread use. This implanted device permits the perception sound for the deaf (see Chapter 7.16). Many groups are working on a related technology for vision by either electrical stimulation of the retina (Humayun *et al.*, 2003) or indirect stimulation near the visual centers of the brain. Recording electrode arrays have permitted mechanical devices to be controlled directly from the brain of an animal. For example, a monkey was able to control the cursor on a computer screen by just "thinking at it." Conversely, electrode arrays have been used to control the actions of an animal, an experiment that raised a number of ethical concerns. The possibilities in this area of research to offer sight to the blind or mobility to the paralyzed are tantalizing. The biocompatibility of the electrodes in contact with tissue is always a central issue in devices that depend on such arrays. Even a thin collagen capsule can impede necessary electrical contact.

GENE EXPRESSION ANALYSIS

It is now possible to scan a large number of genes in a tissue sample at once and to determine which genes are active and used to make a protein (i.e., expressed). Gene expression analysis is done with postage-stamp-sized DNA chips (i.e.,

DNA microarrays)—DNA-covered silicon, glass, or plastic wafers capable of analyzing thousands of genes simultaneously to identify the ones that are active in a sample of cells (Lockhart and Winzlers, 2000; Stears *et al.*, 2003). The genes expressed in the test sample are compared with those of a normal sample. A single chip containing all approximately 30,000 known human genes is available. In experimental work, this will permit identification and quantification of the complex cellular changes that occur in cells during pathologic processes, including biomaterials-tissue interactions, and may facilitate an understanding of the mechanisms of disease. Examples in biomaterials research that exemplify the power of this methodology are beginning to appear (Carinci *et al.*, 2003; Ku *et al.*, 2002; Pioletti *et al.*, 2002; Risbud *et al.*, 2001; Wang *et al.*, 2002a). Clinically, this technology may make it easier to identify cancer-causing mutations and may permit the subclassification of tumors that have a similar appearance by conventional pathological analysis (Lakhani and Ashworth, 2001). Microarrays may provide a genetic profile of a cancerous cell that could reveal where the cancerous cell originated, how far it has progressed, and which therapies will work best to halt its further growth and spread (as in breast cancer; van de Vuver *et al.*, 2002). It is expected that protein microarrays will also soon be widely available and useful (Banks, 2000; Liotta *et al.*, 2001).

CIRCULATING ENDOTHELIAL PROGENITOR CELLS AND OTHER STEM CELLS

It has recently been appreciated that adult bone marrow is a rich source of a large spectrum of tissue-specific stem and progenitor cells that can populate functional organs with tissue-specific cells (Jiang *et al.*, 2002). Evidence suggests that bone marrow-derived endothelial progenitor cells (EPCs) contribute to tissue vascularization (Rafii and Lyden, 2003). Several studies have shown that EPCs contribute to repair of vascular injury, endothelialization of vascular grafts, new blood-vessel formation during wound healing, postmyocardial infarction, and pathologic processes including atherosclerosis and tumor growth (Sata *et al.*, 2002; Shimizu and Mitchell, 2003). The muscle of the heart, called myocardium and formerly considered a terminally differentiated organ incapable of endogenous regeneration, is also now believed to harbor and/or attract precursor cells (Nadal-Ginard *et al.*, 2002). Research is needed to develop strategies to stimulate and regulate the production and release of functionally beneficial cells in the bone marrow, to cause them to target specific anatomic sites, and to induce them to adhere, proliferate, and appropriately differentiate. Moreover, it is possible that organs may themselves harbor endogenous EPC-like or other stem cells. Harnessing the potential of endogenous precursor and stem cells may permit the exciting possibility of directed organ regeneration following injury or repair.

MOLECULAR IMAGING

The noninvasive visualization of specific molecular targets, pathways, and physiological effects *in vivo* would

facilitate study of cell phenotypes and function as well as extracellular synthesis and remodeling in the assessment of biomaterials–tissue interactions and evolution of engineered tissues. Macroscopic optical molecular imaging technologies using specific molecular biomarker targets deep inside living animals (research done primarily to date in mice) has become possible as a result of a number of advances, including design of biocompatible fluorescent probes and mathematical modeling of photon propagation in tissue (Weissleder and Mahmood, 2001; Weissleder and Ntziachristos, 2003). For example, the proteolytic activity in atherosclerotic plaque that potentially causes its rupture, resulting in myocardial infarction, has been visualized, raising the potential of catheter-based monitoring. Using this technology, cell structure and function may be visualized at high spatial and temporal resolution, thereby permitting unique visualization of molecular processes *in vivo*.

DENTAL MATERIALS: A PERSPECTIVE

One perspective related to the evolution and contribution of biomaterials science to the musculoskeletal surgical discipline is specific to dental restorative treatments based on synthetic (biomaterial) implants. Dental implant treatment outcomes have changed very significantly over the decades from 1960 to 2000. For example, some presentations at clinical and basic science meetings in the late 1960s and early 1970s presented success ratios as less than 60% within 5- to 10-year follow-up periods. This was summarized by a commissioned review paper by Natiella, *et al.* in 1972. They reviewed available literature and recommended that dental implant treatments remain in a “longitudinal research phase.”

Results over the following decades were based on combined efforts among many, with major emphasis on the biomaterials and biomechanical sciences and associated clinical trials. The biomaterials research and development focused on bulk and surface properties of synthetics; the biomechanics on device design and functional force transfer; while the clinical studies presented results that included in-depth studies of surgical (procedures and placement), healing (passive versus active loading conditions), restoration (prosthodontics), and longer-term maintenance (hygiene and periodontal health). Associated with these studies were multiple changes in the constituting, manufacturing, sterilizing, and packaging processes. These changes resulted in subsequent descriptions and outcomes associated with “chemically and mechanically clean” devices.

It was realized that more controlled conditions for optimizing biomaterial properties, biomechanical designs, clinical placements, restorations, and maintenance could result in an implant surface-to-bone condition that was called “osseointegration.” This biomaterial-to-bone interface condition was extended to many different device designs and thereby allowed treatments to be extended to a broader patient population, and other areas of musculoskeletal surgery.

The various studies and applications evolved rapidly during the 1980s and 1990s, clearly as a multidisciplinary coordination. Importantly to all involved and society at large, dental

implant treatments now have realized success ratios greater than 95% at 5 years and 90–95% at 10 years. Some studies are now showing greater than 80% survival at 20 years post implant placement. At this time, most endosteal dental implant devices are fabricated from titanium or titanium alloy with or without calcium phosphate (called hydroxyapatite or HA) coatings on the implant body sections. Additionally, it now seems that many are considering the placement of dental implants after tooth loss as a conservative dental treatment. This trend was recognized by the American Dental Association sponsored report on advances in dentistry over the past 100 years, where dental implant treatments were included as an important change in the overall practice of dentistry.

Related to the current book, the success story of dental-implant-based clinical treatments is also a success story related to applications of biomaterials science and technology.

BIOCOMPATIBILITY

The concept of “biocompatibility” is central to biomaterials science and sets biomaterials apart from materials widely used in commerce and technology. In the introductory chapter to this textbook, the widely used definition of biocompatibility was offered: biocompatibility is the ability of a material to perform with an appropriate host response in a specific application. (Williams, 1987). This definition is accurate and serves us well when we consider the performance of implanted devices. However, for the response of the body to the materials themselves, contemporary thinking may call for a restructuring of this definition. Consider these points:

1. All biostable materials that pass routine toxicology and endotoxin assays heal almost indistinguishably when implanted as similar-sized specimens in soft-tissue sites. Why should polyethylene, Teflon, single-crystal alumina, gold, pyrolytic carbon, polyurethane, and a hydrogel all heal similarly, within a collagenous foreign-body capsule, although there are significant differences in surface properties of these materials?
2. Why does the body try to isolate itself from a “biocompatible” biomaterial, rather than integrate it?
3. The body has the ability to heal complex internal wounds with normal, vascularized reconstruction of the tissue. Why do “biocompatible” biomaterials turn off this normal wound-healing response?
4. Why are there activated macrophages around implanted biomaterials even years after implantation? Why is the inflammatory response never resolved?
5. Why do some unique porous structures heal in a more vascularized, less fibrotic manner (Brauker *et al.*, 1995)? Also, some processed natural tissues heal with no fibrotic foreign body reaction (Badylak. . .).
6. If a normal wound-healing reaction could happen around implanted biomaterials, biosensors, bioelectrodes, and drug delivery systems would not be impeded by the dense collagenous capsule. Also, devices such as breast implants, heart valve sewing rings, and intraocular lenses might not encapsulate.

Ideas from modern biology and new developments in materials science may eventually lead us to a new definition of biocompatible and a new generation of biomaterials that seamlessly integrate into the body (Ratner, 1993).

ETHICS

An ever-evolving frontier in biomaterials science is in the areas of ethics. Ethical questions are frequently raised and stimulate us to think about issues such as control and shaping of our own bodies; life and death; relationships among patient, doctor, and attorney; relationships with federal regulatory agencies; relationships between academic scientists and entrepreneurs; the cost of health care; and the use of animals in research. The ubiquity of these ethical issues in our ongoing biomaterials effort highlights a special strength and excitement in the field called biomaterials science: *we have direct impact on people*. The editors and authors of this volume hope that you become as excited about biomaterials—its intellectual challenges, humanitarian aspects, and rewards—as we are.

A

Properties of Biological Fluids

STEVEN M. SLACK

This appendix represents a compilation of information relevant to biomaterials scientists regarding the properties and composition of several body fluids, i.e., blood, plasma (serum), cerebrospinal fluid, synovial fluid, saliva, tear fluid, and lymph. Where possible, ranges of values are provided but the reader should recognize that significant variations are possible, particularly in states of disease. Further, the data reported here reflect adult measurements and may be substantially different in a pediatric population. Values for cerebrospinal fluid refer to the lumbar region, those for synovial fluid refer to the knee joint, and those for lymph refer to the thoracic duct, unless otherwise specified. Table A1 lists the physicochemical properties of these fluids. Table A2 provides the typical cellular composition of human blood. Table A3 shows the normal volumes of these fluids in males and females and presents equations

whereby such volumes can be estimated from the mass of the individual. Next, Table A4 lists the approximate concentrations of the major proteins present in various biological fluids. Tables A5 and A6 present the concentrations of inorganic and organic species, respectively, in these fluids. Table A7 provides data on the major plasma proteins, i.e., concentration, molecular weight, isoelectric point (*pI*), sedimentation coefficient (*S*), diffusion coefficient (*D*), extinction coefficient (E_{280}), partial specific volume (V_{20}), carbohydrate content (*C*), and half-life. Finally, Tables A8 and A9 present information on the proteins involved in the complement pathway and blood coagulation pathway, respectively. Some of the information contained in this appendix have been previously published in Black, J., and Hastings, G. (eds.) (1998). *Handbook of Biomaterial Properties*. Chapman & Hall, New York, pp. 114–124.

TABLE A1 Physicochemical Properties of Several Biological Fluids

Property	Whole blood	Plasma (serum)	Cerebrospinal fluid	Synovial fluid	Saliva	Tear fluid
Freezing-point depression ^a	0.557–0.577	0.512–0.568	0.540–0.603	—	0.07–0.34	0.572–0.642
Osmolality ^b	—	275–295	290–324	292–300	—	309–347
pH ^c	7.35–7.45	7.35–7.43	7.35–7.70	7.29–7.45	5.0–7.1	7.3–7.7
Refractive index ^d	16.2–18.5	1.3485–1.3513	1.3349–1.3351	—	—	1.3361–1.3379
Relative viscosity ^e	2.18–3.59	1.18–1.59	1.020–1.027	> 300	—	1.26–1.32
Specific conductivity ^f	—	0.0117–0.0123	0.0119	—	—	—
Specific gravity ^g	1.052–1.061	1.024–1.027	1.006–1.008	1.008–1.015	1.002–1.012	1.004–1.005
Specific heat ^h	0.87	0.94	—	—	—	—
Surface tension ⁱ	55.5–61.2	56.2	60.0–63.0	—	15.2–26.0	40–50

^aUnits are °C.

^bUnits are mosm/kg H₂O. Calculated from freezing-point depression.

^cpH measured from arterial blood and plasma, and from cisternal portion of CSF.

^dMeasured at 20°C.

^eMeasured *in vitro* at 37°C for whole blood, plasma, and synovial fluid, and at 38°C for cerebrospinal fluid. The viscosity of serum is slightly less than plasma due to the absence of fibrinogen.

^fUnits are S/cm. Measured at 25°C for plasma, 18°C for CSF.

^gRelative to water at 20°C.

^hUnits are cal/g °C.

ⁱUnits are dyn/cm. Measured at 20°C.

TABLE A2 Cellular Composition of Blood

Cell type	Cells/ μ l	Half-life in circulation
Erythrocytes	4.6–6.2 $\times 10^6$ (M) 4.2–5.2 $\times 10^6$ (F)	25 \pm 2 days
Leukocytes		
Neutrophils	3000–5800	6–8 hours
Eosinophils	50–250	8–12 hours
Basophils	15–50	?
Monocytes	300–500	1–3 days
Lymphocytes	1500–3000	Variable
Platelets	1.5–3.5 $\times 10^5$	3.2–5.2 days
Reticulocytes	2.3–9.3 $\times 10^4$	—

TABLE A3 Volumes of Various Biological Fluids^a

Parameter	Whole blood	Erythrocytes	Plasma	CS fluid	Tear fluid
Volume (ml)	4490 (M) 3600 (F)	2030 (M) 1470 (F)	2460 (M) 2130 (F)	100–160	4.0–13

^aThe following equations can be used to estimate blood volume (BV), erythrocyte volume (EV), and plasma volume (PV) from the known body mass (*b*, kg) with a coefficient of variation of approximately 10%:

Males (M)	Females (F)
BV = 41.0 $\times b$ + 1530	BV = 47.16 $\times b$ + 864
PV = 19.6 $\times b$ + 1050	PV = 28.89 $\times b$ + 455
EV = 21.4 $\times b$ + 490	EV = 18.26 $\times b$ + 409

TABLE A4 Protein Concentrations (mg/dl) in Various Biological Fluids

Protein	Plasma (serum)	Cerebrospinal fluid	Synovial fluid	Saliva	Tear fluid	Lymph
Total	6000–8000	20–40	500–1800	140–640	430–1220	2910–7330
Albumin	4000–5500	11.5–19.5	400–1000	0.2–1.2	400	1500–2670

^aSedimentation constant in water at 20°C, expressed in Svedberg units.

^bDiffusion coefficient in water at 20°C, expressed in 10^{-7} cm²/sec.

^cExtinction coefficient for light of wavelength 280 nm traveling 1 cm through a 10 mg/ml protein solution.

^dPartial specific volume of the protein at 20°C, expressed as ml g⁻¹.

^eCarbohydrate content of the protein, expressed as the percentage by mass.

TABLE A8 Properties of Proteins Involved in the Complement System

Protein	Serum concentration (mg/L)	Relative molecular weight M_r (Da)	Sedimentation constant S_{20w} (10^{-13} sec)
C1q	50–100	459,000	11.1
C1r	35–40	83,000	7.5
C1s	32–40	83,000	4.5
C2	20–35	108,000	4.5
C3	1500–1700	185,000	9.5
C4	300–600	200,000	10.0
C5	120–180	185,000	8.7
C6	42–60	128,000	5.5
C7	4–60	121,000	6.0
C8	35–50	151,000	8.0
C9	45–70	71,000	4.5
Factor B	220–330	92,000	5–6
Factor D	Trace	24,000	3.0
Properdin	25–35	220,000	5.4
C1 inhibitor	145–170	100,000	—
Factor H	475–575	150,000	6.0
Factor I	30–45	88,000	5.5

TABLE A9 Properties of Proteins Involved in Blood Coagulation

Protein	Plasma concentration ($\mu\text{g/ml}$)	Relative molecular weight M_r (Da)	Biological half-life $t_{1/2}$ (hours)
Fibrinogen	2000–4000	340,000	72–120
Prothrombin	70–140	71,600	48–72
Factor III (tissue factor)	—	45,000	—
Factor V	4–14	330,000	12–15
Factor VII	Trace	50	2–5
Factor VIII	0.2	330,000	8–12
Factor IX	5.0	57,000	24
Factor X	12	58,800	24–40
Factor XI	2.0–7.0	160,000	48–84
Factor XII	15–47	80,000	50–60
Factor XIII	10	320,000	216–240
Protein C	4.0	62,000	10
Protein S	22	77,000	—
Protein Z	3.0	62,000	60
Prekallikrein	35–50	85,000	—
High-molecular-weight kininogen	70–90	120,000	—
Antithrombin III	210–250	58,000	67

B

Properties of Soft Materials

CHRISTINA L. MARTINS

TABLE B1 Some Mechanical and Physical Properties of the Most Common Polymers Used as Biomaterials and the Respective Application

Polymer	Tensile strength (MPa)	Tensile modulus (GPa)	Elongation (%)	T_g (°C)	T_m (°C)	Water absorption (%)	Water contact angle (°)	Biomedical applications
Polyethylene:								
Low-density polyethylene—LDPE ¹	4–16	0.1–0.3	90–800	–20	95–115	<0.01	93–95	Tubing ^{1,4,5} ; shunts ¹ ; catheters ^{3–5}
High-density polyethylene—HDPE ¹	21–38	0.4–1.2	20–1000	–125	135–138	<0.01	91	Plastic surgery implants
Ultrahigh-molecular-weight polyethylene—UHMWPE ¹⁰	22–42	0.65	—	—	125–135	<0.01	—	Acetabulum in total hip prostheses ⁴ ; artificial knee prostheses ⁴

- Advanced Biomaterials in Biomedical Engineering and Drug Delivery Systems* (1996). O. Naoya, W. Kim Sung, and J. Feijen (eds.). Springer-Verlag, ISBN 443170163X.
- Advances in Biomaterials 1* (1987). S. M. Lee (eds.). Technomic Publishing, ISBN 0877625042.
- Antimicrobial/Anti-Infective Materials: Principles, Applications and Devices* (1999). S. P. Sawan and G. Manivannan (eds.). Technomic Publishing Co. Inc., ISBN 1566767946.
- Applications of Biomaterials in Facial Plastic Surgery* (1991). A. I. Glasgow, and F. H. Silver (eds.). CRC Press, ISBN 0849352517.
- Artificial Humans: Transplants and Bionics* (1985). M. Thomas, H. Julian Menssner (eds.), ISBN 0671443674.
- The Artificial Kidney: Physiological Modeling and Tissue Engineering* (1999). J. K. Leypoldt (ed.). Landes Bioscience, ISBN 1570596026.
- Artificial Organs (Lucent Overview Series)* (1996). J. J. Presnall (ed.). Lucent Books, ISBN 1560062576.
- Atlas of Oral Implantology* (1999). A. N. Cranin, M. Klein, M. Simons, and A. Simons (eds.). Year Book Medical Pub, ISBN 155664552X.
- Bioadhesive Drug Delivery Systems: Fundamentals, Novel Approaches and Developments* (1999). E. Mathiowitz, D. Chickering III, and C.-M. Lehr (eds.). Marcel Dekker, ISBN 0911910131.
- Bioartificial Organs II—Tissue Sourcing, Immunoisolation and Clinical Trials* (2001). D. Hunkeler, A. Cherrington, A. Prokop, and R. Rajotte (eds.). New York Academy of Sciences, ISBN 1573313424.
- Bioartificial Organs II: Technology, Medicine, and Materials (Annals of the New York Academy of Sciences, Vol. 875)* (1999). D. Hunkeler, A. Prokop, and A. D. Cherrington (eds.). New York Academy of Sciences, ISBN 1573311952.
- Bioartificial Organs: Science, Medicine, and Technology (Annals of the New York Academy of Sciences, Vol. 831)* (1997). A. Prokop, D. Hunkeler, and A. Cherrington (eds.). New York Academy of Sciences, ISBN 1573310999.
- Bioceramics* (1999). *Advanced Ceramics*, Vol. 1. J. F. Shackelford (ed.). Gordon and Breach Science Publishers, ISBN 9056996126.
- Bioceramics 16* (2004). M. A. Barbosa, F. J. Monteiro, R. Correia, and B. Leon (eds.). Proceedings of the 16th International Symposium on Ceramics in Medicine, Porto, Portugal, 6–9 November. Trans Tech Publications, ISBN 0878499326.
- Bioceramics of Calcium Phosphate* (1983). K. De Groot (ed.). CRC Press, ISBN 0849364566.
- Bioceramics: Material Characteristics versus in Vivo Behaviour (Annals of the New York Academy of Sciences, Vol. 523)* (1988). P. Ducheyne and J. E. Lemons (eds.). New York Academy of Sciences, ISBN 089766437X.
- Bioceramics: Materials and Applications II (Ceramic Transactions, Vol. 63)* (1996). R. P. Rusin and G. S. Fischman (eds.). American Ceramic Society, ISBN 1574980068.
- Bioceramics: Materials and Applications III (Ceramic Transactions, Vol. 110)* (2000). L. George, R. P. Rusin, G. S. Fischman, and V. Janas (eds.). American Ceramic Society, ISBN 1574981021.
- Biocompatibility Assessment of Medical Devices and Materials* (1997). J. H. Braybrook (eds.). John Wiley & Sons, ISBN 0471965979.
- Biodegradable Hydrogels for Drug Delivery* (1993). K. Park, W. S. W. Shalaby, and H. Park (eds.). Technomic Publishing, ISBN 1566760046.
- Bio-Implant Interface: Improving Biomaterials and Tissue Reactions* (2003). J. E. Ellingsen and S. P. Lyngstadaas (eds.). CRC Press, ISBN 0849314747.
- Bioinstrumentation and Biosensors* (1991). D. L. Wise (ed.). Marcel Dekker, ISBN 0824783379.
- Biological Performance of Materials* (1999). J. Black (ed.). Marcel Dekker, ISBN 0824771060.
- Biology in Physics: Is Life Matter? (Polymers, Interfaces and Biomaterials Series)* (2000). K. Y. Bogdanov (ed.). Academic Press, ISBN 0121098400.
- Biomaterials*, 2nd edition (1992). J. B. Park and R. S. Lakes (eds.). Kluwer Academic/Plenum Publishers, ISBN 0306439921.
- Biomaterials* (1991). D. Byrom (ed.). Macmillan Press, ISBN 0333514076.
- Biomaterials and Bioengineering Handbook* (2000). D. L. Wise (ed.). Marcel Dekker, ISBN 0824703189.
- Biomaterials for Drug and Cell Delivery* (1994). Materials Research Society Symposium, Boston, USA (1993). A. G. Mikos, R. M. Murphy, and H. Bernstein (eds.). Materials Research Society, ISBN 1558992308.
- Biomaterials for Drug Delivery and Tissue Engineering (Materials Research Society Symposia Proceedings, Vol. 662, November 27–29, 2000. Boston, MA)* (2001). S. Mallapragada, M. Tracy, B. Narasimhan, E. Mathiowitz, and R. Korsmeyer (eds.). Materials Research Society, ISBN 1558995722.
- Biomaterials in Artificial Organs* (1985). J. P. Paul, J. M. Courtney, J. D. S. Gaylor, and T. Gilchrist (eds.). Wiley-VCH, ISBN 3527152342.
- Biomaterials in the Design and Reliability of Medical Devices* (2002). M. N. Helmus (ed.). Kluwer Academic, ISBN 0306476908.

- Biomaterials, Mechanical Properties* (ASTM Special Technical Publication, Stp 1173) (1994). H. E. Kambic and A. T. Yokobori (eds.). American Society for Testing & Materials, ISBN 0803118945.
- Biomaterials Regulating Cell Function and Tissue Development* (*Materials Research Society Symposium Proceedings*, Vol. 530, April 13–14, 1998, San Francisco) (2000). R. C. Thomson, D. J. Mooney, K. E. Healy, Y. Ikada, and A. F. Mikos (eds.). Material Research Society, ISBN 155899436X.
- Biomaterials Science and Biocompatibility* (1999). F. H. Silver and D. L. Christiansen (eds.). Springer Verlag, ISBN 0387987118.
- Biomaterials Science and Engineering* (1984). J. B. Park (ed.). Kluwer Academic/Plenum Publishers, ISBN 0306416891.
- Biomaterials: An Introduction* (1992). J. B. Park and R. S. Lakes (eds.). Plenum Publishers, ISBN 0306439921.
- Biomaterials: Interfacial Phenomena and Applications* (1982). S. L. Cooper and N. A. Peppas (eds.). American Chemical Society, ISBN 0841206317.
- Biomaterials: Principles and Applications* (2002). J. B. Park and J. D. Bronzino (eds.). CRC Press, ISBN 0849314917.
- Biomaterial–Tissue Interfaces* (Proceedings of the 9th European Conference on Biomaterials, Chester, UK, 1991) (1992). P. J. Doherty, R. L. Williams, D. F. Williams, and A. J. C. Lee (eds.). Elsevier Science, ISBN 0444890653.
- Biomechanics of Medical Devices* (1981). D. Ghista (ed.). Marcel Dekker, ISBN 0824768485.
- Biomedical Applications of Polyurethanes* (2001). P. Vermette, G. Laroche, and H. J. Griesser (eds.). Landes Bioscience, ISBN 158706023X.
- Biomedical Materials: Drug Delivery, Implants and Tissue Engineering* (symposium held November 30–December 1, 1998, Boston) (1999). T. Neenan, M. Marcolongo and R. F. Valentini (eds.). Materials Research Society, ISBN 1558994564.
- Biomedical Polymers* (1993). D. Cohn and J. Kost (eds.). Elsevier Science, ISBN 1858610435.
- Biomedical Polymers: Designed to Degrade Systems* (1994). S. W. Shalaby (ed.). Rapra Technology Ltd.
- Biomimetic Materials Chemistry* (1995). S. Mann (ed.). Wiley-VCH, ISBN 1560816694.
- Biomimetalization* (2000). E. Baeuerlein (ed.). Wiley, ISBN 3527299874.
- The Bionic Patient: Health Promotion for People with Implanted Prosthetic Devices* (2002). F. E. Johnson and K. S. Virgo (eds.). Humana Press, ISBN 0896039595.
- Biopolymer Methods in Tissue Engineering* (Methods in Molecular Biology Series) (2003). A. P. Hollander and P. V. Hattori (eds.). Humana Press, ISBN 0896039676.
- Biopolymers at Interfaces* (1998). M. Malmsten (ed.). Marcel Dekker.
- Biorelated Polymers and Gels: Controlled Releases and Applications in Biomedical Engineering* (Polymers, Interfaces, and Biomaterials) (1998). T. Okano (ed.). Academic Press, ISBN 0125250908.
- Biosensors* (1992). F. Scheller and F. Schubert (eds.). Elsevier Science, ISBN 0444987835.
- Biosensors in the Body: Continuous in Vivo Monitoring* (1997). D. M. Fraser (ed.). John Wiley & Sons, ISBN 0471967076.
- Blood Substitutes: Principles, Methods, Products and Clinical Trials* (Tissue Engineering, Basel, Switzerland) (1997). T. M. S. Chang (ed.). S. Karger Publishing, ISBN 3805565844.
- Boing-Boing the Bionic Cat* (2000). L. Hench (ed.). Amer. Cream. Pub. ISBN 1574981099.
- Bone Cements: Up-to-Date Comparison of Physical and Chemical Properties of Commercial Materials* (2000). K. D. Kuhn (ed.). Springer-Verlag, ISBN 3540672079.
- Bone Engineering* (2000). J. E. Davies (ed.). Em Squared, ISBN 096869800X.
- Bone Graft Substitutes* (2003). C. T. Laurecin (ed.). ASTM, ISBN 080313561.
- Cardiovascular Biomaterials* (1991). G. W. Hastings (ed.). Springer-Verlag, ISBN 3540196668.

INDEX

A

- Absorbable matrix composites, 191
- Absorbable synthetic fibers, 90
- Absorbable synthetic sutures, 618–621
- Absorption, multilayer polyelectrolyte, 211–212
- Accommodative IOLs, 598–599
- Acids; *See* Poly(amino acids); pseudo-poly(amino acids), 119
- Act, Biomaterials Access Assurance, 803
- Activity, platelet coagulant, 334
- Acute inflammation, 298–299
- Adaptive immunity
 - innate and, 304–318
 - recognition and effector pathways in, 309–311
 - types of, 309
- Adaptor/adhesive molecules, 263
- Adhesion
 - bacterial, 347
 - platelet, 333
- Adhesion proteins, effects of, 238–240
- Adhesive biomaterials, composition and characteristics of, 576–581
- Adhesive molecules; *See* Adaptor/adhesive molecules
- Adhesives
 - hard-tissue, 579–580
 - soft-tissue, 576–579
 - surgical, 590
- Adhesives and sealants, 572–583
 - background concepts, 573–576
 - characteristics of adhesive biomaterials, 576–581
 - composition of adhesive biomaterials, 576–581
 - historical overview, 572–573
 - new research directions, 581–582
- Adjustable power IOLs, 599
- Adsorbed proteins in biomaterials, importance of, 245
 - Adsorbed proteins in tissue response to biomaterials, 237–246
 - adsorption behavior of proteins at solid/liquid interfaces, 240–242
 - conformational and biological changes, 242–245
 - effects of adhesion proteins on cellular interactions, 238–240
 - importance of adsorbed proteins in biomaterials, 245
 - molecular spreading events, 242–245
 - Adsorption behavior of proteins at solid/liquid interfaces, 240–242
 - Adsorption; *See also* PreadSORption; sorption
- AFM (atomic force microscopy), 51–54, 221
- Agar diffusion test, 358
- Agents
 - immobilization of anti-platelet, 465–466
 - immobilization of fibrinolytic, 466
- Aggregation, platelet, 333–334
- Allergies, types of, 330–331
- Allergy and biomaterials, 330
- Allografts
 - from cadavers, 605–606
 - of cultured cells and collagen, 606
- Alloys
 - cobalt-based, 144–148
 - cobalt-chromium, 536–537
 - new cobalt, 538–539
 - new tantalum, 537–538
 - new titanium, 538
 - new zirconium, 537–538
 - stainless steel, 536
 - titanium, 537
 - titanium-based, 148–151
- Alloys, new, 537–539
 - new cobalt alloys, 538–539
 - new stainless steels, 539
 - new titanium alloys, 538
 - new zirconium and tantalum alloys, 537–538
 - surfaces and coatings, 539
- Amino acids; *See* Poly(amino acids); pseudo-poly(amino acids)
- Amorphous matrix, 265
- Analyses, finite element, 32–40
 - continuum equations, 35–36
 - examples from biomechanics, 37–40
 - finite element equations, 36–37
 - overview of finite element method, 33–35
 - surface analysis techniques, 42–56
- Analyses, gene expression, 808
- Animal experimentation, 794
- Animal models and species
 - consideration, 381–390
 - canine, 381–386
 - sheep, 388–390
 - swine, 386–388
- Animal models in cardiac research
 - testing, large, 379–396
- Animal models in research testing, large
 - animal models and species consideration, 381–390
 - responsible use of animals, 380–381
 - testing hierarchies, 390–392
- Animal models in vascular research
 - testing, large, 379–396
- Animal models, selection of for *in vivo* tests, 364–365
- Animal tumors, implants with human and, 339–341
- Animals, responsible use of, 380–381
- Anti-platelet agents, immobilization of, 465–466
- Antibody-mediated disease, pathogenesis of, 313–314
 - antibody bound to cell surfaces or fixed tissue antigens, 313–314

- Antibody-mediated disease, pathogenesis of (*Continued*)
- IC (immune complex)-mediated injury, 314
 - IgE-mediated (immediate hypersensitivity), 313
- Apheresis, 516–524
- centrifugal plasma separation, 519–520
 - cytapheresis, 523–524
 - defined, 518
 - membrane plasma filtration, 522–523
 - membrane plasma separation, 520–522
 - miscellaneous physicochemical methods, 523
 - plasma exchange, 518–519
 - plasma treatment, 522
 - sorption plasma fractionation, 523
- Apoptosis, 258–259
- Apparatus, Golgi, 253–254
- Apparel, drapes and protective, 97–98
- Applications
- bioelectrodes, 654–655
 - EO sterilization, 757–758
 - ophthalmological, 583–591
 - orthopedic, 526–555
 - of scaffolds, 737–740
 - in vivo*, 97–99
- Approaches
- variational, 36
 - weighted residual, 36
- Arms, linker, 692–694
- Arrays, neuronal electrode, 808
- Arrhythmias, cardiac, 483–485
- Artery stents, coronary, 476–479
- Arthroplasty
- mold, 529–531
 - total hip replacement, 531–532
- Arthroplasty, history of total hip, 529–532
- femoral head prostheses, 531
 - long-stem prostheses, 531
 - mold arthroplasty, 529–531
 - short-stem prostheses, 531
 - total hip replacement arthroplasty, 531–532
- Artifacts, 280
- Artificial devices; *See* Bioartificial devices
- Artificial endothelium, 588
- Artificial epithelium, epikeratophakia and, 587–588
- Artificial heart, total implantable, 489
- Artificial heart valves, 38–40, 798–799
- Artificial organs, 709–748
- extracorporeal, 514–526
 - immunoisolation, 728–734
 - overview of tissue engineering, 712–728
 - synthetic bioresorbable polymer scaffolds, 735–747
- Artificial prosthesis, 712
- Artificial red blood cell substitutes, 507–514
- hemoglobin, 507
 - modified hemoglobin, 507–511
 - perfluorochemicals, 511–512
- Assay methods, 357–359
- agar diffusion test, 358
 - direct contact test, 357–358
 - elution test, 358
 - interpretation of results, 358–359
- Assays, new solid-phase materials for
- ligand binding, 686–692
 - miscellaneous biosensor strategies, 691–692
 - molecularly imprinted surfaces, 690–691
 - particles, 686–689
 - self-assembled monolayers, 690
 - surface-enhanced spectroscopies, 691
- Assessment, key considerations for BMI, 370–373
- blood-factors affecting its properties, 370–371
 - blood interaction times, 373
 - how flow affects blood interactions, 371–372
 - properties of biomaterials and devices, 373
 - surfaces, 373
- Assist
- cardiac, 486–490
 - kidney, 514–518
 - lung substitutes and, 524
- Assist devices
- implantable cardiac, 494–503
 - ventricular, 487–489

Chapter 2.4, Fig. 9 (A) Weft knit inflammatory response at 4 weeks (Golaski Microkit); (B) Warp knit inflammatory response at 3 days (Microvel).

Chapter 3.4, Fig. 5 Photomicrographs of basic tissues, emphasizing key structural features. (A–D) Epithelium; (E, F) connective tissue; (G) muscle; and (H) nervous tissue. (A) Skin. Note the thin stratum corneum (c) and stratum granulosum (g). Also shown are the stratum spinosum (s), stratum basale (b), epidermal pegs (ep), dermal papilla (dp), and dermis (d). (B) Trachea, showing goblet cells (g), ciliated columnar cells (c), and basal cells (b). Note the thick basement membrane (bm) and numerous blood vessels (v) in the lamina propria (lp). (C) Mucosa of the small intestine (ileum). Note the goblet (g) and columnar absorbing (a) cells, the lamina propria (lp), muscularis mucosae (mm), and crypts (arrows). (D) Epithelium of a kidney collecting duct resting on a thin basement membrane (arrows). (E) Dense irregular connective tissue. Note the wavy unorientated collagen bundles (c) and fibroblasts (arrows). p, plasma cells. (F) Cancellous bone clearly illustrating the morphologic difference between inactive bone lining (endosteal, osteoprogenitor) cells (bl) and active osteoblasts (ob). The clear area between the osteoblasts and calcified bone represents unmineralized matrix or osteoid. cl, cement lines; o, osteocytes. (H) Small nerve fascicles (n) with perineurium (p) separating it from two other fascicles (n). (A–F and H reproduced by permission from Berman, I., 1993. *Color Atlas of Basic Histology*. Appleton and Lange, 1993. G reproduced by permission from Schoen F. J., *The heart*. in *Robbins Pathologic Basis of Disease*, 7th ed., R. S. Cotran, V. Kumar and T. Collins, eds. Saunders, Philadelphia, in press.)

H

Chapter 3.4, Fig. 5—continued

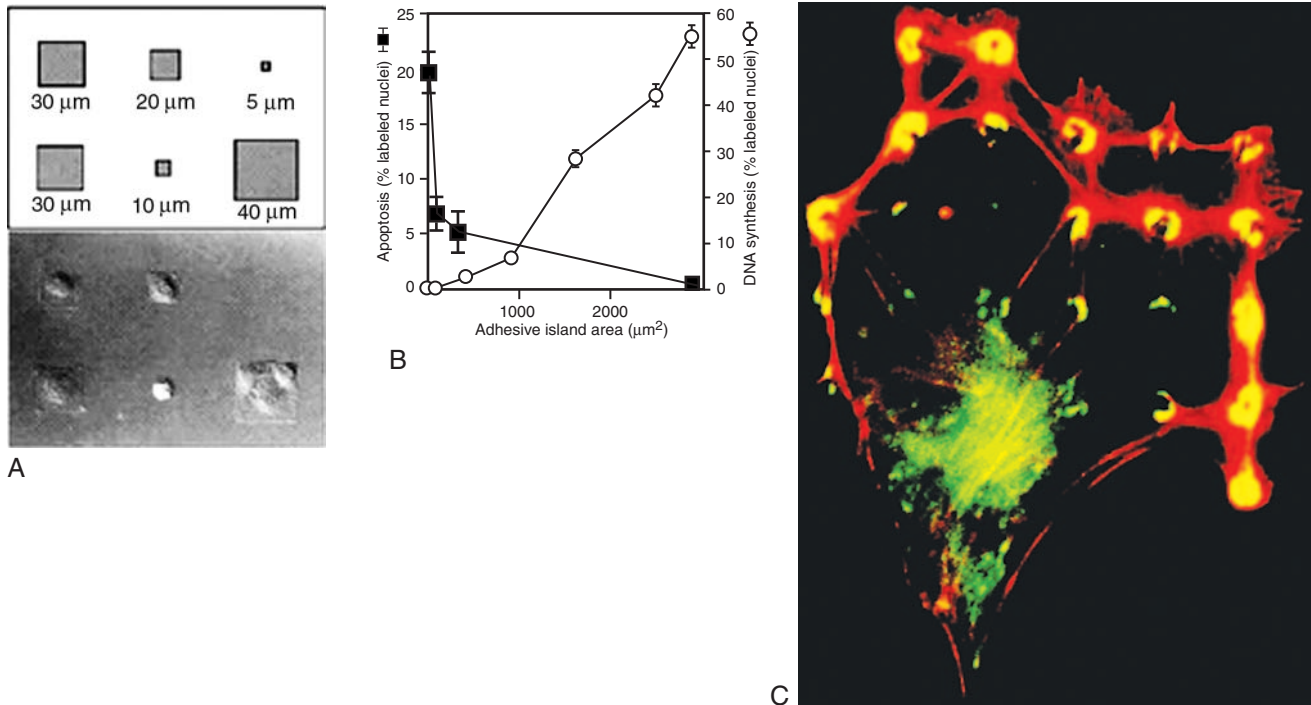

A

B

Chapter 3.4, Fig. 7 (A) Organization of tissue layers in the digestive tract (e.g., stomach or intestines). (B) Photomicrograph of the dog jejunum illustrating villi (v), the muscularis externa (me), and mesentery (m). In this organ the epithelium is organized into folds (the villi) in order to increase the surface area for absorption. (A, Reproduced by permission from Borysenko, M., and Beringer, T., *Functional Histology*, 3rd ed. Copyright 1989 Little, Brown, and Co. B, Reproduced by permission from Berman, I., 1993. *Color Atlas of Basic Histology*, Appleton and Lange.)

Chapter 3.4, Fig. 13 Effect of spreading on cell growth and apoptosis. (A) Schematic diagram showing the initial pattern design containing different-sized square adhesive islands and Nomarski views of the final shapes of bovine adrenal capillary endothelial cells adherent to the fabricated substrate. Distances indicate lengths of the squares' sides. (B) Apoptotic index (percentage of cells exhibiting positive TUNEL staining) and DNA synthesis index (percentage of nuclei labeled with 5-bromodeoxyuridine) after 24 hours, plotted as a function of the projected cell area. Data were obtained only from islands that contained single adherent cells; similar results were obtained with circular or square islands and with human or bovine endothelial cells. (C) Fluorescence micrograph of an endothelial cell spread over a substrate containing a regular array of small (5- μm -diameter) circular ECM islands separated by nonadhesive regions created with a microcontact printing technique. Yellow rings and crescents indicate colocalization of vinculin (green) and F-actin (red) within focal adhesions that form only on the regulatory spaced circular ECM islands. (A, B, Reproduced by permission from Chen, C. S., *et al.*, 1997. Geometric control of cell life and death. *Science* 276: 1425. C, Reproduced by permission from Ingber, D. E., 2003. Mechanosensation through integrins: Cells act locally but think globally. *Proc. Natl. Acad. Sci. USA* 100: 1472.)

Hepatocyte/Endothelial Cell Sorting

Light microscopy (top view)

Histology (vertical cut; hematoxylin and eosin stain)

endothelial cells hepatocytes

Chapter 3.4, Fig. 14 Different levels of type 1 collagen coating on a culture dish result in different organization of endothelial cells and hepatocytes. High collagen levels cause both cell types to spread across the substratum (left). On intermediate collagen levels, endothelial cells form a layer on the substratum whereas hepatocytes form a layer on top of the endothelial cells (center). Low levels of collagen result in an inner layer of hepatocyte aggregate surrounded by endothelial cells (right). (Reproduced by permission from Lauffenburger, D. A., *et al.*, 2001. Who's got pull around here? Cell organization in development and tissue engineering. *Proc. Natl. Acad. Sci. USA* 98: 4282.)

Chapter 4.2, Fig. 2 Acute inflammation, secondary to infection, of an ePTFE vascular graft. A focal zone of polymorphonuclear leukocytes is present at the luminal surface of the vascular graft, surrounded by a fibrin cap, on the blood-contacting surface of the ePTFE vascular graft. Hematoxylin and eosin stain. Original magnification 4 \times .

Chapter 4.2, Fig. 3 Chronic inflammation, secondary to infection, of an ePTFE arteriovenous shunt for renal dialysis. (A) Low-magnification view of a focal zone of chronic inflammation. (B) High-magnification view of the outer surface with the presence of monocytes and lymphocytes at an area where the outer PTFE wrap had peeled away from the vascular graft. Hematoxylin and eosin stain. Original magnification (A) 4 \times , (B) 20 \times .

Chapter 4.2, Fig. 4 Granulation tissue in the anastomotic hyperplasia at the anastomosis of an ePTFE vascular graft. Capillary development (red slits) and fibroblast infiltration with collagen deposition (blue) from the artery form the granulation tissue (arrows). Masson's Trichrome stain. Original magnification 4 \times .

Chapter 4.2, Fig. 6 (A) Focal foreign-body reaction to polyethylene wear particulate from a total knee prosthesis. Macrophages and foreign-body giant cells are identified within the tissue and lining the apparent void spaces indicative of polyethylene particulate. Hematoxylin and eosin stain. Original magnification 20×. (B) Partial polarized light view. Polyethylene particulate is identified within the void spaces commonly seen under normal light microscopy. Hematoxylin and eosin stain. Original magnification 20×.

Chapter 4.2, Fig. 7 Foreign-body reaction with multinucleated foreign body giant cells and macrophages at the periadventitial (outer) surface of a Dacron vascular graft. Fibers from the Dacron vascular graft are identified as clear oval voids. Hematoxylin and eosin stain. Original magnification 20×.

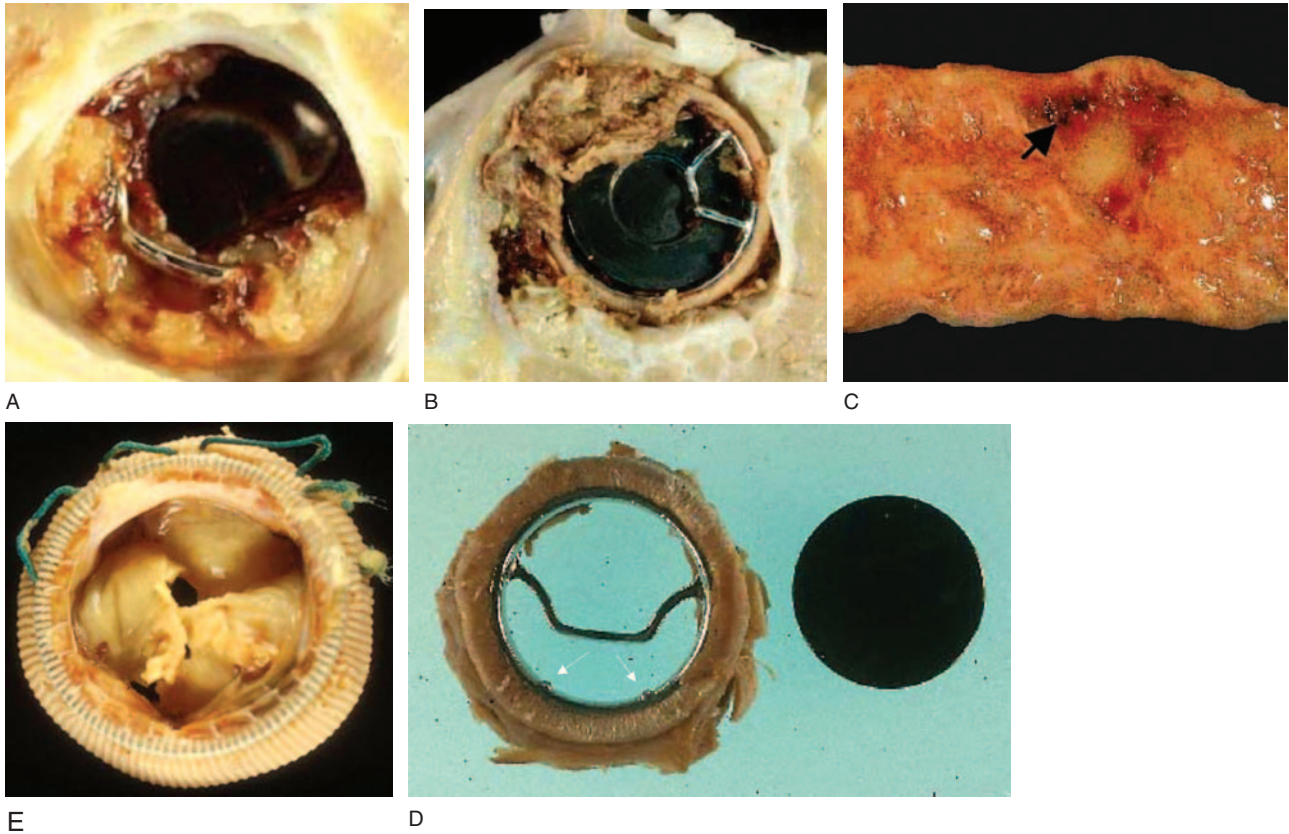

Chapter 4.2, Fig. 9 Fibrous capsule composed of dense, compacted collagen. This fibrous capsule had formed around a Mediport catheter reservoir. Loose connective tissue with small arteries, veins, and a nerve is identified below the acellular fibrous capsule.

Chapter 4.2, Fig. 10 Fibrous capsule with a focal foreign-body reaction to silicone gel from a silicone gel-filled silicone-rubber breast prosthesis. The breast prosthesis-tissue interface is at the top of the photomicrograph. Oval void spaces lined by macrophages and a few giant cells are identified and a focal area of foamy macrophages (arrows) indicating macrophage phagocytosis of silicone gel is identified. Hematoxylin and eosin stain. Original magnification 10 \times .

Chapter 7.3, Fig. 2 (A) Severe degenerative calcification of a previously anatomically normal tricuspid aortic valve, the predominant cause of aortic stenosis. (B) Chronic rheumatic heart disease, manifest as mitral stenosis, viewed from the left atrium. (C) Myxomatous degeneration of the mitral valve, demonstrating hooding with prolapse of the posterior mitral leaflet into the left atrium (*arrow*). A, B: Reproduced by permission from Schoen, F. J., and Edwards, W. D. (2001). Valvular heart disease: General principles and stenosis. in *Cardiovascular Pathology*, 3rd ed. Silver, M. D., Gotlieb, A. I., and Schoen, F. J., eds. Churchill Livingstone, New York. C: Reproduced by permission from Schoen, F. J. (1999). The heart. in *Robbins Pathologic Basis of Disease*, 6th ed., R. S. Cotran, V. Kumar, T. Collins, eds. W.B. Saunders, Philadelphia.

Chapter 7.3, Fig. 6 Prosthetic valve complications. (A) Thrombosis on a Bjork–Shiley tilting disk aortic valve prosthesis, localized to outflow strut near minor orifice, a point of flow stasis. (B) Thromboembolic infarct of the small bowel (arrow) secondary to embolus from valve prosthesis. (C) Prosthetic valve endocarditis with large ring abscess, viewed from the ventricular aspect of an aortic Bjork–Shiley tilting disk aortic valve. (D) Strut fracture of Bjork–Shiley valve, showing valve housing with single remaining strut and adjacent disk. (E) Structural valve dysfunction (manifest as calcific degeneration with tear) of porcine valve. B: Reproduced by permission from Schoen, F. J. (2001). Pathology of heart valve substitution with mechanical and tissue prostheses. in *Cardiovascular Pathology*, 3rd ed. M. D. Silver, A. I. Gotlieb, and F. J. Schoen, eds. Churchill Livingstone, New York. C: Reproduced by permission from Schoen, F. J. (1987). Cardiac valve prostheses: pathological and bioengineering considerations. *J. Card. Surg.* 2: 65. A and D: Reproduced by permission from Schoen, F. J., Levy, R. J., and Piehler, H. R. (1992). Pathological considerations in replacement cardiac valves. *Cardiovasc. Pathol.* 1: 29.

Chapter 7.3, Fig. 7 Atherosclerotic plaque in the coronary artery. (A) Overall architecture demonstrating a fibrous cap (F) and a central lipid core (C) with typical cholesterol clefts. The lumen (L) has been moderately narrowed. Note the plaque-free segment of the wall (*arrow*). (B) Coronary thrombosis superimposed on an atherosclerotic plaque with focal disruption of the fibrous cap (*arrow*), triggering fatal myocardial infarction. A: Reproduced by permission from Schoen, F. J., and Cotran, R. S. (1999). Blood vessels. in *Robbins Pathologic Basis of Disease*, 6th ed., R. S. Cotran, V. Kumar, and T. Collins, eds. W.B. Saunders, Philadelphia. B: Reproduced by permission from Schoen, F. J. (1989). *Interventional and Surgical Cardiovascular Pathology: Clinical Correlations and Basic Principles*. W.B. Saunders, Philadelphia.

Chapter 7.3, Fig. 10 Stent grafts. (A) Configuration of device showing composite metal and fabric portions. (B) Low-power photomicrograph of well-healed experimental device explanted from a dog aorta. The lumen is widely patent and the fabric and metal components are visible. (C) High-power photomicrograph of stent graft interaction with the vascular wall, demonstrating mild intimal thickening. B and C: courtesy Jagdish Butany, MD, University of Toronto.

Chapter 7.3, Fig. 17 Complications of cardiac assist devices. (A) Cuspal tear in inflow valve of LVAD. (B) Hemorrhage into the brain in a patient with an LVAD. (C) Fungal infection in LVAD outflow graft. (D) Thrombosis on pumping bladder. A: Reproduced by permission from Schoen, F. J., and Padera, R. F. (2003). Pathologic considerations in the surgery of adult heart disease. in *Cardiac Surgery in the Adult*, 2nd ed., L. H. Cohn, ed. McGraw-Hill, New York. C: Reproduced by permission from Schoen, F. J., and Edwards, W. D. (2001). Pathology of cardiovascular interventions. in *Cardiovascular Pathology*, 3rd ed., M. D. Silver, A. I. Gotlieb, and F. J. Schoen, eds. Churchill Livingstone, New York. D: Reproduced by permission from Fyfe, B., and Schoen, F. J. (1993). Pathologic analysis of 34 explanted Symbion ventricular assist devices and 10 explanted Jarvik-7 total artificial hearts. *Cardiovasc. Pathol.* 2: 187–197.

Chapter 7.8, Fig. 21 (A) Electron discharge machining or spark erosion techniques were used to mill this mesostructure bar shown attached to implants with fixation screws. (B) The armature or skeleton to which the porcelain is baked and the denture teeth are processed is milled intimately to fit by a precise frictional relationship to the mesostructure bar. (C) The external surface of this structure is prepared to receive the processed prosthesis. (D) The completed spark erosion fabricated mesostructure bar, with a totally porcelain baked superstructure, may be maintained by a frictional relationship or, if additional retention is desired, by the use of strategically related latches, such as Ceka-like attachments.
